Preface to the Second Edition

The landscape of computer vision has undergone dramatic changes mainly due to the introduction of machine learning (ML) techniques, including deep learning, since the publication of the first edition 6 years ago. ML techniques have made inroads into almost every corner of computer vision, provided significant impacts, and established high-performance modules. The impact has been so great that certain researchers call, for a joke, the post-introduction period of ML as AD-CV era and the pre-introduction period as BC-CV era. It was natural to cover these ML techniques in the AD-CV era, and the primal purpose of this revision was, thus, to collect AD-CV topics.

On the other hand, the classic BC-CV methods are not well shared by the younger generations. Especially, the development speed has been so rapid and most of the presentations have been made in conference papers with page limits. As a result, older BC-CV methods have often been neglected and forgotten in spite of their fundamental importance. The Master said, “温故知新。” Bernard de Chartres also said, “*nani gigantum umeris insidentes.*” The wisdom of mankind can only progress on the basis of what has been accumulated so far. Otherwise, it will become a tower on sand, developing the same methods over and over again, without any progress. To avoid this, I decided to retain those old BC-CV techniques under the title “Traditional Approaches.”

I hope this book will contribute toward a prosperous development of the computer vision community.

Preface to the First Edition

Computer vision is a field of computer science and engineering; its goal is to make a computer that can see its outer world and understand what is happening. As David Marr defined, computer vision is “an information processing task that constructs efficient symbolic descriptions of the world from images.” Computer vision aims to create an alternative for human visual systems on computers.

Takeo Kanade says, “computer vision looks easy, but is difficult. But, it is fun.” Computer vision looks easy because each human uses vision in daily life without any effort. Even a new-born baby uses its vision capability to recognize the mother. It is computationally difficult, however, because the original outer world is made up of three dimensional objects, while those projected on the retina or an image plane, are of only two dimensional images. This dimensional reduction from 3D to 2D occurs along the projection from the outer world to images. “Common sense” needs to be used to augment the descriptions of the original 3D world from the 2D images. Computer vision is fun, because we have to discover this common sense. This search for common sense attracts the interest of vision researchers.

The origin of computer vision can be traced back to Lawrence Roberts’ research, “Machine Perception of Three-Dimensional Solids.” Later, this line of research has been extended through Project MAC of MIT. Professor Marvin Minski, the then director of Project MAC, initially believed that computer vision could be solved as a summer project of an MIT graduate student. His original estimation was wrong, and for more than 40 years we have been investigating various aspects of computer vision.

This 40-year effort proved that computer vision is one of the fundamental sciences, and the field is rich enough for researchers to devote their entire research lives to it. This period also reveals that the field contains a wide variety of topics from low-level optics to high-level recognition problems. This richness and diversity were an important motivation for us to decide to compile a reference book on computer vision.

Lawrence Roberts’ research contains all of the essential components of the computer vision paradigm, which modern computer vision still follows: homogeneous coordinate system to define the coordinates, cross operator for edge detection, and object models represented as a combination of edges. David Marr defines his paradigm of computer vision: shape-from-x low-level vision, interpolation and fusion of such fragmental representations, 2-1/2D viewer-centered representation as the result of interpolation and fusion,

and 3D object-centered representation. Roughly, this reference guide follows these paradigms, and defines the sections accordingly.

The online version of the reference guide is intended to be developed continuously, both by the updates of existing entries and by the addition of new entries. In this way, it will provide the resources to help both vision researchers and newcomers to the field be on the same page with the continuing and exciting developments in computer vision.

This reference guide has been completed through a team effort. We are most grateful for all the contributors and section editors who have made this project possible. Our special thanks go to Ms. Neha Thapa and other Springer colleagues for their assistance in the development and editing of this reference guide.

March 2014

Katsushi Ikeuchi, Editor in Chief

Contents

Illumination and reflection

Section Editor: *Kyros Kutulakos, Yasuyuki Matsushita, Yoav Schechner and Todd Zickler*

- Asperity Scattering
- Blackbody Radiation
- Cook-Torrance Model
- Dichromatic Reflection Model
- Diffuse Reflectance
- Fluorescent Lighting
- Illumination Estimation, Illuminant Estimation
- Interreflections
- Irradiance
- Lambertian Reflectance
- Mirrors
- Opacity
- Oren-Nayar Reflectance Model
- Penumbra and Umbra
- Phong Reflectance Model
- Planckian Locus
- Polarization
- Polarized Light in Computer Vision
- Radiance
- Reflectance Map
- Reflectance Models
- Retroreflection
- Specularity, Specular Reflectance
- Standard Illuminants
- Surface Roughness
- Transparency and Translucency
- Transparent Layers

Sensing

Section Editor: *In So Kweon, Sang Wook Lee, Mac Pollefeys and Sudipta Sinha*

- Bas-Relief Ambiguity
- Affine Camera
- Affine Projection
- Bidirectional Texture Function and 3D Texture Calibration
- Calibration of a Non-single Viewpoint System
- Calibration of Radiometric Falloff (Vignetting)
- Camera Calibration
- Camera Extrinsic Parameters
- Camera Model
- Camera Parameters (Intrinsic, Extrinsic)
- Camera Pose
- Catadioptric Camera
- Center of Projection
- Chromaticity
- Color Constancy
- Color Model
- Color Similarity
- Color Spaces
- Field of View
- Fisheye Lens
- Focal Length
- Fresnel Equations
- Gamut Mapping
- High Dynamic Range Imaging
- Hyperspectral/Multispectral Imaging
- Image Plane
- Image Sensors

Incident Light Measurement
 Infrared Thermal Imaging
 Intrinsic Properties
 Lens Distortion, Radial Distortion
 Lens Flare and Lens Glare
 Motion Blur
 Multi-focus Images
 Multiplexed Illumination
 Omnidirectional Camera
 Omnidirectional Vision
 Optical Axis
 Pan-Tilt-Zoom (PTZ) Camera
 Perspective Camera
 Photo-Consistency
 Photometric Invariants
 Photon, Poisson Noise
 Pinhole Camera Model
 Plane Sweeping
 Polarizer
 Radiometric Calibration
 Radiometric Response Function
 Recovery of Reflectance Properties
 Saturation (Imaging)
 Trichromatic Theory
 Underwater Effects
 Vignetting
 Visual Hull
 von Kries Hypothesis
 White Balance

Image Processing

Section Editor: *Kyoung Mu Lee, Jitendra Malik, James Rehg and Wenjun Zeng*

Blind Deconvolution
 Blur Estimation
 Boundary Detection
 Change Detection
 Corner Detection
 Deblurring
 Defocus Blur
 Dehazing and Defogging
 Denoising
 Descattering
 Edge Detection
 Ego-Motion and EPI Analysis
 Image Decomposition: Traditional Approaches

Image Enhancement and Restoration:
 Traditional Approaches
 Image Pyramid
 Interactive Segmentation
 Intrinsic Images
 Optical Flow: Traditional Approaches
 Photometric Stereo
 Retinex Theory
 Scale Selection
 Semantic Image Segmentation:
 Traditional Approach
 Shape from Focus and Defocus
 Shape from Interreflections
 Shape from Scatter
 Shape from Shading
 Shape from Shadows
 Shape from Silhouette
 Shape from Specularities
 Image Super-Resolution

Iconic matching

Section Editor: *Andrew Fitzgibbon, Luc van Gool, Sing Bing Kang, Jun Sato and Zhengyou Zhang*

Affine Invariants
 Affine Registration
 Binocular Stereo
 Calibration of Multi-camera Setups
 Calibration of Projective Cameras
 Dense Reconstruction
 Depth Distortion
 Depth Estimation
 Eight-Point Algorithm
 Epipolar Constraint
 Epipolar Geometry
 Essential Matrix
 Fundamental Matrix
 Geometric Calibration
 Hand-Eye Calibration
 Image Descriptors and Similarity Measures
 Image Registration
 Iterative Closest Point (ICP)
 Multi-baseline Stereo
 Multiview Stereo
 Occlusion
 Occlusion Detection

| | |
|---|--|
| Occlusion Handling | Scene Classification |
| Omnidirectional Stereo | Texture Classification |
| Perspective Transformation | Video Anomaly Detection for Smart Surveillance |
| Photogrammetry | View- and Rate-Invariant Human Action Recognition |
| Projection | View-Invariant Action Recognition |
| Projection Transformation | Facial Attribute Recognition: A Survey |
| Projective Reconstruction | Video-Based Face Recognition |
| Reference Plane | |
| Rigid Registration | |
| Shiftable Windows for Stereo | |
| Subpixel Estimation | |
| Triangulation | |
| Uncalibrated Camera | |
| Vergence | Reasoning |
| Weak Calibration | |
| Weak Perspective Projection | Section Editor: <i>Rama Chellappa, Rei Kawakami, Nikolaos Papanikolopoulos and John Tsotsos</i> |
| Wide Baseline Matching | |
| Recognition | |
| Section Editor: <i>Larry Davis, Martial Hebert, Chen Change Loy, Gerard Medioni, Mubarak Shah and Xiaou Tang</i> | |
| Action Recognition in Real-World Videos | Active Recognition |
| Activity Recognition | Active Sensor (Eye) Movement Control |
| Appearance-Based Human Detection | Active Stereo Vision |
| Appearance-Based Human Tracking: | Animat Vision |
| Traditional Approaches | Cognitive System |
| Ellipse Fitting | Cognitive Vision |
| Face Detection | Data Fusion |
| Face Modeling | Evolution of Robotic Heads |
| Face Recognition | Exploration: Simultaneous Localization and Mapping (SLAM) |
| Gait Recognition: Databases, Representations, and Applications | Face Alignment |
| Gesture Recognition | Feature Selection |
| Hand Pose Estimation | Hashing for Face Search |
| Human Pose Estimation | Image Forensics |
| Linguistic Techniques for Event Recognition | Invariant Methods in Computer Vision |
| Model-Based Object Recognition: Traditional Approach | Learning from a Neuroscience Perspective |
| Monocular and Binocular People Tracking | Learning-from-Observation |
| Multi-camera Human Action Recognition: traditional approaches | Machine Recognition of Objects |
| Object Detection | Mobile Observers |
| Obstacle Detection | Person Re-identification: Current Approaches and Future Challenges |
| Prototype-Based Methods for Human Movement Modeling | Rationale for Computational Vision |
| | Sensor Fusion |
| | Simplified Active Calibration |
| | Three Dimensional View Integration |
| | Unsupervised Visual Domain Adaptation Using Generative Adversarial Networks |
| | Visual Cognition |
| | Visual Cortex Models for Object Recognition |
| | Visual Servoing |

Representation

Section Editor: *Atsuto Maki, Ko Nishino,
Jean Ponce and Jun Takamatsu*

- Active Appearance Models
- Algebraic Curve
- Algebraic Surface
- Aspect Graph
- Computational Symmetry
- Curvature
- Curves in Euclidean Three-Space
- Differential Geometry of Surfaces
 - in Three-Dimensional Euclidean Space
- Differential Invariants
- Extended Gaussian Image (EGI)
- Geodesics, Distance Maps,
and Curve Evolution
- Geons
- Isotropic Differential Geometry
in Graph Spaces
- Kinematic Motion Models
- Line Drawing Labeling
- Many-to-Many Graph Matching
- Numerical Methods in Curve
 - Evolution Theory
- Osculating Paraboloids
- Parametric Curve
- Parametric Surface
- Shock Graph
- Situation Graph Trees
- Splines
- Three-Dimensional Shape Descriptor

Methodologies

Section Editor: *Daniel Cremers, Koichiro
Deguchi, Hiroshi Ishikawa, Kenichi Kanatani,
Tomas Pajdla and Song-Chun Zhu*

- Boosting
- Compressive Sensing
- Constrained Optimization
- Cross Entropy
- Description logics: retrospective survey
- Diffusion Filtering
- Digitization
- Dimensionality Reduction
- Discriminative Random Fields

Dynamic Programming

- Eigenspace Methods
- Energy Minimization
- Euclidean Geometry
- Expectation-Maximization Algorithm
- Factorization
- Fisher-Rao Metric
- Geometric Algebra
- Gradient Vector Flow
- High-Performance Computing
 - in Computer Vision
- Histogram
- Inverse Compositional Algorithm
- Kalman Filter
- Lie Algebra
- Linear Programming
- Maximum Likelihood Estimation
- Multidimensional Scaling
- Optimal Estimation
- Partial Differential Equations
- Principal Component Analysis (PCA)
- Regularization
- Riemannian Manifold
- Robust Estimation Techniques
- Semidefinite Programming
- Simulated Annealing
- Singular Value Decomposition
- Sparse Coding
- Statistical Independence
- Statistical Shape Analysis
- Stochastic Partial Differential
 - Equations
- Subspace Methods
- Swendsen-Wang Algorithm
- Swendsen-Wang Cut Algorithm
- Total Variation
- Variational Analysis
- Variational Method
- Viscosity Solution

Machine learning

Section Editor: *Tatsuya Harada,
Gang Hua, Victor Lempitsky, Cha Zhang
and Lei Zhang*

- AdaBoost
- Autoencoder

Convolutional Sparse Coding
Data Augmentation
Deep CNN-Based Face Recognition
Deep Generative Models
Deep Learning Based 3D Vision
Deep Style Transfer
Domain Adaptation Using

Lumigraph
Matte Extraction
Motion Capture
Plenoptic Function
Video Mosaicing
Video Retrieval

Editor's Biography

Katsushi Ikeuchi is a senior principal research manager at Microsoft. He received his B.Eng. degree in mechanical engineering from Kyoto University in 1973 and his Ph.D. degree in information engineering from the University of Tokyo in 1978. After working at the MIT Artificial Intelligence Laboratory as a postdoctoral fellow for 3 years, at the MITI Electro-Technical Laboratory as a research fellow for 5 years, at the CMU Robotics Institute as a faculty member for 10 years, and at the University of Tokyo as a faculty member for 19 years, he joined Microsoft Research Asia (Beijing) in 2015 and was transferred to Microsoft (Redmond) in 2017.

His research activities span computer vision, computer graphics, robotics, and intelligent transportation systems.

In the field of computer vision, he is considered one of the founders of physics-based vision: modeling image-forming processes, using physics and optics laws, and applying those inverse models in recovering shape and reflectance from observed brightness in a rigorous manner. He developed the “smoothness constraint,” a constraint to force neighboring points to have similar surface orientations. The constraint optimization method based on the smoothness constraint, later referred to as the regularization method, has evolved into one of the fundamental paradigms, commonly employed in various low-level vision algorithms. In 1992, his paper with Prof. B.K.P. Horn, describing the constraint-minimization algorithm with the smoothness constraint [Ikeuchi K, Horn BKP (1981) Numerical shape from shading and occluding boundaries. *Artif Intell J* 17(1–3):141–184], was recognized as one of the most influential papers to have appeared in the *Artificial Intelligence Journal* within the past decade.

Dr. Ikeuchi and his students developed a technique to automatically generate a virtual reality model by observing actual objects along the line of the physics-based vision paradigm [Sato Y, Wheeler MD, Ikeuchi K (1977) Object shape and reflectance modeling from observation. In: Computer graphics proceedings, SIGGRAPH97, Los Angeles, pp 379–387]. This early work is considered one of the starting points of the area later referred to as “image-based modeling.” After returning to Japan, he and his team began to apply the image-based modeling technique to model various cultural heritage sites that were in danger of being lost due to natural and man-made disasters. This project is now known as the e-Heritage Project. He and his team succeeded in modeling all three big Buddha statues in Japan as well as the complicated stone temple, Bayon, at Angkor Wat and Preah Vihear temple, in Angkor ruins, to name a few [Ikeuchi K, Miyazaki D (2008) Digitally archiving cultural objects. Springer, New York]. Through these efforts, he received IPSJ Contribution Award 2015, Funai Achievement Award 2017, and IEICE Distinguished Achievement and Contributions Award 2021.

Dr. Ikeuchi has also been working on robot vision. In this area, he has been concentrating research on how to reduce the cost of production by using robot vision technologies. This includes how to make efficient production lines and, more importantly, how to reduce the cost of making robot programs for use in such production lines. In the early 1980s and even today, one of the obstacles to the introduction of robot technologies to production lines is the so-called bin-picking problem: how to pick up one part from a stack of the same parts. Using shape-from-shading techniques, he was successful in making a robot system that could pick up a mechanical part from a stack [Horn BKP, Ikeuchi K (1984) The mechanical manipulation of randomly oriented parts. *Sci Am* 251(2):100–111].

It was evident that the next obstacle was the cost of programming after completing the bin-picking system. In the early 1990s, he began a project to make a robot program that learns robot motions from observing human operators’ performances [Ikeuchi K, Suehiro T (1994) Toward an assembly plan from observation, part 1: task recognition with polyhedral objects. *IEEE Trans Robot Autom* 10(3):368–385]. He and his team demonstrated that this method, programming-by-demonstration, can be applied to handle not only assembling block-world objects, but also machine parts as well as flexible objects such as rope knotting tasks [Takamatsu J et al (2006) Representation for knot-tying tasks. *IEEE Trans Robot* 22(1):65–78]. Along with his students, he further extended the method in the domain of whole body motions by a humanoid robot [Nakaoka S et al (2007) Learning from observation paradigm: leg task models for enabling a biped humanoid robot to imitate human dance. *Int J Robot Res* 26(8):829–844]. They succeeded in making a dancing robot, which can learn Japanese folk dance from observation, and mimic such dance. He received several best paper awards from this line of work, including IEEE KS Fu Memorial Best Transaction Paper Award and three RSJ Best Transaction Paper awards.

Besides these research activities, he has also devoted his time to community service. He chaired a dozen major conferences, including 1995 IEEE-IROS (General), 1996 IEEE-CVPR (Program), 1999 IEEE-ITSC (General), 2001 IEEE-IV (General), 2003 IEEE-ICCV (Program), 2009 IEEE-ICRA (Program), 2012 IAPR-ICPR (Program), 2015 IEEE-ICCV (Program), and 2017 IEEE-ICCV (General). His community service also includes IEEE RAS Adcom (1998–2004, 2006–2008), IEEE ITSS BOG, IEEE Fellow Committee (2010–2012), and 2nd VP of IAPR. He was an editor-in-chief of the *International Journal of Computer Vision* (Springer) and *International Journal of Intelligent Transport System* (ITS Japan).

Through these research activities and community service, Dr. Ikeuchi received the IEEE-PAMI Distinguished Researcher Award, the Shiju Hou Sho (Medal of Honor with Purple Ribbons) from the Japanese Emperor, and Okawa Prize as well as fellow awards from IEEE, IAPR, IEICE, IPSJ, and RSJ.

Yasuyuki Matsushita received his B.S., M.S., and Ph.D. degrees in EECS from the University of Tokyo in 1998, 2000, and 2003, respectively. From April 2003 to March 2015, he was with Visual Computing group at Microsoft Research Asia. In April 2015, he joined Osaka University as a professor. His research area includes computer vision, machine learning, and optimization. He is Editor-in-Chief of *International Journal of Computer Vision* (IJCV) and is or was on editorial board of *IEEE Transactions on Pattern Analysis and Machine Intelligence* (TPAMI), *The Visual Computer* journal, *IPSJ Transactions on Computer Vision Applications* (CVA), and *Encyclopedia of Computer Vision*. He served or is serving as a Program Co-Chair of PSIVT 2010, 3DIMPVT 2011, ACCV 2012, and ICCV 2017 and a General Co-Chair for ACCV 2014 and ICCV 2021.

Yasuyuki Matsushita Professor, Graduate School of Information Science and Technology, Osaka University, Suita, Osaka, Japan

Rei Kawakami is a specially appointed associate professor at Tokyo Institute of Technology, Tokyo, Japan, and a senior researcher at DENSO IT laboratory. She received her B.S., M.S., and Ph.D. degrees in information science and technology from the University of Tokyo in 2003, 2005, and 2008, respectively. After working as a researcher at the University of Tokyo, the University of California, Berkeley, and Osaka University, she joined Tokyo Institute of Technology in 2020. Her research interests are in computer vision and multi-media processing. She has been serving as an associate editor in *International Journal of Computer Vision*; an area chair in International Conference on Computer Vision and Pattern Recognition (CVPR), ACM Multimedia, Winter Conference on Applications of Computer Vision (WACV), Asian Conference on Computer Vision (ACCV), International Conference on 3D Vision (3DV); a program chair in International Conference on Machine Vision and Applications (MVA); and as an organizer of E-heritage workshop, and Physics-Based Vision Meets Deep Learning workshop held in conjunction with ICCV and CVPR.

Synonyms

Detection and localization; Event recognition

Definition

The goal of human action recognition is to temporally or spatially localize the human action of interest in video sequences. Temporal localization (i.e., indicating the start and end frames of the action in a video) is referred to as frame-level detection. Spatial localization, which is more challenging, means to identify the pixels within each action frame that correspond to the action. This setting is usually referred to as pixel-level detection. In this chapter, we are using action, activity, and event interchangeably.

Background

Three main ingredients of action research are visual features, machine learning methodology, and datasets. Recent years have witnessed a tremendous increase in research and development in all these areas of research. Several new visual features have been proposed which range from handcrafted local and global features and deeply learned visual features for action recognition and detection. Almost all the machine learning techniques have been applied to achieve robust action classification. Most of the action classifications methods gear around supervised approach [1–3]. Since obtaining labels of videos for the supervised approach is quite a time-consuming and costly, several weakly supervised [4–8] and unsupervised approaches [9–11] have been proposed.

The availability of diverse and real-world representative datasets plays a crucial role in research and development in any field. Several large scales, diverse, real-world representative datasets have been introduced in recent years. These datasets include videos from sports, movies, daily lives, and person-environment interaction videos [12–20].

In what follows, we provide a brief review of some of the very important visual features techniques, machine learning approaches to learn action classifiers, and some of the recent action datasets.

Visual Features for Action Recognition

To recognize and localize human action in videos, several recent visual features have been proposed. Good visual features are invariant to scale, rotation, affine transformation, brightness changes, occlusion and camera motion, and position. Overall, there are two types of features, i.e., handcrafted features and features, learned through deep networks. In handcrafted features, there are further two categories. Local features are extracted by the dense sampling of the videos or finding interest points in frames, whereas

holistic features gather features that extract global shape, structure, and contextual information of the human body and make a 3D volume of space-time. These features contain the human pose information at a different time and spatial location of the person in video frames. Deeply learned features capture both local and global information in the same framework.

Hand-Crafted Visual Features

Holistic Features Holistic representations extract features from global regions (whole frame or whole human body) which are invariant to the cluttered background and appearance changes. Yilmaz et al. [21] purpose space-time volume (STV) to take space-time information of action. STV is generated by stacking the 2D object contour in the image plane with respect to time to make a space-time volume. Differential geometric properties from STV are shown to be the invariant viewpoint. Another technique of getting motion information is through algorithm optical flow which computes the direction of motion on two consecutive frames. The shape model presented in [22] learned a prototype tree for action recognition.

Local Features In local representation, spatiotemporal keypoints (corners, edges, etc.) are detected in the video and descriptors made over these key points are used to capture the local motion information. Laptev et al. [23] (called STIP) extended Harris corner detector in space-time domain. They used a normalized spatiotemporal Laplacian operator to detected events over temporal and spatial scales. Local representation overcomes the problems in holistic representation.

Spatiotemporal interest points capture information for a short duration of time and hence cannot capture long-term duration information. Wang et al. [24] extract dense trajectory features for capturing long-duration information. Feature points are densely extracted on grid of pixels, and these points are tracked in consecutive frames to make dense trajectory. HOG (histograms of oriented gradients), HOF (histograms of optical

flow), and MBH (motion boundary histogram) are computed along the trajectory to extract static appearance information, local motion information, and encode relative motion information, respectively. This method is shown to perform much better than STIP because trajectory captures the motion and dynamic information.

Deep Network-Based Features

With the resurgence of deep learning, several new features are introduced for action recognition. Below, we briefly explain some of the most used deep features.

Two-Stream Convolutional Networks Simonyan et al. [25] proposed two-stream deep networks for action recognition that have two separate input streams (spatial, temporal). The spatial stream uses information from still video frames, while the temporal stream uses the dense optical flow. Both streams are fused to produce the final output. Their model is inspired by the two-stream hypothesis in which the human visual cortex contains two paths: the ventral stream (which performs object recognition) and the dorsal stream (which recognizes motion).

3D ConvNets (C3D) Tran et al. [26] propose deep three-dimensional convolutional networks (3D ConvNets) for learning of spatiotemporal features and a simple linear classifier. They showed good performance on different video analysis tasks with these learner features. Network architecture is as follows: it has eight convolution layers, five pooling layers, followed by two fully connected layers, and a softmax output layer. Convolution kernels are of size $3 \times 3 \times 3$, whereas the pooling kernels are of size $2 \times 2 \times 2$ except for first pooling layer which has $1 \times 2 \times 2$. Finally, each fully connected layer has 4096 output units.

Inception-3D Carreira et al. [27] propose a new two-stream inflated 3D ConvNet called I3D in which 2D ConvNet trained for image classification is expanded to 3D ConvNet that extract spatiotemporal feature from a video. They convert 2D ConvNets that accurately work with 2D-

image classification models into a 3D model by adding one additional dimension to 2D filter and kernel. Resulted kernel and filters have an additional temporal dimension where $2D - N \times N$ filters converted into $3D - N \times N \times N$. As mentioned before, inspired by two-stream networks [25] for videos classification, Carreira et al. [27] use two 3D-Streams; one for RGB and other for optical flow. Both networks are trained separately, and the results are averaged.

Multi-fiber Networks Chen et al. [28] proposed multi-fiber networks architecture that composed of separately connected multiple fibers or lightweight 3D convolutional networks which are independent of each other. In this way, a complicated neural network is divided into a group of different small networks. They increase the model efficiency by reducing the number of connections in the network. The number of connections is reduced by slicing the conventional complex residual unit into fixed separate parallel paths (called fibers). They solve the information blockage problem across the paths using fully convolution layer at the beginning and end of each unit and use a multiplexer that redirects and amplifies features from all fibers. The paper shows state-of-the-art action recognition accuracy with less computational time.

Action Datasets

In this section, we briefly review some of the recent action detection datasets.

THUMOS-14

THUMOS-14 [20] contains videos of a large number of human action classes. The dataset contains a variety of actions including normal daily life activity (brushing teeth) and sports actions (golf swing). It contains a total of 18,394 video sequences. They have used the entire UCF101 data for training, and testing is done on 1579 videos that contain one or more action instances in it.

UCF-Crime

Sultani et al. [19] proposed a new anomaly detection dataset named as UCF-Crime. The UCF-Crime dataset contains untrimmed real-world surveillance videos. It contains 13 real-world anomalies, including abuse, arrest, arson, assault, road accident, burglary, explosion, fighting, robbery, shooting, stealing, shoplifting, and vandalism. This dataset contains a total of 1900 video clips. The total duration of 1900 clips is 128 h at 30 fps with 240×320 resolutions. They use 800 normal and 810 anomalous videos for training, and the remaining 150 normal and 140 anomalous videos are used for testing (Fig 1).

ActivityNet

ActivityNet [18] is a large-scale action dataset that contains 203 activity classes like eating, drinking, sport, exercise, and relaxing. This dataset contains a total of 1900 video clips. The total duration of 19,994 clips is 849 h at 30 fps with 1280×720 resolutions. They have used 50% videos for training, 25% videos for testing, and the remaining 25% videos for validation.

EPIC-Kitchens

The EPIC-Kitchens dataset [17] contains videos of different kitchen actions. In these videos, the camera is mounted on the face of the person.

Videos are taken from 32 different kitchens. The dataset contains 819 different actions like a wash, adjust heat, pour oil, and put the bottle. The total duration of video clips is 55 h having 45 million frames at 60 fps and 1920×1080 resolutions. They split the dataset in which 80% videos are used for training and the remaining 20% are used for testing.

UT Egocentric

UT Egocentric dataset [16] contains four videos of different action captured by a camera mounted on the head of a person. The duration of these videos are about 3–5 h long and are captured in a natural and uncontrolled environment. The actions include driving, eating, shopping, cooking, and attending lectures. The total duration of 4 clips is 17 h at 15 fps with 320×480 resolutions. In this dataset three videos are used for training, and one video is used for testing.

Moments in Time

Moments in Time dataset [15] is generated by MIT-IBM Watson AI Lab to help the vision system to understand and recognize the action in the videos. The dataset contains videos of people, animals, objects, or natural phenomena. It contains 339 action classes and one million labeled 3-s videos at 5fps. They generate a training set

Action Recognition in Real-World Videos, Fig. 1 Typical frames from some of the most popular action datasets

of 802,264 videos having 500 to 5000 videos per class. The test set of 67,800 videos has 200 videos per class.

YouTube M8

YouTube M8 [14] was generated by Google in 2016 which contains 6.1 million video ID taken from YouTube and duration of video clips are 350,000 h at 1fps. There are approximately 3862 classes in this dataset, and class labels are machine-generated. In this dataset, a single video has multiple labels, and average labels per video are around three. The dataset contains pre-computed audio and visual features from video frames that are easily used to train machine learning models. Both feature and video-level labels are available for download. They split videos into three partitions, train 70%, validate 20%, and test 10%. They want to make their dataset as a baseline to evaluate the various classification models using popular evaluation metrics.

Charades

Charades [13] is a very large temporal video action dataset that is presented in ECCV 2016. To make their dataset more realistic, they record different indoor action videos by 267 unique users according to predefined sentences. These sentences are made from fixed vocabulary which includes objects and actions of different kinds. The dataset contains a total of 9848 annotated videos of 157 different actions having a length of 30s. The annotation contains both descriptions of the video and temporal intervals of different performing actions.

AVA Actions Dataset

Atomic visual actions (AVA) [12] is a densely labeled video action dataset of untrimmed videos. In this dataset, actions are labeled with respect to both temporal and spatial locality and have 80 different atomic visual actions. Multiple labels on single humans are annotated, resulting in 1.62M of total dens labels. It contains 430 different video clips having a duration of 15 min. Every person is labeled with a bounding box and type of action from its atomic visual action vocabulary.

Action Recognition Approaches

In what follows, we briefly review some of the recent fully supervised, weakly supervised, and unsupervised action recognition approaches.

Supervised Action Recognition

Supervised action recognition assumes the availability of complete labels of all the classes to be learned. Although, getting videos annotated is quite a time-consuming and costly task, the supervised action recognition methods have much higher detection accuracy as compared to unsupervised or weakly supervised approaches.

Jain et al. [1] presented that object encoding improves the performance of action localization and classification. They have obtained responses of 15,000 object detectors for each frame of video and averaged those responses to video representation. They demonstrated that these object-based representations provide good action recognition and detection accuracy. They also demonstrated that object-action relations are generic and it can be used for transfer learning between different datasets.

Choutas et al. [2] proposed an interesting approach for robust human recognition using a new representation called potion. The potion is obtained by temporally aggregating the probability maps of the human pose estimator. They assigned different colors to human poses depending on their relative temporal location in the videos.

Recently, Hu et al. [3] proposed an encoder-decoder framework using 3D separable convolution for the pyramid pooling of efficient human action recognition and segmentation. Their proposed approach is efficient and provide very good segmentation and action detection as compared to several competitive baselines.

Weakly Supervised Action Detection

Weakly supervised action detection falls between supervised learning (labeled data) and unsupervised learning (no labels). In weakly supervised learning, the complete annotations of the concepts to be learned are not available during training. For example, for spatiotemporal action

detection, instead of spatiotemporal bounding boxes, only the video-level labels are available during training. However, on testing, the classifier needs to provide spatiotemporal bounding boxes of actions. Weakly supervised approaches help in reducing the time, effort, and cost of annotations.

Nguyen et al. [7] proposed a sparse pooling network to temporally localize human action in the videos. They introduced a method to generate temporal class activation mapping in the two-stream framework and demonstrated improved detection results.

Wang et al. [6] introduced a new end to end architecture, called UntrimmedNet. It generates short clips proposal from videos by uniformly sampling. After extracting the network from a pre-trained network, action labels are predicted for each temporal segment. Furthermore, the selection module is proposed to rank important action proposals. Finally, the output of the classification and selection module are fused to produce a final classification.

Singh et al. [5] used a different and new approach to that problem called Hide and Seek. Instead of changing the algorithm, they change the input video. During training, they randomly remove the frames and hence force the network to learn all the discriminative frames which produce good classification results. These automatically discovered frames are then used for action classification.

Chang et al. [4] purposed Discriminative Differentiable Dynamic Time Warping (DTW) that uses weak supervision to segments and aligns the video frames. At training time, only the ordered list of action is provided. The main contribution of their work is to make an alignment loss to be differentiable.

Weakly supervised anomaly detection algorithms in [29] developed multiple instance ranking loss for criminal activity detection in surveillance videos. Training labels of being normal and abnormal are assigned at video level, and a model is trained to temporally detect abnormal activists in videos.

Unsupervised Action Recognition

Due to the availability of free humongous visual data, several researchers have worked on design-

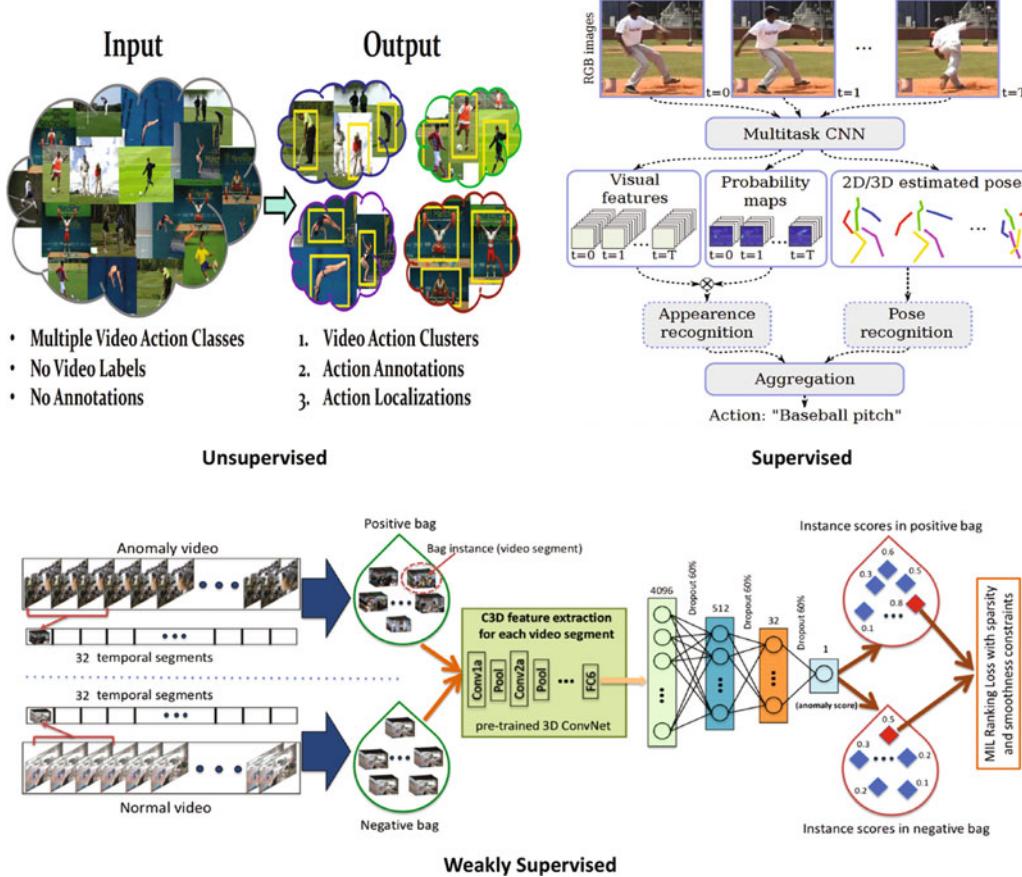

ing unsupervised approaches for action recognition. The key advantage of unsupervised action recognition is that it does not need any kind of manual annotations. The design of such unsupervised methods can save time and cost and evade manual annotations biases.

Generally, in unsupervised action recognition, the first step is clustering. The visual features are extracted from the videos, and based on feature similarities, videos are grouped into separate clusters. After that, the classifier is learned on these clusters. This is followed by the iterative process in which both classifiers and clusters are improved. As compared to fully supervised action recognition, less research work has been done in unsupervised action recognition. Below, we describe some of the recent works for unsupervised action recognition.

Jones et al. [11] proposed feature grouped spectral multigraph (FGSM) approach for unsupervised action recognition. Firstly, feature clustering generates the number of action classes or feature space. Secondly, for each feature, a separate graph is generated. Multigraph Spectral Embedding is found on each graph, and these embeddings are combined into a single representation.

Yu et al. [10] introduced a technique in which video frames are categories by a collection of spatiotemporal interest points (STIPs). They use the histogram of gradient (HOG) and histogram of flow (HOF) as a descriptor of STIP. A random forest is built to model the distribution of high-dimensional feature space. After that, from this random forest, each STIP is matched to the query class and provides a voting score for each action type.

Recently, Soomro et al. [9] proposed a novel unsupervised approach for action detection. They clustered action videos using a dominant set clustering algorithm. After that discriminative clustering is applied which is followed by the variant of knapsack optimization. They have demonstrated competitive results compared to several baselines. Finally, Sultani et al. [30] proposed an unsupervised way to rank the action proposal in the videos. They demonstrated that better re-ranking of action proposals leads to better action detection accuracy (Fig. 2).

Action Recognition in Real-World Videos, Fig. 2 Examples of recently proposed unsupervised [9], weakly supervised [29], and supervised [31] action classification approaches

Action Segmentation

The desired output of the action segmentation is to generate a segmentation mask on the regions of video where the action is being performed including start time, end time, and action class label. Many papers use different techniques for action segmentation. Jhuang et al. [32] describe the importance of action segmentation in video data. They show that different types of annotations on the same dataset change the performance of the algorithm. They described that 2D puppet model of humans (made from 10 body parts connected by 13 joints) show significant improvement in classification rather than using bounding boxes, class level label, or temporal localization of action in the video. Lu et al. [33] found a single and hierarchical MRF model which showed significantly improved results in

action segmentation. They also found that bounding box and action segmentation mask improve results over the video-level label, and specifically segmentation mask gets better results than bounding box. Ghosh et al. [34] introduced stacked spatiotemporal graph CN for action segmentation. Graph-based CNN uses a combination of spatial and temporal dynamics for better segmentation. Their method is an extension of the spatiotemporal graph CN that was developed for skeleton-based action recognition.

Trimmed Video Action Classification

Trimmed action videos contain single action from start to end of the video. These types of videos are usually shorter in length around 10–15 s. Sultani et al. [35] introduced a novel approach in which

they used web images to achieve spatial action localization in trimmed action videos. Soomro et al. [36] used supervoxels for capturing the relation between spatiotemporal segmentation in the video. Initially, they started with random supervoxels during training and then found matching supervoxels and used those to localize action at testing time. Carreira et al. [27] propose a two-stream Inflated 3D ConvNet called I3D that extracts spatialtemporal feature from video. The idea behind I3D is to expand 2D ConvNet trained for image classification into 3D ConvNet for video action classification. They convert 2D ConvNets that accurately work with 2D-image classification models into a 3D model by adding one additional dimension to the 2D filter and kernel.

Untrimmed Video Classification

Untrimmed videos are comparatively longer in time and contain multiple actions and/or single action which is repeated several times in the same video. They are more close to real-world settings. These types of videos are usually around 5 to 15 min long. Singh et al. [37] introduced a method in which they performed the tasks of action classification by combining video-level global feature and frame-level features and generated temporal action proposals by using dynamic programming. Montes et al. [38] introduced a simple method in which they used the features from 3D Convolutional Neural Network (C3D) and employ recurrent neural networks (RNN) to perform action classification.

Temporal Action Detection

Temporal action detection algorithms seek to identify the frames of the video where the action is being performed. Recently, several approaches are being presented for the temporal action detection including [37–39]. Zhao et al. [39] proposed a novel approach called a structured segment network (SSN) in which the temporal structure of action is represented with a structured temporal pyramid.

Spatiotemporal Action Detection

Spatiotemporal action classification is a much harder problem where we want to do temporal

localization (starting and ending frame of the action) as well as spatial localization. Several of the above mentioned papers accomplished spatiotemporal action classification [35, 40]. Singh et al. [40] introduced a new efficient action tube generation algorithm employing optical flow for action localization and classification.

Action Recognition Challenges

Action Recognition Challenges aim to mature the computer vision algorithm across different domains such as surveillance videos, indoor/outdoor activities, wildlife observation, and action anticipation. Generally, the organizing committees of these challenges release some new large-scale datasets, and participants across all over the world compete with each other on these datasets. Below are some of the famous computer vision competitions.

THUMOS Challenge

THUMOS workshop and challenge (<http://www.thumos.info/home.html>) contributes a lot in defining new challenges and approaches in automatic action recognition and localization. The challenge is performed on the THUMOS 2015 dataset which is a very large action recognition dataset of untrimmed videos recorded in realistic scenes taken from YouTube. THUMOS 2015 is an extension of THUMOS14, but it has 430 h of videos that are 70% larger than THUMOS14. The participants trained their models and checked their performance on both action classification and temporal action localization.

AVA Challenge

AVA Action challenge (<https://research.google.com/ava/challenge.html>) aims at exploring new approaches for action recognition in both space and time on the AVA dataset. In this challenge, participants have to identify 80 video classes of actions. Performance is evaluated on the localization of action in both time and space. AVA dataset is quite challenging as multiple people are doing multiple actions in the video. In 2019

Facebook AI Research (FAIR) won this challenge with 34.24% mAP at 0.5 IOU.

EPIC-Kitchens Action Recognition Challenge

EPIC-Kitchens Action Recognition Challenge (<https://epic-kitchens.github.io/2020>) aims to classify trimmed videos of seen and unseen kitchens action in EPIC-Kitchens dataset. Videos are recorded by a camera mounted on the face of people in 32 different kitchens. The task in this challenge is to classify the action segments from a trimmed video. Noun and verb classes jointly define the action class for a segment. Participants have to provide confidence scores for each noun and verb class for their submission. The highest top-1 accuracy of this challenge in 2019 on the action recognition task is 41.37% with 25.13% precision and recall 26.39%.

Charades Activity Challenge

Charades Activity Challenge (<http://vuchallenge.org/charades.html>) aims to explore challenges and methods on automatic action recognition tasks on indoor daily life activities of people, by providing realistic videos from Charades dataset. Charades is a very large dataset of diverse videos from daily life activities including sitting on a chair, opening doors, working on computers, and drinking water. The aim is to boost the action recognition accuracy in real daily life tasks. There are two separate tracks in this challenge: classification track and localization track. The classification track is to classify all activities/actions of the given video. The localization track is to localize the intervals of a specific action. The top accuracy of the winning team in this challenge is 34% mAP.

Open Problems

Although tremendous research work has been done in different areas of action recognition problems, there are still several areas that are less explored. CCTV surveillance cameras are ubiquitous nowadays and recording humongous about of data 24/7. Most of these videos are of

low quality. There is not much research work for the detection of actions in CCTV cameras. State of the art action recognition methods performed quite poorly on CCTV videos. Action detection under different weather conditions (rain, snow, shadow) is not much explored. Action detection in the videos capturing night scenes is still an unexplored area. Only a little research work has been done for action recognition from far cameras (cameras mounted to the top of the building). Furthermore, a lot of work needs to be done for action detection and localization in crowded environments.

Active Appearance Models

Hiroaki Kawashima
Graduate School of Information Science,
University of Hyogo, Kobe, Japan

Synonyms

[Linear shape and appearance models](#)

Definition

An active appearance model (AAM) is a statistical generative model of deformable objects, which simultaneously models shape and appearance variation. The term AAM often refers to not only a model but also a fitting algorithm associated with the model.

Background

When a deformable object changes its shape, the deformation affects both the 2D shape and appearance (texture) on the captured images of the object. Modeling such shape and appearance variation enables us not only to synthesize photo-realistic images but also to interpret images (*interpretation by synthesis*). That is, once a parametric generative model is fit to an object in an image, the model parameters “explain” the object in terms of its position, orientation, scale, shape, and appearance. Therefore, a variety of parametric shape and appearance models were extensively studied in the late 1980s to the early 1990s to realize efficient and stable deformable

object detection and fitting algorithms. In particular, statistical linear models have been considered as promising models for shape [5, 6] and appearance [19] variation because they are trainable and therefore more suitable for describing the actual distribution in the real world.

A statistical linear model of shape variation is referred to as a point distribution model (PDM) [5], where a shape is described by a vector (a list of landmark points), and its statistical distribution is trained from examples. The active shape model (ASM) [6] is a typical method in which 2D PDMs are applied. Similar to active contour models (snakes) [14], the ASM algorithm iteratively moves each point of a shape toward local features (e.g., edges) to find the pose and shape of a deformable object in an image. Here, PDMs globally constrain shape variation, i.e., deformation is only allowed in the range learned from a given training set. This is in contrast to active contour models, which impose local smoothness constraint through the internal spline energy.

In the late 1990s, several methods were proposed to combine appearance models with PDMs [7, 12, 13, 18]. Active blobs describe the appearance information of a deformable object with patches, where pixel values are interpolated along with shape warp [18]. 3D morphable models (3DMMs) utilize a linear model to deal with texture variation while using a 3D shape model (3D PDM) for shape deformation [2, 13, 20]. AAMs also employ linear models to describe 2D shape deformation and appearance variation [7, 12]. There are several variants of AAMs. The original AAM [6] uses “combined” parameters to model the correlation between shape and appearance, while certain other variants of AAMs [3, 15] model shape and appearance separately. Furthermore, several fitting algorithms have been studied with associated models [3, 15], as will be explained later.

Theory

Model

Suppose that N labeled landmark points, $\{(x_i, y_i)\}_{i=1}^N$, describe a 2D shape of a single

deformable object. Assume that all points are aligned in a common coordinate frame of the object (which will be referred to as the *object coordinate frame*), and let $\mathbf{x} = (x_1, y_1, \dots, x_N, y_N)^\top$ be a shape vector. In AAMs, shape variation is modeled by a linear combination of orthogonal modes $\mathbf{p}_{s,1}, \dots, \mathbf{p}_{s,n} \in \mathbb{R}^{2N}$:

$$\mathbf{x} = \bar{\mathbf{x}} + \sum_{i=1}^n b_{s,i} \mathbf{p}_{s,i} = \bar{\mathbf{x}} + P_s \mathbf{b}_s, \quad (1)$$

where $\bar{\mathbf{x}}$ is the mean shape vector, the columns of $P_s = [\mathbf{p}_{s,1}, \dots, \mathbf{p}_{s,n}] \in \mathbb{R}^{2N \times n}$ are the orthogonal modes of shape variation, and $\mathbf{b}_s = (b_{s,1}, \dots, b_{s,n})^\top$ are shape parameters, each of which corresponds to each shape mode.

Given a set of shape examples (shape vectors) in the object coordinate frame as a training set, the orthogonal modes, P_s , can be obtained through principal component analysis (PCA) by considering n eigenvectors corresponding to the largest n eigenvalues of the covariance matrix of shape examples. A model of Eq. (1) trained from shape examples is referred to as a PDM [5], as explained in the Background. Once a PDM is trained, a variety of deformed shapes can be generated by changing its shape parameters.

Appearance is typically defined within the mesh with the mean shape, $\bar{\mathbf{x}}$, where an image defined over the pixels inside the region of mesh $\bar{\mathbf{x}}$ is referred to as a *shape-normalized image*. Let $\mathbf{g} \in \mathbb{R}^M$ be an appearance (texture) vector constructed by sampling intensity information of the shape-normalized image, where M is the number of sampling points. We here assume gray-scale images for simplicity, while the model can be easily extended to color images. In AAMs, appearance variation is described by a linear combination of the orthogonal modes $\mathbf{p}_{g,1}, \dots, \mathbf{p}_{g,n} \in \mathbb{R}^M$ similar to shape variation:

$$\mathbf{g} = \bar{\mathbf{g}} + \sum_{i=1}^m b_{g,i} \mathbf{p}_{g,i} = \bar{\mathbf{g}} + P_g \mathbf{b}_g, \quad (2)$$

where $\bar{\mathbf{g}}$ is the mean appearance vector, the columns of $P_g = [\mathbf{p}_{g,1}, \dots, \mathbf{p}_{g,m}] \in \mathbb{R}^{M \times m}$ are orthogonal modes of appearance variation,

and $\mathbf{b}_g = (b_{g,1}, \dots, b_{g,m})^\top$ are appearance parameters.

Each example image is warped to obtain a shape-normalized image to train the model. Assume that each example image in a training dataset is annotated with N labeled landmark points, $\mathbf{X} = (X_1, Y_1, \dots, X_N, Y_N)^\top$. By warping the intensity information within the mesh with vertices \mathbf{X} to the mesh with $\bar{\mathbf{x}}$, we obtain a shape-normalized image. Here, piece-wise affine warp of triangle patches is typically used considering mesh correspondence between \mathbf{X} and $\bar{\mathbf{x}}$. The total appearance information inside the shape-normalized image is then sampled and vectorized to obtain a training example of appearance vector \mathbf{g} , where the intensity values are standardized appropriately. Through the warping step, the pixel correspondence among training examples is achieved, which is a key to successful appearance variation modeling based on Eq. (2). Once all training images are aligned as the shape-normalized images, PCA can be employed to compute P_g from the training data (a set of appearance vectors obtained from image dataset), similar to shape modeling. The obtained modes, i.e., the columns of P_g , are considered as *shape-normalized eigenimages*.

In the original AAM [8], the correlation of shape and appearance variations is further modeled as follows. Consider a concatenated vector of shape and appearance parameters

$$\mathbf{b} = \begin{pmatrix} W_s \mathbf{b}_s \\ \mathbf{b}_g \end{pmatrix}, \quad (3)$$

where W_s is a diagonal weight matrix that balances the scale between shape and appearance parameters. The concatenated vector is again described by a linear model

$$\mathbf{b} = Q_c \mathbf{c} = \begin{pmatrix} Q_s \\ Q_g \end{pmatrix} \mathbf{c}, \quad (4)$$

where \mathbf{c} is a vector of shared parameters and $Q_s \in \mathbb{R}^{n \times l}$ and $Q_g \in \mathbb{R}^{m \times l}$ are the submatrices of Q_c . The columns of $Q_c \in \mathbb{R}^{(n+m) \times l}$ are l eigenvectors corresponding to the largest l eigenvalues of the covariance matrix of \mathbf{b} , where the training examples of \mathbf{b} are given by Eq. (3)

with the pairs of \mathbf{b}_s and \mathbf{b}_g obtained through the computation of P_s and P_g , respectively.

Equations (1) to (4) can be summarized as follows [4]:

$$\begin{aligned}\mathbf{x} &= \bar{\mathbf{x}} + P_s W_s^{-1} Q_s \mathbf{c} = \bar{\mathbf{x}} + \tilde{Q}_s \mathbf{c}, \\ \mathbf{g} &= \bar{\mathbf{g}} + P_g Q_g \mathbf{c} = \bar{\mathbf{g}} + \tilde{Q}_g \mathbf{c}.\end{aligned}\quad (5)$$

In this model, the change of shared parameter vector \mathbf{c} generates correlated shape \mathbf{x} and appearance \mathbf{g} learned from training examples. This enables us to simultaneously fit shape and appearance models to a given image using optimization with respect to \mathbf{c} . If Q_c is the identity matrix, the two models, i.e., Eqs. (1) and (2), become independent of each other (this is referred to as an *independent AAM* in [15]).

Fitting Algorithm

Given a target image, I , and an AAM expressed by Eq. (5), a fitting algorithm searches several parameters, including \mathbf{c} , to optimally fit the model to the image I . Let $\mathbf{X} = S(\mathbf{x}; \mathbf{t})$ be a transformed point set on the target image frame from a point set (shape) \mathbf{x} in the object frame using *similarity transformation* S with parameter \mathbf{t} , where $\mathbf{t} = (s_x, s_y, t_x, t_y)^\top$. Here, $(s_x, s_y) = (s \cos \theta - 1, s \sin \theta)$ describes scaling s and rotation θ , and (t_x, t_y) describes translation. Note that $\mathbf{t} = \mathbf{0}$ yields the identical transformation (i.e., $\mathbf{x} = S(\mathbf{x}; \mathbf{0})$) and $S(\mathbf{x}; \mathbf{t} + \delta\mathbf{t}) \approx S(S(\mathbf{x}; \delta\mathbf{t}); \mathbf{t})$. Let $\mathbf{g}_s(I, \mathbf{X}) \in \mathbb{R}^M$ denote the sampled intensity values of the shape-normalized image warped from target image I using the mesh correspondence between \mathbf{X} and $\bar{\mathbf{x}}$. Intensity values should also be normalized appropriately by searching for additional normalization parameters [9]; however, these parameters are omitted here for simplicity.

Let $r(\mathbf{p})$ be the fitting error between target and generated intensity values in the shape-normalized images, with respect to parameter $\mathbf{p} = (\mathbf{c}^\top, \mathbf{t}^\top)^\top$:

$$r(\mathbf{p}) = \mathbf{g}_s(I, S(\mathbf{x}(\mathbf{c}); \mathbf{t})) - \mathbf{g}(\mathbf{c}), \quad (6)$$

where \mathbf{x} and \mathbf{g} are given by Eq. (5). The fitting algorithm finds parameter \mathbf{p} by solving

$$\min_{\mathbf{p}} E(\mathbf{p}) = \|\mathbf{r}(\mathbf{p})\|^2. \quad (7)$$

An iterative algorithm can be utilized to minimize $E(\mathbf{p})$ [3]. The first-order Taylor expansion of $r(\mathbf{p})$ gives

$$\mathbf{r}(\mathbf{p} + \delta\mathbf{p}) = \mathbf{r}(\mathbf{p}) + \frac{\partial \mathbf{r}}{\partial \mathbf{p}} \delta\mathbf{p}, \quad (8)$$

where $\frac{\partial \mathbf{r}}{\partial \mathbf{p}}$ is the Jacobian whose (i, j) element is $\frac{\partial r_i}{\partial p_j}$. By solving $\operatorname{argmin}_{\delta\mathbf{p}} \|\mathbf{r}(\mathbf{p} + \delta\mathbf{p})\|^2$, we obtain an update rule $\mathbf{p} \leftarrow \mathbf{p} + k\delta\mathbf{p}$ with

$$\delta\mathbf{p} = - \left(\frac{\partial \mathbf{r}^\top}{\partial \mathbf{p}} \frac{\partial \mathbf{r}}{\partial \mathbf{p}} \right)^{-1} \frac{\partial \mathbf{r}^\top}{\partial \mathbf{p}} \mathbf{r}(\mathbf{p}), \quad (9)$$

where $k = 1$ for the initial step size and k is adjusted (using, e.g., $k = 0.5, 0.25$) during iteration steps so that $E(\mathbf{p})$ decreases. As the computation cost of $\frac{\partial \mathbf{r}}{\partial \mathbf{p}}$ is high, it is assumed to be approximately fixed and pre-computed using numerical differentiation before the search. In practice, several techniques, e.g., a multiresolution (hierarchical) approach with a Gaussian image pyramid, are used to improve efficiency and robustness (e.g., to prevent falling into a local minimum) [9].

When shape and appearance are separately modeled by Eqs. (1) and (2) (i.e., in the case of independent AAMs), other efficient fitting methods are available including the *inverse compositional image alignment* algorithm [15].

Applications

AAMs have been used for a variety of applications of deformable object fitting (e.g., detection and tracking) and image synthesis. In particular, registration on facial images [12] and medical images [4] are well-known examples.

The relationship between AAMs (to be precise, independent AAMs) and 3DMMs, which utilize 2D and 3D shape models, respectively, has been discussed in detail in [16]. The work has shown that the parameter size of AAMs becomes larger compared to 3DMMs in modeling similar 3D deformation and that the 2D shape models

in AAMs have too much representational power (i.e., they are able to generate physically unrealizable shapes). Therefore, the combination of AAMs and 3D shape models have also been proposed to impose 3D shape constraint for robust real-time fitting applications [16, 22].

Open Problems

A drawback of the original AAM for object tracking is its sensitivity to appearance changes (e.g., change in lighting conditions) because it models the holistic appearance of a deformable object. Instead of modeling the total appearance within an object, recent fitting approaches exploit constrained local models (CLMs) [10, 11]. Note that while the term CLM was originally used for a particular AAM variant in which texture was sampled only around landmark points [11], it has often referred to more general models that incorporate local feature detectors [10] (ASMs are considered as CLMs in this context [17]).

CLMs combine the local information of landmark points, e.g., response maps computed by a feature detector, with the global shape constraint imposed by PDMs. In many cases, CLMs show better fitting performance compared to the original AAM. Since the late 2000s, many facial tracking methods have therefore utilized CLMs with various extensions of fitting objective functions and optimization strategies for achieving accuracy, stability, and computational efficiency [17, 21]. 3D shape models, similar to 3DMMs, have also been used in [1, 17] for facial landmark tracking in uncontrolled environments.

Definition

Active Recognition is the task of processing visual information in order to determine the presence and identity of a particular element in a scene by employing an agent that knows why it wishes to achieve that recognition, chooses what to sense toward that goal, and determines how, when, and where to execute the sensing and recognition actions. Some methods have been termed active if they emit or project signals whose reflections back to the sensor play a role in the processing of visual information. Others emphasize that processing requires image sequences rather than a static image, in a way such that dynamic control of imaging geometry is not explicitly considered. These methods are not part of Active Recognition as described here, and the discussion will focus only on visible light camera sensors.

Background

Active Recognition is a necessary methodology for intelligent agents that need to function in the real world. This was recognized early with the 1969 presentation of the SHAKEY robot, the first general-purpose mobile robot that could reason about its actions [1]. Employing cameras, rangefinders, and bumpers as sensors, it could be given a task and then planned how to deploy its resources, specifically in our context its sensing resources, to complete that task. From within this team, emerged perhaps the earliest Doctoral Dissertation on active perception by Tenenbaum in 1970 [2], where he described methods to control camera parameters by computer. For Tenenbaum, sensor accommodation is automatic and improves the reliability and efficiency of machine perception by matching the information provided by the sensor with that required by specific per-

ceptual functions. The advantages of accommodation are demonstrated in the context of five key functions in computer vision: acquisition, contour following, verifying the presence of an expected edge, range-finding, and color recognition. Shortly after, Barrow and Popplestone [3] pointed out that object recognition is a naturally active process because a recognition agent can interact with its environment by shifting its viewpoint, walk around an object, or even manipulate or handle it in order to gain more information and resolve ambiguities. They presented a broader perspective by noting that such activities involve planning, inductive generalization, and indeed, most of the capacities required by an intelligent machine. Even so, the idea of active perception seemed to lay relatively dormant for some time until Bajcsy [4] wrote: *Active sensing is the problem of intelligent control strategies applied to the data acquisition process which will depend on the current state of data interpretation including recognition.* Her paper was titled “Active Perception” because she correctly noted that not only vision but all the sensing modalities can benefit from active methodologies. Active Recognition, the focus of the current article, is but one of many visual functionalities within this broader view of perception. Aloimonos, Weiss, and Bandyopadhyay [5] added further structure to the concept by putting more emphasis on the observer and its purpose. They suggested that active observation is driven by an agent’s purpose and the agent’s activity is intended to manipulate the constraints underlying the observed phenomena in order to improve the quality of the perceptual results.

Bajcsy et al. [6] define the broad category of active perception as follows: *The processing of visual information is active if its agent knows why it wishes to sense, and then chooses what to perceive, and determines how, when and where to achieve that perception.* In other words, an actively perceiving agent is one which dynamically determines the *why* of its behavior and then controls the *what, how, where, and when* for each behavior. Active Recognition limits the perceptual component of this definition to the aspects that directly impact visual recognition, which for this purpose will be taken to mean

the detection, identification and localization of a particular element of a visual scene (e.g., a car, my cup, etc.). The explicit connection of sensing to behavior was nicely described by Ballard [7] in his *animate vision* concept, writing: *An animate vision system with the ability to control its gaze can make the execution of behaviors involving vision much simpler.* In addition, resource constraints play an important role not only because of computer power and memory capacity but also because in practice, the number of sensors (and other physical components of an agent) is limited as well. Any agent at any point during the execution of its task, will necessarily consider several options or hypotheses about what its next action should be. Thus, choices must be made and in part, this is the role of attentive processes. As Tsotsos [8] wrote: *Since several simultaneous [interpretation] hypotheses can co-exist, a focus of attention mechanism is necessary in order to limit the number of hypotheses under consideration.* Matching an agent’s capabilities (physical behaviors, sensors, computational power, timing constraints, etc.) to its current task requirements (environment, timing and accuracy of required response) is an attentive tuning process [9] and is critical for any real-world agent.

With respect to Active Recognition specifically, the first system to embody all of the elements of the active vision definition was that of Wilkes and Tsotsos in 1992 [10]. The motivation for their approach stemmed from the fact that single-view object recognition is subject to many difficulties, mainly due to viewpoint-related ambiguities, occlusions, and coincidences [11]. In this work, low-level image data was used to drive the sensor to a special viewpoint with respect to the object to be identified. From such a viewpoint, the three-dimensional object recognition problem is reduced to a two-dimensional pattern recognition problem. Solutions for tasks such as robust tracking of image primitives from one sensor position to the next, a simple behavior-based viewpoint control driven primarily by the current image data (three behaviors perform image-line-centering, image-line-following, and camera-distance-correcting), probabilistic algorithms for efficient

storage and retrieval of sets of feature vectors, and a method for selecting additional special views in the case that there remains uncertainty in the identity of the object of interest are presented.

Ikeuchi and Hebert [12] considered the task component of visual recognition and described two vision systems (a rock sampling system for planetary rovers and a bin-picking system for industrial use). They argued for a *task-oriented vision* approach to the design of vision systems. The task-oriented vision approach proposes to change the architecture of a vision system in a systematic fashion which depends on each task specification. They specifically considered the localization and grasping of 3-D objects. Their general methodology involved analyzing the task specification to derive the constraints on its solution as well as any constraints or requirements on the vision components. This analysis started with the type of representation, derived from the type of grasping selected, and continued down to the type of sensor.

Dickinson et al. connect attention to Active Recognition [13]. The attention mechanism consists of a probabilistic search through a hierarchy of predicted feature observations, taking objects into a set of regions classified according to the shapes of their bounding contours, and choosing which predictions to further explore. The probabilistic feature hierarchy encodes viewpoint changes possible in order to achieve a particular view and thus can be used to guide the camera to a new viewpoint from where the object can be disambiguated. Further integration of attention with active recognition is presented by Rasouli and Tsotsos [14] where saliency measures are included as a means of non-combinatorial lookahead for next view determination.

There are other examples of early work that used multiple viewpoints but, mostly, these were pre-determined, such as placing an object on a turntable and via its rotation acquiring several viewpoints that were integrated (e.g., [15]). These approaches do not satisfy several of the elements of our definition. Recently, interest has resurfaced in the deep learning community with several examples of learned systems that purport to accomplish active recognition. But again, those

do not fit our definition. They focus on learning an environment fully or learning the appearance of objects from many viewpoints and then performing a classification (e.g., [16]).

In addition to the already cited sources, the interested reader can examine the following collections and reviews [17–27]. Good sources for active vision as a human capability include [28, 29].

Theory

A Passive Recognition strategy (recognition from a single image) might suffice for many visual scenes. However there have always been the tacit assumption that the image is well-formed, that is, that the subject of interest is represented roughly in the center of the image (to avoid boundary issues), that the subject is sufficiently well lit (the light is bright enough but not too bright, the location of the light source relative to subject and camera does not cause interfering highlights and shadows), that the pose of the subject in 3D is one from which recognition can be expected to be reasonable, that the subject is not overly occluded, and so on. Whenever any of these assumptions are violated, an active approach is the proper remedy. These assumptions are generally invalid for recognition systems embodied in a mobile agent operating in the natural world. These scenarios provide the starting points for any theoretical or practical development toward Active Recognition. Below is a table that lists a few such scenarios plus the kinds of actions a sensing system might use as part of an Active Recognition method.

For particular applications, it is sometimes possible to reduce or eliminate the need for some of these by engineering the environment appropriately (e.g., ensure sensors always see the items of interest with sufficient resolution and lighting, or, objects of interest are always within a known sub-image). However, for a general-purpose agent operating in a dynamic 3D world, this is usually not feasible. How exactly each of these or other sensing system actions are deployed, how the situations for each are

detected (e.g., [11]), how these contribute to the successful completion of some task in a given domain (e.g., [12]), how is an overall recognition system orchestrated to include multiple behaviors (e.g., [10, 13, 14]) are all important questions for any theory of Active Recognition.

Yet another dimension of theoretical analysis is related to the real world in the sense that any actual system must live with resource constraints. A key resource is that of the amount of computation possible within the physical resources and time constraints of the agent. The relative computational complexity of active vision when compared to passive vision was laid out [30]. Active vision includes sampling a scene over time; in the trivial case with a fixed camera this is simply processing image sequences. The non-trivial case of active vision includes any hypothesize-and-test strategy where the choice of next image sample is determined by the state of the interpretation hypothesis space. Typically, there are many possible interpretations for what is being observed and the agent must manage this large set of hypotheses. The solution was formulated using a strategy that generates many hypotheses for a potential solution at first, but then with more data, gradually tightens acceptability constraints and thus eliminates falsified hypotheses until the best one remains. The additional data comes naturally with each image sample in time. Using such a technique, Tsotsos [30] showed the conditions under which active sensing approaches actually provide lower complexity solutions than passive techniques.

Theoretical analysis also can play the important role as a guide to the kind of solution that is possible. Careful examination of the computational nature of a problem points the way to appropriate solutions. For example, for the sensor planning problem – how one determines the best sequence of sensing actions for an object search task in an unknown 3D space – Ye and Tsotsos [31] proved that this problem was NP-hard. This means that no single solution that is optimal for all problem instances is possible. As a result, they developed a robust heuristic solution [32]. In general, understanding the computational nature of a problem at the computational level as

Marr [33] noted, and at the complexity level as Tsotsos [34] argues, provides a solid foundation for developing solutions.

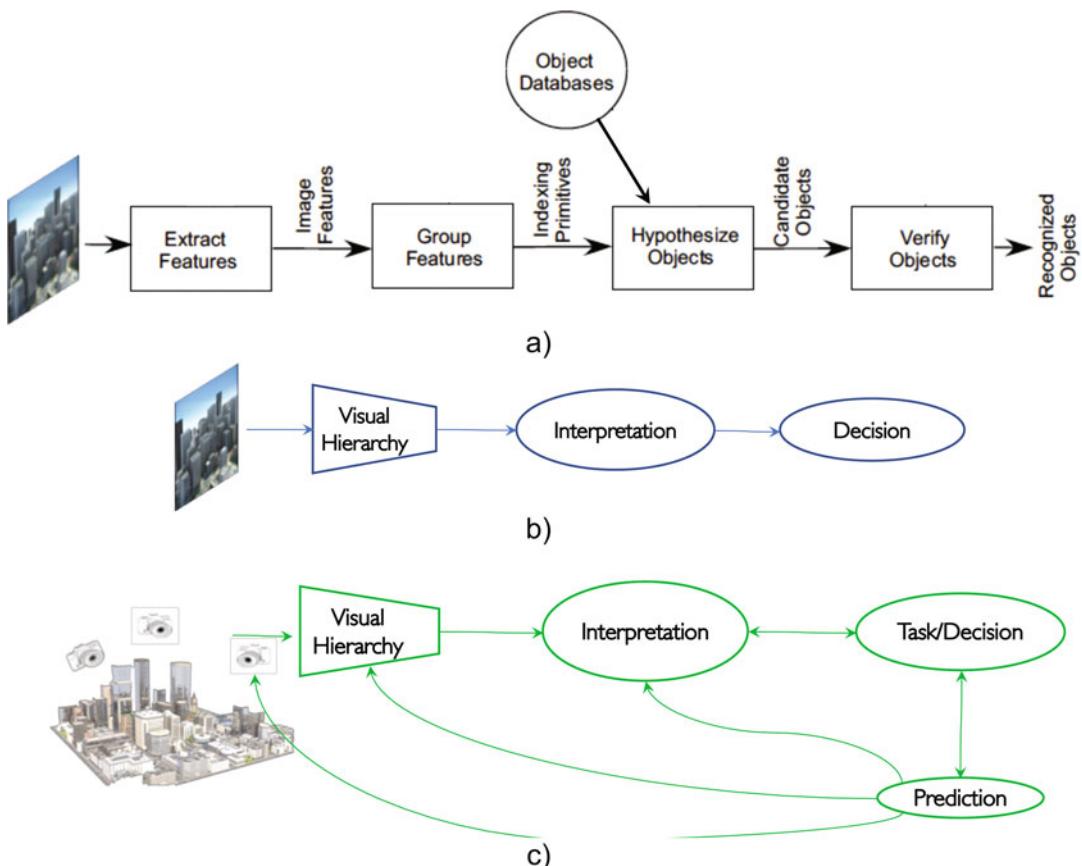

Active Recognition necessarily must interact with any inference processes within a real-world agent. Considering the big picture of robotics research and development, it can be argued that among the main open questions are the following: How can robots figure things out? How can they reason about their circumstances and tasks? How can they exploit attention and context, which seem to be key elements for figuring things out? The current state of the art includes major advancements largely facilitated by major developments in computing power and in data-driven learning methodologies. There is no question that data sets and benchmarking have played major roles. However, they also have drawbacks: they are static and mostly of unspecified provenance, i.e., all aspects of imaging/scene geometry, illumination, etc., are decided separately, often unknown to the interpretation system. In other words, the image acquisition process is decoupled from the image interpretation process. Such a decoupled process simply records whatever appears within a field of view, independently of how any parameters are set or the purpose served by sensing. No matter how much data is collected or its statistical value, a passive strategy gives up control over the specific characteristics of what is sensed, at what time and for which purpose.

Intelligent agents need to be maximally sensitive to the task-relevant while remaining vigilant about the task-irrelevant, and thus some connection between perception, their mission, and task/world knowledge must exist. One such connection could be an effective use of inductive reasoning. Inductive reasoning takes specific information (premises) and makes a broader generalization (conclusion) that is considered probable. The only way to know is to test the conclusion; a passive sensing strategy could only do this by accident. Passive sensing thus impedes the use of any form of inductive reasoning. It is certainly possible to restrict an application domain so that passive sensing suffices (point a sensor in the right direction in advance, frame the object of

interest manually, ensure figure-ground segregation is easy, etc.), but this cannot satisfy the goal of real-world functionality.

Active inductive inference seems to require a world model from which to draw inferences and direct their testing. Figure 1 shows the kinds of recognition pipelines that depict the differences just described in terms of the main elements of recognition paradigms. Figure 1a portrays the recognition pipeline found in classic computer vision, adapted from [26]. Figure 1b shows the typical pipeline used in systems based on CNN's or Deep Learning. Note the major difference with this and part a; in the classic version, object

classes are represented separately and accessed as needed, whereas in the learned system, knowledge about object is embedded within the network weights and parameters. Finally, Fig. 1c lays out the recognition pipeline that uses an active observer. The visual hierarchy and interpretation stages may be either of the classical or modern type; however they must be able to accept and use feedback from the prediction stage to guide processing. Figure 1c portrays the active recognition strategy with the key components of prediction and closed loop processing including sensor control. The key point here is that the prediction stage, based on the current state of

Active Recognition, Fig. 1 Recognition Pipelines. (a) This is the recognition pipeline found in classic computer vision. (Adapted from [26]). (b) This is a typical pipeline used in systems based on CNN's or Deep Learning. Note the major difference with this and part (a); in the classic version object classes are represented separately and accessed as needed, whereas in the learned

system knowledge about object is embedded within the network weights and parameters. (c) This is a recognition pipeline with an active observer. The visual hierarchy and interpretation stages may be either of the classical or modern type; however they must be able to accept and use feedback from the prediction stage to guide processing

Active Recognition, Table 1 Linkage between scene characteristics and sensing actions that might ameliorate the difficulties a single image exhibit

| | |
|--|---|
| Visual scene includes | Sensing actions to assist |
| Scene objects are in motion | Move fixation to track motion (pursuit motion) |
| Scene objects extend beyond the camera image boundary | Move to a different fixation spatial point (saccade) |
| Scene objects are occluded making recognition difficult | Change camera viewpoint to reduce or eliminate occlusion |
| Scene too large to be captured by a single image | Move viewpoint to explore the scene |
| If sensor is foveated, the scene is not uniformly sampled | Change fixation location to increase resolution of portions of interest |
| Resolution of image is insufficient to enable recognition | Lens zoom Move camera viewpoint closer |
| Scene object not sufficiently well focused | Change aperture (depth of field) For binocular cameras, change stereo vergence to appropriate depth plane Adjust focal length |
| Illumination of scene is too high or too low to permit good recognition | Adjust shutter speed |
| Degenerate views (such as accidental alignments) cause recognition ambiguities | Adjust camera viewpoint Adjust lighting levels |

decisions for the task of the moment, provides three kinds of control for processing: it directs the choice of imaging geometry and sensor parameters to apply for the next scene sample to acquire; it tunes the visual hierarchy, where possible, to be most receptive to the kinds of visual information needed for the task at that moment; and it biases the interpretation process for the categorical classes expected from the current sampling action. The task/decision stage also provides a bias to the interpretation stage so that regardless of moment-to-moment bias provided by the prediction stage, the main objective of the current task will remain active.

Application

Recognition is obviously a function necessary for any intelligent agent (robot) operating in the real world. There are many examples of active agents mostly in the robotics domain. For example, consider robots for household tasks such as help with laundry, load and unload dishwashers, do preparatory work for cooking meals (e.g., chopping vegetables), pick up objects (e.g., toys, newspaper, clothes, sneakers) from the floor and move them to the right location, unload groceries

from the car parked in garage, assemble furniture, or help with moving heavy objects. In each case, if the agent is to engage with the objects mentioned (e.g., grasping as in [12]), the object needs to be recognized and localized. If it is currently within the robot's camera view, and the assumptions listed earlier are valid, passive recognition might suffice. If one of the scenarios of Table 1 are present however, active methods are needed. The term visual search refers to the process of examining different images within a scene until a target object is found, and this is a very common function in everyday visual behavior. Examples of such visual search tasks have been presented [35–38]. The 2012–2015 DARPA Robotics Challenge included a different class of applications, all which can benefit from Active Recognition methods. These were more clearly industrial tasks, such as driving a vehicle; traverse a rough-terrain course covered with tripping hazards; clear lumber and pipes that are blocking an entryway; open doors of any type (push door, a pull door, door with a self-closing hinge); climb a ladder; open and close valves; and more. A nice survey of active search applications can be found in [37].

Open Problems

Perhaps the most pressing need is for the creation of appropriate test environments that permit active observation. Computer vision researchers have become accustomed to the use of datasets and benchmarks in their work. It is a good practical way to measure how much progress one is making. But for an active observer, the next image sample depends on context and the state of current interpretation; it thus can only be found in a live environment or in an environment that is generated in real time given dynamically set imaging geometry parameters. Protocols to fairly evaluate performance with such data need to be agreed on as do methods for creating test data sets. An example of an early such test environment is that of the *Animat* framework [39], while more recent ones include [40], *Gibson* [41] and the *Polyhedral Scene Generator* [42].

Another open issue is how much control over camera and imaging geometry is actually necessary for a given application environment? In the early days of active vision, a great deal of effort was put into the design and testing of binocular camera systems (see [6, 22] for reviews). Such developments are still ongoing, but with seemingly lesser intensity (e.g., [43]) and replacements such as the several good RGB-D sensors (e.g., Microsoft's Kinect) seem to dominate due to their ease of use and strong performance in many environments. Nevertheless, these do not support several of the *why's* of active vision (specifically, functionality that requires control of imaging properties such as binocular vergence, zoom, cyclotorsion, aperture, focal length, voltage gain, shutter speed, white balance). Is it really the case that these are not necessary? Since each has shown value in the past (for pointers see [6]), and most are also part of biological vision, this question is important. What capabilities exactly are lost by the adoption of RGB-D sensors? In general, the impact of variation in sensing parameters and configuration has not been adequately considered. Andreopoulos and Tsotsos [44] show the large impact on performance of such variations for a large class of computer vision algorithms. The need for new sensing hardware that lends itself to active

control of a broad set of imaging parameters is strong.

The great majority of active vision approaches consider one dimension of active functionality at a time (viewpoint only for example). As should be clear there are many variables that define an overall imaging and interpretation scenario and more emphasis should be placed on how the control of many variables can be accomplished in concert rather than separately (e.g., [13, 14]).

A final important research direction concerns the role of machine learning. One example of a computational learning theory of active object recognition appears in Andreopoulos and Tsotsos [45]. Brynjolfsson and Mitchell [46] looked more deeply into the kinds of domains where ML can be effective. They concluded that the key characteristics of such domains include learning a function that maps well-defined inputs to well-defined outputs; large data sets exist or can be created containing input-output pairs; the task provides clear feedback with clearly definable goals and metrics; no long chains of logic or reasoning that depend on diverse background knowledge or common sense; no need for detailed explanation of how the decision was made; a tolerance for error and no need for provably correct or optimal solutions; the phenomenon or function being learned should not change rapidly over time; no specialized dexterity, physical skills, or mobility required. As should be clear, the characteristics of active vision depart significantly from most of these. In fact, it has been asserted that active perception breaks deep learning methods. Yet, the need for systems that learn is undeniable. Most current examples of learned active recognition focus on learning how objects appear with different viewpoints. This seems an important distinction. It seems that a major direction for the future will be into developing new learning paradigms that can deal with actively observing agents; perhaps Fig. 1c points to the possibilities. Specifically, the strategy of learning the views needs to mature into a strategy of learning how to select views (including imaging geometry properties).

Conclusions

Everyday behavior for humans or computational agents relies on sequences of perceptual, decision-making, and physical actions selected from a large set of elemental capabilities. The problem of selecting a sequence of actions to satisfy a goal under resource constraints is known to be NP-hard [31]. Nevertheless, humans are remarkably capable. However, the theoretical results tell us that an end-to-end solution that covers the full scope of the problem is unlikely. Perhaps our human capability is due to the fact that we are active observers and actors within the world. Active vision has the goal of providing the computational embodiment of these characteristics and will be a fundamental methodology for future intelligent agents that can deal with the enormous breadth of visual settings and behaviors in a reliable, safe, and predictable manner.

Definition

Active sensors are those whose generalized viewpoint (such as sensor aperture, position, and orientation) is under computer control. Control is done so as to improve information gathering and processing.

Background

The *generalized viewpoint* [1] of a sensor is the vector of values of the parameters that are under the control of the observer and which affect the imaging process. Most often, these parameters will be the position and orientation of the image sensor, but may also include such parameters as the focal length, aperture width, and the nodal point to image plane distance, of the camera. The definition of generalized viewpoint can be extended to include illuminant degrees of

freedom, such as the illuminant position, wavelength, intensity, spatial distribution (for structured light applications), and angular distribution (e.g., collimation) [2].

Changes in observer viewpoint are used in active vision systems for a number of purposes. Some of the more important uses include tracking moving objects, searching for objects, and increasing the dynamic range of the sensor, through adjustment of parameters such as sensor sensitivity, aperture, and focus.

To carry out these changes in the sensor's generalized viewpoint requires computer control of the sensor's actuators based on processing done on the camera video signal. As such, design of active sensing systems needs the integration of computer vision and motor control processes.

robotic vision control systems employ aspects of the Robinson model.

The control of an active camera system is both simple and difficult at the same time. Simplicity arises from the relatively unchanging characteristics of the load or "plant" being controlled. For most systems the moment of inertia of the camera changes only minimally over the range of motion, with slight variations arising when zoom lenses are used. The mass of the camera and associated linkages does not change. Inertial effects become more important for control of the "neck" degrees of freedom due to the changing orientation and position of the camera bodies relative to the neck. The specifications on the required velocities and control bandwidth for the neck motions are typically much less stringent than those for the camera motions, so that the inertial effects for the neck are usually neglected. The relatively simple nature of the oculomotor plant means that straightforward proportional-derivative (PD) or proportional-integral-derivative (PID) control systems are often sufficient for implementing tracking or pursuit motion. Some systems have employed more complex optimal control systems (e.g., [5]) which provide improved disturbance rejection and trajectory following accuracy compared to the simpler approaches.

There is a serious difficulty in controlling camera motion systems, however, caused by delays in the control loops. Such delays include the measurement delay due to the time needed to acquire and digitize the camera image and subsequent computations, such as feature extraction and target localization. There is also a delay or latency arising from the time needed to compute the controller output signal [6]. If these delays are not dealt with, a simple PD or PID controller can become unstable, leading to excessive vibration or shaking and loss of target tracking.

There are a number of approaches to dealing with delay. PID or PD systems can be made robust to delays simply by increasing system damping by reducing the proportional feedback gain to a sufficiently low value [7]. This results in a system that responds to changes in target position very slowly, however, and is unacceptable for most applications. For control of saccadic

Theory

Low-Level Camera Motion Control Systems

Most robotic active vision control systems act mainly to produce either smooth pursuit motions or rapid saccadic motions. Pursuit motions cause the camera to move so as to smoothly track a moving object, maintaining the image of the target object within a small region (usually in the center) of the image frame. Saccadic motions are rapid, usually large, jumps in the position of the camera, which center the camera field of view on different parts of the scene being imaged. This type of motion is used when scanning a scene, searching for objects or information, but can also be used to recover from a loss of tracking of an object during visual pursuit.

Much has been learned about the design of pursuit and saccadic motion control systems from the study of primate oculomotor systems. These systems have a rather complicated architecture distributed among many brain areas, the details of which are still subject to vigorous debate [3]. The high-level structure, however, is generally accepted to be that of a feedback system. A very influential model of the human oculomotor control system is that of Robinson [4], and many

motion, a *sample/hold* can be used, where the position error is sampled at the time a saccade is triggered, and held in a first-order hold (integrator) [8]. In this way, the position error seen by the controller is held constant until the saccadic motion is completed. The controller is insensitive to any changes in the actual target position until the end of this *refractory* period. This stabilizes the controller, but has the drawback that if the target moves during the refractory period, the position error at the end of the refractory period can be large. In this case, another, corrective or secondary, saccadic motion may need to be triggered. For stabilization of pursuit control systems in the presence of delay, an internal positive feedback loop can be employed [4, 8]. This positive feedback compensates for delays in the negative feedback servo loop created by the time taken to acquire an image and compute the target velocity error. The positive feedback loop sends a delayed *efference copy* of the current commanded camera velocity (which is the output of the pursuit controller) back to the velocity error comparator where it is added to the measured velocity error. The positive feedback delay is set so that it arrives at the velocity error comparator at the same time as the measurement of the effect of the current control command, effectively canceling out the negative feedback and producing a new target velocity for the controller. Another delay handling technique is to use *predictive control*, such as the Smith Predictor, where the camera position and controller states are predicted for a time T in the future, where T is the controller delay, and control signals appropriate for those states are computed and applied immediately [6, 7]. Predictive methods make strong assumptions on changes in the external environment (e.g., that all objects in the scene are static or traversing known smooth trajectories). Such methods can perform poorly when these assumptions are violated.

The Next-Look Problem and Motion Planning

The control of pursuit and saccadic motions is usually handled by different controllers. While pursuit or tracking behavior can be implemented using frequent small saccade-like motions, this

can produce jumpy images which may degrade subsequent processing operations. With multiple controllers, there needs to be a way for the possibly conflicting commands from the controllers to be integrated and arbitrated. The simplest approach uses the output of the pursuit control system by default, with a switchover to the output of the saccade control system whenever the position error is greater than some threshold and switching back to pursuit control when the position error drops below another (lower) threshold.

Pursuit or tracking of visual targets is just one type of motor activity. Activities such as visual search may require large shifts of camera position to be executed based on a complex analysis of the visual input. The process of determining the active vision system controller set point is often referred to as *sensor planning* [1] or the *next-look problem* [9]. The next-look problem can be interpreted as determining sensor positions which increase or maximize the information content of subsequent measurements. In a visual search task, for example, the next-look may be specified to be a location which is expected to maximally discriminate between target and distractor. One principle that has been successfully employed in next-look processes is that of entropy minimization over viewpoints. In an object recognition or visual search task, this approach takes as the next viewpoint that which is maximally informative relative to the most probable hypotheses [10]. A common approach to the next-view problem in robotic systems is to employ an *attention mechanism* to provide the location of the next view. Based on models of mammalian vision systems, attention mechanisms determine *salient* regions in visual input, which compete or interact in winner-takes-all fashion to select a single location as the target for the subsequent motion [8].

Application

The earliest robotic eye movement control system was found in Stanford's Shakey robot [11]. There was a resurgence in research on robotic vision systems in the late 1980s and early 1990s.

However, at that time commercial camera motion platforms lacked the performance needed by robotics researchers and manufacturers. This led many universities to construct their own platforms and develop control systems for them. These were generally binocular camera systems with pan and tilt degrees of freedom for each camera. Often, to simplify the design, a common tilt action was employed for both cameras, and the pan actions were sometimes linked together to provide vergence and/or version motions only. Examples include the UPenn head [12], the Harvard head [13, 14], the KTH head [15], the TRISH head from the University of Toronto [16], the Rochester head [17], the SAGEM-GEC-Inria-Oxford head [18], the Surrey head [19], the LIFIA head [20], the LIA/AUC head [21], and the Technion head [5]. These early robotic heads generally used PD servo loops, some with delay compensation mechanisms as described above, and were capable of speeds up to 180 degrees per second. The pan axis maximum rotational velocities were usually higher than those of the tilt and vergence speeds. The axes were most often driven either by DC motors or by stepper motors.

A more recent example of a research system is the head of the iCub humanoid robot [22]. Unlike the early robotic heads, which were one-off systems limited to use in a single laboratory, this robot was developed by a consortium of European institutions and is used in many different research laboratories. It has independent pan and common tilt for two cameras as well as three neck degrees of freedom. The maximum pan speed is 180 degrees per second, and the maximum tilt speed is 160 degrees per second.

Currently, most robotic active vision systems are based on commercially available monocular pan-tilt platforms. The great majority of commercial platforms are designed for surveillance applications and are relatively slow. There are a few systems with specifications that are suitable for robotic active vision systems. Perhaps the most commonly used of these fast platforms are made by FLIR Motion Control Systems, Inc. (formerly Directed Perception). These are capable of speeds up to 120 degrees per second and can

handle loads of up to 90 lbs. Commercial systems generally lack torsional motion and hence are not suitable for precise stereo vision applications.

The fastest current commercial pan/tilt units, as well as the early research platforms, only reach maximum speeds of around 200 degrees per second. This is sufficient to match the speeds of human pursuit eye movements, which top out around 100 degrees per second. However, if these speeds are compared to the maximum speed of 800 degrees per second for human saccadic motions, it can be seen that the performance of robotic active vision motion platforms still has room for improvement.

Definition

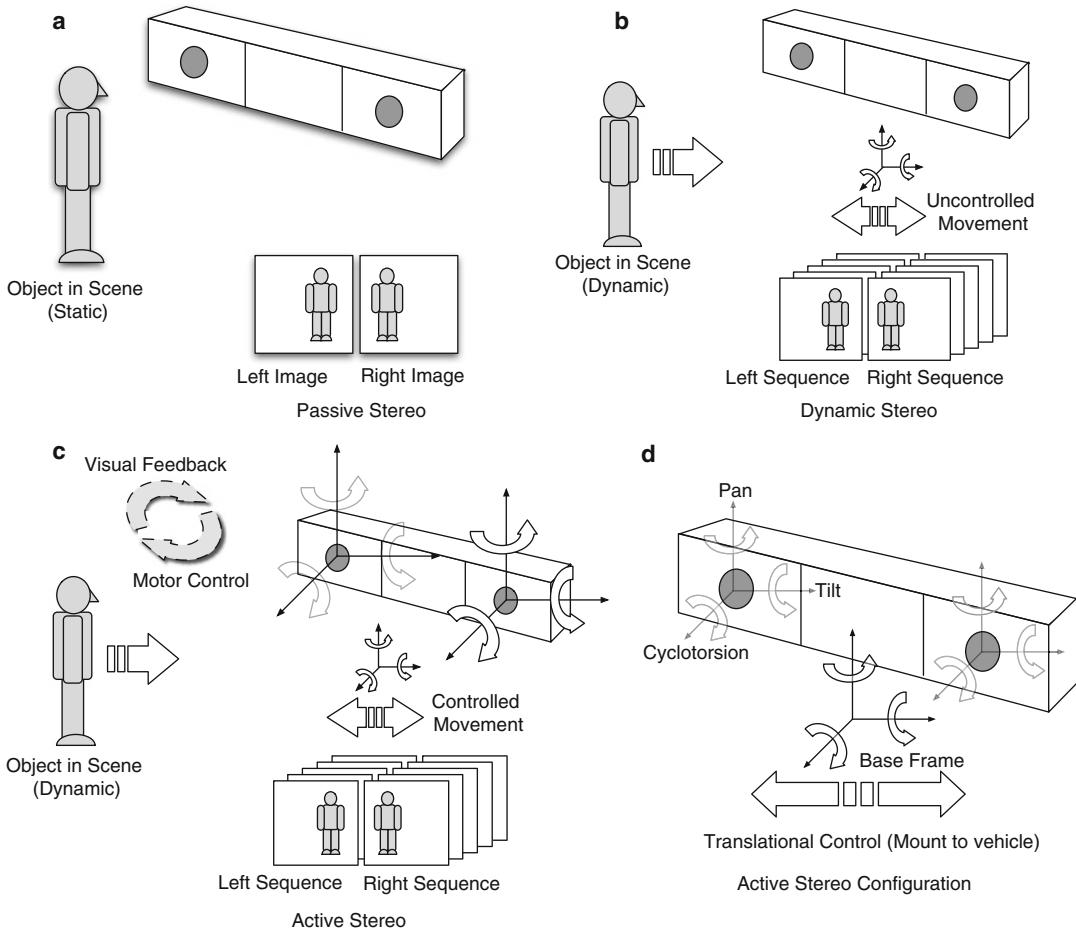

Active stereo vision utilizes multiple cameras for 3D reconstruction, gaze control, measurement, tracking, and surveillance. Active stereo vision is to be contrasted with passive or dynamic stereo vision in that passive systems treat stereo imagery as a series of independent static images while active and dynamic systems employ temporal constraints to integrate stereo measurements over time. Active systems utilize feedback from the image streams to manipulate camera parameters, illuminants, or robotic motion controllers in real time.

A

Background

Stereo vision uses two or more cameras with overlapping fields of view to estimate 3D scene structure from 2D projections. Binocular stereo vision – the most common implementation – uses exactly two cameras, yet one can utilize more than two at the expense of computational speed within the same algorithmic framework.

The “passive” stereo vision problem can be described in terms of a system of at least two cameras attached rigidly to one another with constant intrinsic camera calibration parameters. Stereo pairs captured from this geometry are considered to be temporally independent. Thus no assumptions are made, nor propagated, about camera motion within the algorithmic framework. Passive vision systems are limited to the extraction of metric information from a single set of images taken from different locations in space (or at different times) and treat individual frames in stereo video sequences independently. Dynamic stereo vision systems are characterized by the extraction of metric information from sequences of imagery (i.e., video) and employ temporal constraints or consistency on the sequence (e.g., optical flow constraints). Thus, dynamic stereo systems place assumptions on the camera motion such as its smoothness (and small motion) between subsequent frames and proper temporal synchronization between

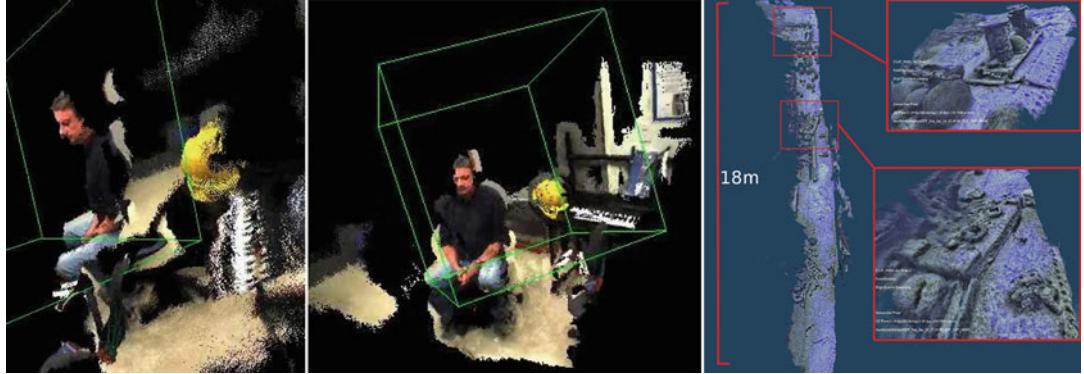

Active Stereo Vision, Fig. 1 Different types of stereo systems. (a) shows a traditional passive stereo system. (b) shows an active stereo system in which a moving but uncontrolled stereo camera views an active environment.

(c) shows an active stereo system in which image capture geometry is controlled based on previously captured imagery. (d) shows various degrees of freedom that can be controlled in an active stereo system

the cameras that make up the system. Active stereo vision systems subsume both passive and dynamic stereo vision systems and are characterized by the use of robotic camera systems (e.g., stereo heads) or specially designed illuminant systems (e.g., structured light) coupled with a feedback system (see Fig. 1) for motor control. Although systems can be designed with more modest goals – object tracking, for example – the common computational goal is the construction of large-scale 3D models of extended environments.

Theory

Fundamentally, active stereo systems (see [2]) must solve three rather complex problems: (1) spatial correspondence, (2) temporal correspondence, and (3) motor/camera/illuminant control. Spatial correspondence is required in order to infer 3D depth information from the information available in camera images captured at one time instant, while temporal correspondence is necessary to integrate visual information over time. The spatial and temporal correspondence

A

Active Stereo Vision, Fig. 2 Point cloud datasets obtained by the active stereo system described in [1]

problems can either be treated as problems in isolation or integrated within a common framework. For example, stereo correspondence estimation can be seeded using an ongoing 3D representation using temporal coherence (e.g., [3, 4]) or considered in isolation using standard disparity estimation algorithms (see [5]).

Motor or camera control systems are necessary to move (rotate and translate) the cameras so they look in the appropriate direction (i.e., within a tracking or surveillance application), change their intrinsic camera parameters (e.g., focal length or zoom), or to tune the image processing algorithm to achieving higher accuracy for a specific purpose. Solving these three problems in an active stereo system enables one to develop algorithms that infer ego-motion [6], autonomously control vehicles throughout the world [7], and/or reconstruct 3D models of the environment [1, 8]. Examples of the output of such a system is shown in Fig. 2, and [9] provides an example of an active system that interleaves the vergence and focus control of the cameras with surface estimation. In [10] an active stereo head with pan-tilt-servo mechanisms and an automatic calibration algorithm is developed. The algorithm uses feature matching and geometric constraints to automatically determine the relationships between the cameras which is maintained with high accuracy motor encoders.

Although vision is a powerful sensing modality, it can fail. This is a critical issue for active

stereo vision where data is integrated over time. The use of complementary sensors – traditionally Inertial Measurement Units (see [11]) – augments the camera hardware system with the capability to estimate the system dynamics using real-world constraints. Accelerometers, gyroscopes, and compasses can provide timely and accurate information either to assist in temporal correspondences and ego-motion estimation or as a replacement when visual information is unreliable or absent (i.e., dead reckoning). See [12] for an example of this type of integrated approach.

Relation to Robotics and Mapping

A wide range of different active and dynamic stereo systems have been built (e.g., [1, 8, 13, 14]). Active systems are often built on top of mobile systems (e.g., [1]) blurring the distinction between active and dynamic systems. In robotics, active stereo vision has been used for vehicle control in order to create 2D and 3D maps of the environment. Commonly the vision system is complemented by other sensors. For instance, in [15], active stereo vision is combined with sonar sensors to create 2D and 3D models of the environment. Murray and Little [16] use a trinocular stereo system to create occupancy maps of the environment for in-the-loop path planning and robot navigation. Diebel et al. [17] employ active stereo vision for simultaneous estimation of the robot location and 3D map construction,

and [1] describes a vision system used for in-the-loop mapping and navigational control for an aquatic robot. Davison, in [7], was one of the first to effectively demonstrate the use of active stereo vision technology as part of the navigation loop. The system used a stereo head to selectively fixate scene features that improve the quality of the estimated map and trajectory.

Autocalibration

A fundamental issue with active stereo vision is the need to establish and maintain calibration parameters online. Intrinsic and extrinsic parameters are necessary to the 3D estimation process as they define the epipolar constraints which enable efficient disparity estimation algorithms [18, 19]. Each time the camera parameters are modified (e.g., vergence of the cameras, change of focus), the epipolar geometry must be re-estimated. Although kinematic modeling of motor systems provides good initial estimates of changes in camera pose, this is generally insufficiently accurate to be used by itself to update camera calibration. Thus, autocalibration becomes an important task within active stereo vision. Approaches to autocalibration are outlined in [18, 20]. In [18], the autocalibration algorithm operates on pairs of stereo images taken in sequence. A projective reconstruction for motion and structure of the scene is constructed. This is performed for each pair of stereo images individually for the same set of features (thus they must be matched in the stereo pairs as well as tracked temporally). The projective solutions can be upgraded to an affine solution (ambiguous up to a rigid rotation/translation/scale) by noting these features should match in 3D space as well as in 2D space. A transformation can be linearly estimated that constrains the projective solution to an affine reconstruction. Once the plane at infinity is known, the affine solution may be upgraded to a metric solution. In order to achieve the desired accuracy in the intrinsic parameters, a nonlinear minimization scheme is employed to improve the solution. If one trusts the accuracy of the camera motion control system, the extrinsics can be seeded with this information in a nonlinear optimization scheme that minimizes the reprojection error of the image matching

points and their 3D triangulated counterparts. This nonlinear optimization is known as bundle adjustment [21] and is used in a variety of forms in the structure-from-motion literature (see [18, 19]). These concepts are applied to an active-stereo head in [10] to estimate both the lens properties and rigid transformations between the servo-controlled camera motors automatically.

Relation to Other Types of Stereo Systems

Since active stereo systems are characterized by the use of visual feedback to inform motor control systems (or higher-level vehicular navigational systems), they are related to a wide range of research areas and hardware systems. Mounting a stereo system to a robotic vehicle is common in the robotics literature to inform the navigation system about the presence of obstacles [22] and to provide input to mapping algorithms [23]. The use of such active systems is applicable directly to autonomous systems as they provide a high amount of controllable accuracy and dense measurements at relatively low computational cost. One significant example is the use of active stereo in the Mars Rover autonomous vehicles [14].

Estimating 3D information from stereo views is problematic due to the lack of unambiguous texture in many man-made environments. This can be alleviated with the use of active illumination [24]. Projecting a known or even stochastic pattern, rather than uniform lighting, into the scene enables the estimation of a more dense disparity field using standard stereo disparity estimation algorithms due to the added texture in textureless regions (see [25]). The illumination may be controlled actively depending on perceived scene texture, the desired range, or the ambient light intensity of the environment. The illumination may be within the visible light spectrum or in the infrared spectrum as most camera sensors are sensitive to IR light. This has the added advantage that humans in the environment are not affected by the additional illumination. In [26], an approach is developed that uses a mirror-galvanometer-controlled laser beam to project light into the scene and alleviate the stereo matching problem. However, factors such as camera exposure, material light absorption properties,

and laser power output limit the speed at which the laser can travel throughout the scene and ultimately reduce performance

Machine Learning

In recent years traditional computer vision techniques suitable for active stereo vision have been augmented with data-driven and machine learning approaches. For example, [27] describes a neural net auto-encoder to perform point cloud matching. In [28] a neural network is employed to learn the nonlinear function that converts matched features in stereo pairs into 3D locations, thus demonstrating the ability to learn complex functions that include lens distortions and affine transformations. In [29] a neural network training algorithm is employed to estimate the matching score between stereo image pairs resulting in a dense stereo result. Also, [30] describes a Convolutional Neural Network trained with RGB + Stereo Depth estimates to track a person as input to a robot navigation control scheme.

Application

Active stereo vision is characterized by the use of visual feedback in multi-camera systems to control the intrinsics and extrinsics of the cameras and any underlying vehicular platform. Active stereo vision systems find a wide range of application in autonomous vehicle navigation, gaze tracking, and surveillance. Commonly, active stereo systems are used to estimate visual odometry of a robotic platform such as in [31–33] and can be coupled with inertial measurement units such as in [34]. A host of hardware systems exist and commonly utilize two cameras for binocular stereo and motors to control the gaze/orientation of the system. Visual attentive processes (e.g., [35, 36]) may be used to determine the next viewpoint for a particular task, and dense stereo algorithms can be used for estimating 3D structure of the scene. Fundamental computational issues include autocalibration of the sensor with changes in its configuration and the development of active stereo control and reconstruction algorithms.

Definition

Activity recognition refers to the process of identifying the types of movement performed by humans over a certain period of time. It is also known as action recognition when the period of time is relatively short.

Background

The classic study on visual analysis of biological motion using moving light display (MLD) [1] has inspired tremendous interests among the computer vision researchers in the problem of recognizing human motion through visual information.

The commonly used devices to capture human movement include human motion capture (MOCAP) with or without markers, multiple video camera systems, and single video camera systems. A MOCAP device usually works under controlled environment to capture the three-dimensional (3D) joint locations or angles of human bodies; multiple camera systems provide a way to reconstruct 3D body models from multiple viewpoint images. Both MOCAP and multiple camera systems have physical limitations on their use, and single camera systems are probably more practical for many applications. The latter, however, captures least visual information and, hence, is the most challenging setting for activity recognition. In the past decade, research in activity recognition has mainly focused on single camera systems. The development of commodity depth cameras, such as Microsoft Kinect sensor, provides another feasible and economic way to capture simultaneously two-dimensional color information and depth information of the human movement. In addition, techniques for locating two-dimensional (2D) or three-dimensional (3D) joints of human bodies directly from video frames and depth maps

offer practical alternatives to traditional MOCAP devices.

Regardless of which capturing device or which modality, RGB (Red-Green-Blue) video, depth, or skeleton, is used, a useful activity recognition system has to be independent of anthropometric differences among the individuals who perform the activities, independent of the speed at which the activities are performed, robust against varying acquisition settings and environmental conditions (for instance, different viewpoints and illuminations), scalable to a large number of activities, and capable of recognizing activities in a continuous manner. Since a human body is usually viewed as an articulated system of the rigid links or segments connected by joints, human motion can be considered as a continuous evolution of the spatial configuration of the segments or body posture, and effective representation of the body configuration and its dynamics over time has been central to the research of human activity recognition.

Theory

Let $O = \{o_1, o_2, \dots, o_n\}$ be a sequence of observations of the movement of a person over a period of time. The observations can be a sequence of joint angles, a sequence of color images or silhouettes, a sequence of depth maps, or a combination of them. The task of activity recognition is to label O into one of the L classes $C = \{c_1, c_2, \dots, c_L\}$. Therefore, solutions to the problem of activity recognition are often based on pattern recognition and machine learning approaches, and an activity recognition system usually involves extracting features from the observation sequence O , learning a classifier from training samples and classifying O using the trained classifier. The spatial and temporal complexity of human activities has led researchers to cast the problem from different perspectives. Early work is mainly based on handcrafted features for recognition, and recent work has been driven greatly by deep learning.

Handcrafted-feature-based methods The existing techniques based on handcrafted features can be broadly divided into two categories according to whether the dynamics of the activities is implicitly or explicitly modelled. In the first category, the problem of activity recognition is cast from a temporal classification problem to a static classification one by representing activities using descriptors. A descriptor is extracted from the observation sequence O , which intends to capture both spatial and temporal information of the activity and, hence, to model the dynamics of the activity implicitly. Activity recognition is achieved by a conventional classifier such as support vector machines (SVM) or K-nearest neighborhood (KNN). There are three commonly used approaches to extract activity descriptors. The first approach builds upon motion energy images (MEI) [2], a binary image representing the presence of motion in regions, and motion history images (MHI) [2], a static image representing motion location and progressing path, and their variants. The second approach considers a sequence of silhouettes as a spatiotemporal volume, and an activity descriptor is computed from the volume. Typical examples are differential geometric surface properties [3], space-time saliency, action dynamics, and shape structure and orientation [4]. The third approach describes an activity using a set of spatiotemporal interest points (STIPs). The general concept is first to detect STIPs [5] from the observations O which is usually a video sequence. Features are then extracted from a local volume around each STIP, and a descriptor can be formed by simply putting them together to become a bag-of-features or by classifying the STIPs into a set of vocabulary (i.e., a bag of visual words) and calculating the histogram of the occurrence of the vocabulary within the observation sequence O . In addition to SVM and KNN, latent topic models such as the probabilistic latent semantic analysis (pLSA) model and latent Dirichlet allocation (LDA) were used in [6].

In the second category, the proposed methods usually follow the concept that an activity is a temporal evolution of the spatial configuration

of the body parts and, hence, emphasize more on the dynamics of the activities than the methods in the first category. They usually extract a sequence of feature vectors, each feature vector being extracted from a frame, or a small neighborhood, of the observation sequence O . The two commonly used approaches are temporal templates and graphical models. The temporal-template-based approach, typically, directly represents the dynamics through exemplar sequences and adopts dynamic time warping (DTW) to compare an input sequence with the exemplar sequences, for instance, the work in [7]. The graphical-model-based approach includes both generative and discriminative models. The most prominent generative model is the hidden Markov model (HMM), where sequences of observed features are grouped into similar configuration, i.e., states, and both the probability distribution of the observations at each state and the temporal transitional functions between these states are learned from training samples [8]. A more general generative graphical model, referred to as an action graph, was established in [9], in which an activity is encoded by one or multiple paths in the action graph. Due to the sharing mechanism, the action graph can be trained and also easily expanded to new actions with a small number of training samples. The generative graphical models often rely on an assumption of statistical independence of observations to compute the joint probability of the states and the observations. This makes it hard to model the long-term contextual dependencies which is important to the recognition of activities over a long period of time. The discriminative models, such as conditional random fields (CRF) [10], offer an effective way to model long-term dependency and compute the conditional probability that maps the observations to the motion class labels.

Deep-learning-based methods There are four commonly used approaches to leveraging the capability of deep neural networks for action recognition from RGB video or depth sequences [11]. The first approach is to employ convolu-

tional neural networks (CNNs) to extract features from single frames or a stack of frames sampled from a video sequence representing an instance of actions. The widely used two stream architecture [12] is a typical example. The second approach is to apply three-dimensional (3D) convolution to a segment of frames and then temporal pooling to form video-based features, such as C3D [13], or to simply apply 3D convolution to an entire action instance [14]. The third approach is to first extract frame-based features using a CNN and then model temporal dynamics using a recurrent neural network (RNN), such as ConvLSTM [15]. Typically, video-based features are obtained from the last time-step of the RNN. The fourth approach is to generate dynamic images [16] through rank pooling and to apply a CNN to extract features from the dynamic images. Each approach has its own strength and weakness. For instance, the first approach tends to focus on short-term rather than long-term temporal information. The second approach, if it is implemented using temporal pooling, is also weak at capturing long-term temporal information. Such weakness can be mitigated to some extent by applying 3D convolution to the entire action instance. In the third approach, extraction of spatial information (e.g., using a CNN) is separated from temporal modeling (e.g., using a RNN). It tends to model long-term dynamics more effectively than short-term dynamics. The dynamic image approach depends on how effectively both spatial and temporal information can be encoded into one or multiple images. The commonly used ranking pooling method to generate the dynamic images tends to suppress small motion. Similar approaches have been developed to extract deep features from skeleton sequences [11]. For instance, Yan et al. [17] proposed Spatial-Temporal Graph Convolutional Networks (ST-GCN). In [18], spatial and temporal information in a skeleton sequence is encoded into multiple texture images, and CNNs are used to extract features. In [19], a skeleton sequence is fed into an RNN directly, and features are extracted from the last-time step of the RNN. Compared with traditional RNN, the recently

proposed independently recurrent neural network (IndRNN) [20] is promising and achieves the state-of-the-art results.

In many realistic applications, an activity may occupy only a small portion of the entire space-time volume of a video sequence. In such situations, it does not make sense to classify the entire video. Instead, one needs to locate the activity in space and time. This is commonly known as an activity detection or action detection problem. In addition, continuous recognition of activities under realistic conditions, such as with viewpoint invariance and large number of activities, remains challenging though the extensive effort, and progress have been made in activity recognition research in the past decade.

Application

Activity recognition has many potential applications. It is one of the key enabling technologies in security and surveillance for automatic monitoring of human activities in a public space and of activities of daily living of elderly people at home. It is also essential for autonomous retail shops and autonomous driving. Robust understanding and interpretation of human activities also allows a natural way for humans to interact with machines. A proper modeling of the spatial configuration and dynamics of human motion would enable realistic synthesis of human motion for gaming and movie industry and help train humanoid robots in a flexible and economic way. In sports, activity recognition technology has also been used in training and in sports video retrieval.

Definition

The *AdaBoost algorithm* learns a classifier from data by combining additively a number of weak classifiers. The weak classifiers are incorporated sequentially, one at a time, in order to reduce the empirical exponential classification risk of the combined classifier.

Background

Boosting [1, 2], introduced by Robert Schapire in [3], is a general technique for combining the response of several predictors with limited accuracy into a single, more accurate prediction. AdaBoost is a popular implementation of boosting for binary classification [4]. Soon after its introduction, AdaBoost became one of the most popular learning algorithms; for example, Breiman [1] described AdaBoost with trees as the “best off-the-shelf classifier in the world.”

Much of the popularity of AdaBoost was due to its performance, which was comparable to the one of *support vector machines* [5], and its algorithmic simplicity. In the computer vision community, AdaBoost became very popular due to the work of Viola and Jones in face detection [6], which used it to demonstrate accurate face detection in real time; key to their method is a classifier obtained by boosting (combining) weak classifiers, each incorporating a single Haar wavelet [6, 7]. Haar wavelets can be computed very efficiently using *integral images*. Furthermore, the weak classifiers can be computed sequentially, in a cascade, and the computation terminated as soon as sufficient evidence to reject a hypothesis is accumulated.

The additive boosting framework is fairly general, and several variants have been proposed, among which are AdaBoost [4]; Real AdaBoost, LogitBoost, and GentleBoost [1]; Regularized AdaBoost [8]; or extensions to multiple classes such as AdaBoost.MH [9].

Theory

This section describes the AdaBoost algorithm as originally given by Freund and Schapire [4]. The particular variant below, also known as discrete AdaBoost [1], is summarized in Algorithm 1.

The purpose of AdaBoost is to learn a *binary classifier* that is a function $H(\mathbf{x}) = y$ which maps data $\mathbf{x} \in \mathcal{X}$ (e.g., a scrap of text, an image, or

Algorithm 1 Discrete AdaBoost

- 1: Initialize $F_0(\mathbf{x}) = 0$ for all $\mathbf{x} \in \mathcal{X}$.
- 2: Initialize $w_i = 1$ for all $i = 1, 2, \dots, n$.
- 3: **for** $t = 1$ to m **do**
- 4: Find the weak hypothesis $h_t \in \mathcal{H}$ that minimizes

$$\epsilon(h_t; \mathbf{w}) \propto \sum_{i=1}^n w_i [h_t(\mathbf{x}_i) \neq y_i].$$

- 5: Let the weak hypothesis coefficient be:

$$\alpha_t \leftarrow \frac{1}{2} \log \frac{1 - \epsilon(h_t; \mathbf{w})}{\epsilon(h_t; \mathbf{w})};$$

- 6: Update the weights

$$w_i \leftarrow w_i e^{-y_i \alpha_t h_t(\mathbf{x}_i)};$$

- 7: Update the function $F_t = F_{t-1} + \alpha_t h_t$.

- 8: **end for**

- 9: Return the classifier $H(\mathbf{x}) = \text{sign } F_m(\mathbf{x})$.
-

a sound wave) to its class label $y \in \{-1, +1\}$. The classifier H is obtained as the sign of an additive combination of simple classifiers $h : \mathcal{X} \rightarrow \{-1, +1\}$, called *weak hypotheses*. Given coefficients $\alpha_t \in \mathbb{R}$, the classifier can then be written as:

$$H(\mathbf{x}) \doteq \text{sign} \left(\sum_{t=1}^m \alpha_t h_t(\mathbf{x}) \right), \quad (1)$$

The input to AdaBoost is a set \mathcal{H} of weak hypotheses and n data-label pairs $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)$; the output is a combination H of m weak hypotheses in \mathcal{H} and their coefficients $\alpha_1, \dots, \alpha_m$. The algorithm is designed so that the combined classifier closely fits the training data, i.e., $H(\mathbf{x}_i) = y_i$ for most $i = 1, \dots, n$.

Let us denote with H_m the classifier H with m weak hypotheses shown in Eq.(1). AdaBoost operates sequentially by adding to H_{m-1} one new weak hypothesis (h_m, α_m) . While any weak hypothesis with performance better than chance can be used, it is more common to select the weak hypothesis h_m in the set \mathcal{H} that minimizes the

weighted *empirical error*

$$\epsilon(h; \mathbf{w}) \doteq \frac{\sum_{i=1}^n w_i [y_i \neq h(\mathbf{x}_i)]}{\sum_{i=1}^n w_i}.$$

where $\mathbf{w} = (w_1, \dots, w_n)$ are non-negative data weights, as given below. Here the term $[y_i \neq h(\mathbf{x}_i)]$ is equal to 1 if $y_i \neq h(\mathbf{x}_i)$ and 0 otherwise. Hence, the empirical error $\epsilon(h; \mathbf{w})$ is the average number of incorrect classifications of the weak hypothesis h on the weighted training data.

The selected weak hypothesis h_m can be written as $\epsilon(h; \mathbf{w})$, i.e., $h_m = \operatorname{argmin}_{h \in \mathcal{H}} \epsilon(h; \mathbf{w})$ and is added to the current combination H_{m-1} with coefficient

$$\alpha_m = \frac{1}{2} \log \frac{1 - \epsilon(h_m; \mathbf{w})}{\epsilon(h_m; \mathbf{w})}. \quad (2)$$

While AdaBoost minimizes the empirical error of the weak hypothesis h_m at each iteration, the weights \mathbf{w} are chosen so that the empirical error of H_m is reduced as well. AdaBoost starts with uniform weights $\mathbf{w} = (1, \dots, 1)$ and updates them according to the rule

$$w_i \leftarrow w_i e^{-y_i \alpha_m h_m(\mathbf{x}_i)}, \quad i = 1, \dots, n. \quad (3)$$

One intuitive interpretation of this rule is that it gives more importance to examples that are incorrectly classified. A formal justification is given in the next paragraph.

AdaBoost as Stagewise Minimization Denote by $F_m(\mathbf{x}) = \sum_{t=1}^m \alpha_t h_t(\mathbf{x})$ the additive combination of the first m weak hypotheses, so that the classifier $H_m(\mathbf{x})$ can be written as $\operatorname{sign} F_m(\mathbf{x})$. AdaBoost performs a stagewise minimization of the cost

$$\frac{1}{n} \sum_{i=1}^n e^{-y_i F_m(\mathbf{x}_i)}.$$

This cost is known as the *empirical exponential loss* and is a convex upper bound to the empirical classification error of H_m , in the sense that:

$$\epsilon(H_m) \doteq \frac{1}{n} \sum_{i=1}^n [y_i \neq H_m(\mathbf{x}_i)] \leq \frac{1}{n} \sum_{i=1}^n e^{-y_i F_m(\mathbf{x}_i)}.$$

To understand the effect of the AdaBoost update on the empirical exponential loss, let $F_m(\mathbf{x}) = F_{m-1}(\mathbf{x}) + \alpha_m h_m(\mathbf{x})$ be the updated additive combination at iteration m . As the parameters of F_{m-1} are fixed, the empirical exponential loss is a function E of α_m and h_m :

$$E(\alpha_m, h_m) \doteq \frac{1}{n} \sum_{i=1}^n w_i e^{-y_i \alpha_m h_m(\mathbf{x}_i)},$$

where $w_i = e^{-y_i F_{m-1}(\mathbf{x}_i)}$. (4)

By taking the derivative of E with respect to α_m and by setting it to zero, one obtains the optimality condition

$$0 = \sum_{i=1}^n w_i y_i h_m(\mathbf{x}_i) e^{-y_i h_m(\mathbf{x}_i)} e^{\alpha_m}$$

$$= \sum_{i:y_i \neq h_m(\mathbf{x}_i)} w_i e^{\alpha_m} - \sum_{i:y_i = h_m(\mathbf{x}_i)} w_i e^{-\alpha_m}$$

which results in the optimal coefficient given in Eq. (2):

$$\alpha_m(h_m) = \frac{1}{2} \log \frac{\sum_{i=1}^n w_i [y_i = h_m(\mathbf{x}_i)]}{\sum_{i=1}^n w_i [y_i \neq h_m(\mathbf{x}_i)]}$$

$$= \frac{1}{2} \log \frac{1 - \epsilon(h_m; \mathbf{w})}{\epsilon(h_m; \mathbf{w})}.$$

By substituting this expression back in the cost (4), one obtains

$$E(\alpha_m(h_m), h_m) = 2 \sqrt{\epsilon(h_m; \mathbf{w})(1 - \epsilon(h_m; \mathbf{w}))} \sum_{i=1}^n w_i$$

which achieves its smallest value when the empirical classification error $\epsilon(h_m; \mathbf{w})$ approaches either 0, its minimum, or 1, its maximum. Notice that if the error $\epsilon(h_m; \mathbf{w}) > 1/2$, then

the corresponding weight α_m is negative. In other words, when the weak hypothesis h_m makes more mistakes than correct classifications, AdaBoost automatically swaps the sign of the output label so that $\epsilon(-h_m; \mathbf{w}) < 1/2$. Finally, the weight update Eq. (3) follows from

$$\begin{aligned} w_i &\leftarrow e^{-y_i F_m(\mathbf{x}_i)} = e^{-y F_{m-1}(\mathbf{x}_i)} e^{-y_i \alpha_m h_m(\mathbf{x}_i)} \\ &= w_i e^{-y_i \alpha_m h_m(\mathbf{x}_i)}. \end{aligned}$$

Applications

One of the main uses of AdaBoost is for the recognition of patterns in data. Recognition can be formulated as a binary classification problem: Find whether data points match the pattern of interest or not. In computer vision, AdaBoost was popularized by its application to object detection, where the task is not only to recognize but also to localize within an image an object of interest (e.g., a face). Most of the ideas summarized in this section were first proposed by Viola and Jones [6].

A common technique for object detection is the *sliding window* detector. This method reduces the object detection problem to the task of classifying all possible image windows (i.e., patches) to find which ones are centered around the object of interest. In practice, windows may be sampled not only at all spatial locations but also at all scales and rotations. This results in a very large number of evaluations of the classifier function for each input image. Therefore, the computational efficiency of the classifier is of paramount importance.

Classifiers computed with AdaBoost can be made very computationally efficient by using weak hypotheses that are fast to compute and by letting AdaBoost select a small set of hypotheses most useful to the given problem. For example, in the Viola-Jones face detector, a weak hypothesis is computed by thresholding the output of a linear filter that computes averages over rectangular areas of the image. These filters are known as

Haar wavelets and, because of their special structure, can be computed in constant time by using the *integral image* [6].

In order to further improve the speed of a sliding window detector, AdaBoost classifiers are often combined in a *cascade* [6]. A cascade exploits the fact that the vast majority of image windows are *not* centered around the object of interest and that, furthermore, most of these negative windows are easy to recognize as such. A cascade is built by appending one AdaBoost classifier after another. Classifiers are evaluated sequentially, and an image window is rejected as soon as the response of a classifier is negative. All the classifiers are tuned to almost never reject a window that matches the object of interest (i.e., high recall). However, the first classifiers in the cascade are allowed to return several false positives (i.e., low precision) in exchange for a significantly reduced evaluation cost, obtained, for instance, by limiting the number of weak hypotheses in them. By using this scheme, the computationally costly and highly accurate classifiers are evaluated only on the most challenging cases: windows that resemble the object of interest and that therefore contain either the object (i.e., a positive sample) or a visual structure that can be easily confused with it (i.e., a hard negative sample).

Finally, since each weak hypothesis is usually associated with an elementary feature, AdaBoost is also often used for *feature selection*. In some cases, feature selection improves the *interpretability* of the classifier. For instance, in the Viola-Jones face detector, the first few Haar wavelets selected by AdaBoost usually capture semantically meaningful anatomical structures such as the eyes and the nose.

Definition

An *affine camera* is a linear mathematical model to approximate the perspective projection followed by an ideal pinhole camera.

Background

Perspective projections give accurate models for a wide range of existing cameras, especially after calibration for a limited volume of workspace. However, the relationship from a 3D point to its 2D image point is nonlinear due to a scalar factor dependent of each individual point (see entry ► “[Perspective Camera](#)” for details). *Affine cameras* are introduced to make the projection model more mathematically tractable. An affine camera model is a first-order approximation obtained from Taylor expansion of the perspective camera model around a reference point. The reference point can be any point, but it may be set to the centroid of the 3D points, which results in a more accurate approximation. There are three important instances of an affine camera when the camera’s intrinsic parameters

are known: orthographic, weak perspective, and paraperspective projections. The reader is referred to entry ▶ “[Weak Perspective Projection](#)” for a detailed description of the affine camera model and its three instances.

Affine Invariants

Michael Werman

The Institute of Computer Science, The Hebrew University of Jerusalem, Jerusalem, Israel

Definition

Affine invariants are properties that are invariant under an affine map.

Different images of the same object can be different and undergo various transformations depending on changes in the camera and its settings, the lighting, and the object itself. One of the ways to handle some of these changes, for tracking, search, and understanding images, is to use a description of the object that is oblivious to some of the abovementioned transformations. Affine invariants, due to their expressiveness-simplicity trade-off, are commonly used for this purpose.

Background

There is a vast literature relating to affine invariants, and only a small selection will be mentioned [[4](#), [5](#), [11](#), [13](#), [16](#)].

Affine Transformation

$$x \Rightarrow Lx + t$$

is an affine transformation of x , where $x \in R^n$ is a vector, $L \in R^{n \times n}$ a matrix, and $t \in R^n$ a vector. L is a linear transformation, and t is a translation [[2](#)].

Affine transformations are used to describe different changes that images can undergo, such as an affine transformation of the (r, g, b) color values of an object under different lighting conditions or the transformation the shape of the image of an object undergoes when the camera and object are in different relative positions. The affine transformation in these cases does not necessarily model the exact physical distortion that is seen but often is a good approximation.

Affine Invariant

In order to have a property of an object that is invariant to an affine transformation, affine invariants can be used.

Let f be a function such that $f(a, b, \dots) = f(T(a), T(b), \dots)$ for any affine transformation T and $a, b, \dots \in R^n$, f is an affine invariant.

A d -dimensional affine transformation has $d^2 + d$ parameters, so in order to have a nontrivial affine invariant, one needs a function with at more than that many arguments, where the result can be computed using algebraic elimination [[9](#)]. For example, two simplices in R^d have at least $d + 2$ different points which are $d^2 + 2d$ arguments.

In a certain sense, the number of independent invariants is the #(of parameters of a configuration) $-(d^2 + d)$.

Noise

Even though the group of affine transformation may be only a subgroup of the possible transformations, for example, projective transformations for an image of planar scene, being affinely invariant may be an overkill as most of the radical transformations never really happen. Thus, noise can be explained by affine transformations making too many things close to each other.

Examples

First example Let p, q, r be real numbers; then an affine transformation is of the form $x \Rightarrow \alpha x + \beta$; it is easy to check that for any three numbers p, q, r and affine transformation parameters α, β ,

$$\frac{p-q}{p-r} = \frac{(\alpha p + \beta) - (\alpha q + \beta)}{(\alpha p + \beta) - (\alpha r + \beta)}$$

[15, 17]

Second example We can generalize the first example to any dimension, d . The ratio of the volume of two $d+1$ sets of vectors in R^n is an affine invariant (constant Jacobian, $|L|$) where the volume is the $d+1 \times d+1$ determinant:

$$\begin{vmatrix} p & q & \dots & r \\ 1 & 1 & \dots & 1 \end{vmatrix}$$

Algebraic curves Not only points can be used to define affine invariance; other common examples are the parameters of curves, such as the equations of lines, conics, or other algebraic curves. For degree two curves in the plane, all ellipses are affinely equivalent.

Affine differential geometry There are affine invariant analogues of arc length and curvature. In general it is possible to find affine invariants involving points and their derivatives [3, 10, 12, 14].

Other parameters of the object Fourier coefficients and moments.

There are other properties that are affine invariant, such as incidence, parallelism, centroids, barycentric coordinates, convexity, tangency, bi-tangency, Euler number, and connectivity.

If an object's area is A , then integrating by the area element divided by A is affine invariant, for example, $\frac{1}{A} \int_{\text{Object}} g(I(x, y)) dx dy$ is affine invariant, g being any function of the pixel's color.

Moments have been used to make affine invariants [21], and CNNs have been used to learn affine independence [19, 20].

Applications

Affine Invariant Feature Detection

There are a number of affine invariant feature detectors that find affine invariant local features in an image [7, 16]. One of the successes in recent practice of computer vision was the SIFT, a similarity invariant feature, and its extension to an affine invariant feature, ASIFT [6, 8].

Normalization

There are normalizations that can be done to an object that remove all/some of the possible affine variation.

The center of gravity is a linear invariant, so it is possible to translate the object so that the object's center is at a fixed coordinate, thus removing the translation term, changing the problem from one of finding an affine invariant to a linear invariant.

The whitening transform canonically transforms a set of points using an affine transformation so that the average is 0 and the covariance matrix is the identity, I .

Grassmannians

The set of labeled points modulo affine transformations are isomorphic to Grassmannians; using this one can define a geometry of affine invariant point sets and, for example, measure the distance between affine invariant point sets [1, 18].

Correspondence

Another thing to notice is that usually there needs to be some correspondence of the objects in order to use these invariants, namely, the order of the arguments of the function f needs to be known, and the way to overcome this problem is summing over all permutations making this function invariant both to permutations. Another possibility is using permutation invariant features, for example, moments, which are built from summing over all the points.

Definition

The goal of affine registration is to find the affine transformation that best maps one data set (e.g., image, set of points) onto another.

Background

In many situations data is acquired at different times, in different coordinate systems, or from different sensors. Such data can include sparse sets of points and images both in 2D and 3D, but the concepts generalize also to higher dimensions and other primitives. *Registration* means to bring these data sets into alignment, i.e., to find the “best” transformation that maps one set of data onto another, here using an *affine transformation*. For the sake of brevity, in this entry only the registration of two data sets is discussed, although approaches exist for finding consistent transformations that align more than two sets at once (e.g., [1]). While intuitively in 1D affine transformations compensate for scale and offset, in any dimension they can represent the first-order Taylor approximation (local linearization) for nonlinear functions.

For more complicated transformations, often a first affine registration is used as an initial solution that roughly aligns the data sets, followed by some (potentially local or nonlinear) search for more complicated parameters. In contrast to rigid registration, which allows only an offset and a rotation between the data sets, the affine model allows also for the full set of linear shape changes, including (nonisotropic) scale and shear. In particular, locally this approximates perspective effects or other nonlinear warps. On the other hand, affine registration uses still a single global transformation with a set of a few global parameters, which makes it mathematically easier to handle but also less powerful as compared to general nonrigid registration of deformable or articulated objects.

Theory

Two important cases can be distinguished for registration, the purely geometrical case, where two (finite) sets of points have to be registered, or the continuous/functional case, where the similarity of two functions must be maximized by an affine transformation of the functions’ domain.

The Purely Geometrical Case

Let X and Y be two sets of points from \mathbb{R}^m and \mathbb{R}^n , respectively, and without loss of generality, it is assumed that $m \geq n$. For now it is assumed that the sets are of the same size and that there exists an (unknown) affine transformation, such that each element in X is mapped to an element in Y . Then, the goal of affine registration is to find this transformation, i.e., the matrix $A \in \mathbb{R}^{n \times m}$ and the offset $t \in \mathbb{R}^n$, such as to minimize an energy:

$$E_d = \sum_{x \in X} \min_{y \in Y} d_g(Ax + t, y) \quad (1)$$

Here $d_g(a, b)$ encodes the distance between a and b . Usually the points in X or Y are not available directly but only their noisy observations (e.g., when y are observed 2D projections of known

3D points and the parameters of the affine camera [2] are sought). In that case affine registration is based on these observations, and d_g should be chosen according to the noise distribution. If the sets are not of the same size or not each point in X corresponds to a point in Y , or in case there are gross errors in the data, still E_d can be minimized, e.g., with a robust cost function d_g to obtain some alignment between the sets [3]. Intuitively, in all these cases, A and t are sought which minimize the average distance for a transformed point of X to the closest point in Y .

In case bounds on A and t are known, a simple way to find an approximate solution is to sample the (continuous) space of all possible matrices A and offsets t , but this is usually computationally intractable. If it is known which points in X correspond to which others in Y , i.e., there is a set of pairs (x_i, y_i) , the energy can be rewritten as

$$E_c = \sum_{x_i \in X} d_g(Ax_i + t, y_i) \quad (2)$$

In case $d_g(a, b) = \|(a - b)\|_2^2$, this can be solved explicitly. A contains mn unknowns, t contains n unknowns, and from each correspondence n observations can be obtained, so from counting it is clear that at least $m + 1$ correspondences are required to uniquely determine a solution (assuming they are in a general configuration and not, e.g., only on a line). In case the correspondences contain gross errors (mismatches, outliers), then the solution can be obtained using robust estimation techniques such as least median of squares [4] or RANSAC [5].

In case correspondences are not known but the data sets are already approximately aligned, it can be assumed that the closest neighbors are in correspondence. In this case the problem can be solved by using the iterative closest points (ICP) method [6–8]. Locally, for each point the offset to the closest point in the other data set is computed, and by collecting all the local offsets, a global affine transformation is estimated that aligns these sets (in a least squares sense according to Eq. 2). This transformation is applied to recalculate the nearest neighbor correspondences,

and the estimation step is repeated with these. In [9] efficient implementations and practical aspects of ICP have been studied. However, since ICP relies on local neighborhoods, it cannot cope well with situations where initially close points must be moved far away.

A technique proposed for this is based on normalization (as suggested, e.g., by [10]): Here, the means of the data sets are computed individually and t is defined as the difference of the means. Then, for each data set, the (unbiased) covariance is computed, and the matrices A_X, A_Y are searched that bring the respective point distributions to a unit covariance matrix (whitening of covariance). The two data sets now only differ by an orthogonal matrix that may be obtained by sampling or finding other characteristics in the data (cf. also [11]). However, this normalization approach assumes that the data sets overlap fully.

In general, similar concepts can be applied as for rigid registration, however, with a slightly different set of parameters.

The Continuous/Functional Case

Let I and J be functions (images) from \mathbb{R}^n to \mathbb{R}^d , assigning some color value to each position, typically in the plane or in space. The function value will be referred to as the color hereafter, regardless of its physical meaning. In this case the affine registration can be stated as the minimization of an energy:

$$E = \int_x d_c(I(Ax + t), J(x))dx \quad (3)$$

Here, d_c is a distance between two colors that should be chosen according to the expected measurement uncertainty of the colors. Very similar to the discrete case, a naive strategy to minimize this energy would be sampling; however, this is again computationally expensive and requires bounds on the parameters.

A possible solution is to compute local image features, such as corners, blobs, and so on (cf. to [12]), and – if possible – find correspondences among these features. There has been a huge body of work to particularly define features that can be detected reliably with affine changes of

image coordinates. A comparison can be found in [13]. Given those the discrete methods of the previous section can be used to find an alignment A, t .

Afterward, or in case A and t were approximately known from the beginning and if I and J are smooth, then the alignment can be performed by local linearization as proposed by Lucas and Kanade [14]. The assumption is that locally the image can be represented by its first-order Taylor approximation, i.e., the local color and the gradient:

$$I(x) \approx I(x_0) + \frac{\partial I}{\partial x} \underbrace{(x_0 - x)}_{\Delta x} \quad (4)$$

Consequently, given two almost aligned images, at position x_0

$$\underbrace{J(x_0) - I(x_0)}_{\Delta I_0} \approx \left. \frac{\partial I}{\partial x} \right|_{x_0} \Delta x \quad (5)$$

Stacking r of these equations on top of each other, an equation system is obtained:

$$\begin{pmatrix} \Delta I_0 \\ \Delta I_1 \\ \dots \\ \Delta I_{r-1} \end{pmatrix} \approx \begin{pmatrix} \left. \frac{\partial I}{\partial x} \right|_{x_0} \\ \left. \frac{\partial I}{\partial x} \right|_{x_1} \\ \dots \\ \left. \frac{\partial I}{\partial x} \right|_{x_{r-1}} \end{pmatrix} \Delta x \quad (6)$$

This can be solved in a least squares sense to obtain Δx .

Similar to the local image gradient with respect to position, also the partial derivatives with respect to affine transformation parameters can be computed [14]. In this case, Δx (and also ∂x) contains $n(n+1)$ parameters (n^2 for the linear shape change and n for the offset). At least $n(n+1)$ equations are required to uniquely solve this. Often, to increase the basin of convergence, coarse-to-fine registration is applied. This can be implemented using image pyramids in case the uncertainty lies mostly in the offset parameters or by propagation of the affine parameter uncertainty to position uncertainty in

the image and appropriate smoothing [15]. After having applied the estimated update Δx on the parameters, the steps can be applied repeatedly to register the two images. In [16] Baker and Matthews compare different formulations of such iterative, gradient-based image alignment, particularly the question of how to compose and parameterize the warps across multiple iterations.

On top of transformations on the domain of the images, often the two images differ in target (e.g., the colors of corresponding positions are related by some brightness offset), in which case also parameters for the change of color need to be estimated. In case the corresponding image colors are only statistically related but no explicit transformation model between colors is known, the concept of mutual information [17] might be used, where the entropy of the joint color histogram is minimized. An overview of image-based alignment can be found in [18, 19].

Application

Affine cameras [2] approximate a real camera by an affine mapping of 3D points to 2D image coordinates. For tracking local regions through videos, it has been shown [20] that keeping track of the affine deformations of local regions can help detecting tracking failures. Such affine warps, or those implied by correspondences of affine features between different images, represent the local linearization of a potentially nonlinear image warp (e.g., of perspective effects). If the structure of this nonlinear warp is known, the affine registration can allow inferring the global warp directly [21] or provide more constraints than just using the position of a region correspondence. In general, affine registrations often provide a reasonable solution to align mean, linear shape, and orientation of data without making the transformation too problem specific, or the affine solution can serve as a basis for further more advanced alignment. Furthermore, multiple independent or coupled local affine registrations can help in registering articulated or deformable models.

Algebraic Curve

Bo Zheng

Computer Vision Laboratory, Institute of Industrial Science, The University of Tokyo, Meguro-ku, Tokyo, Japan

Synonyms

[Implicit polynomial curve](#)

Related Concepts

► [Algebraic Surface](#)

Definition

An *algebraic curve* is a curve determined by a 2-D *implicit polynomial* (IP) of degree n :

$$f_n(\mathbf{x}) = \sum_{0 \leq i, j; i+j \leq n} a_{ij} x^i y^j = \underbrace{(1 x \dots y^n)}_{\mathbf{m}^T} \underbrace{(a_{00} a_{10} \dots a_{0n})}_{\mathbf{a}}^T = 0, \quad (1)$$

where $\mathbf{x} = (x, y)^T$ is the coordinate of a point on a curve. That is, the curve is always represented by f_n 's zero level set: $\{\mathbf{x}|f_n(\mathbf{x}) = 0\}$.

The polynomial function is usually denoted by an inner product between two vectors: monomial vector \mathbf{m} and coefficient vector \mathbf{a} . For the entries in these vectors, indices $\{i, j\}$ can be arranged in different orders, such as *lexicographical order* or *inverse lexicographical order*. In addition, the *homogeneous binary polynomial* of degree r in x and y , $\sum_{i+j=r} a_{ij} x^i y^j$, is called the r -th degree form of the IP. The form of degree n is called the *leading form*. The degree of an algebraic curve is the degree of the polynomial (e.g., n). An algebraic curve of degree 2 is called a conic, degree 3 a cubic, degree 4 a quartic, and so on.

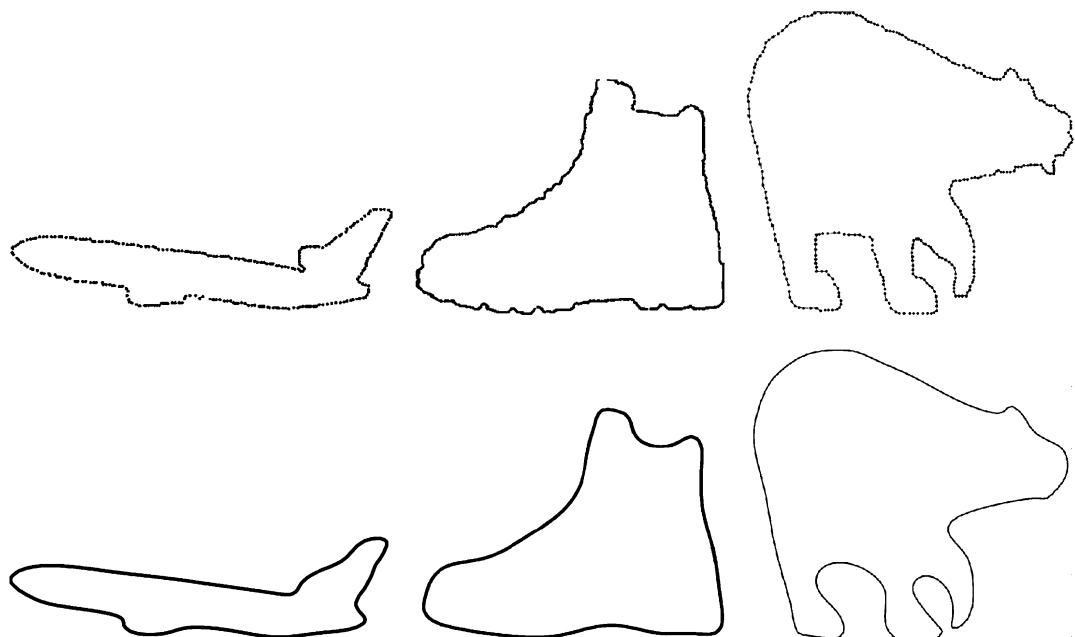

Background

In computer vision, representing 2-D data sets with algebraic curves has been studied extensively for the past three decades. It is attractive for vision applications due to its applicability to object recognition, pose estimation, and registration. In contrast to the curves represented by other functions such as splines, Fourier, rational Gaussian, and radial basis function, algebraic

curve is superior in such areas as fast fitting, few parameters, algebraic/geometric invariants, and robustness against noise and occlusion. Algebraic curve is also capable of modeling non-star shapes, open curves, curves that contain gaps, and unordered curve data. However, algebraic curve representation still suffers from some major issues such as the lack of local accuracy and global stability when representing a complex 2-D shape (see [7]). Figure 1 shows some example algebraic curves successfully used to represent closed 2-D curves.

Application and Theory

Algebraic curve representation is mainly attractive for vision applications such as fast shape registration or pose estimation [3, 6, 8, 9, 12] and recognition [2, 4–6, 9–11]. To achieve these purposes, many efforts have been made in three topics: curve fitting, algebraic/geometric invariants, and curve registration. The first is about solving the problem of accurately and stably fitting an algebraic curve to a complex shape, the

Algebraic Curve, Fig. 1 Examples of algebraic curves. *Top row:* original data sets; *bottom row:* represented algebraic curves

second is on extracting algebraic or geometric invariants from the algebraic curve representing a shape, and the third concerns estimating the Euclidean transformation(s) between two or more algebraic curves representing different instances of the same shape.

Curve Fitting. There have been great improvements concerning algebraic curve fitting with its increased use during the late 1980s and early 1990s [8]. Recently, new robust and consistent fitting methods like 3L fitting [1], gradient-one fitting with Rigid regression [7], and degree-adaptive fitting [13] that are suitable for vision applications have been introduced.

Algebraic/Geometric Invariants. The main advantage of the use of algebraic curves for recognition is the existence of algebraic/geometric invariants, which are functions of the polynomial coefficients that do not change after a coordinate transformation. To some major contributions, the global Euclidean invariants are found by Taubin and Cooper [9], Tarel and Cooper [6], and Keren [2], which can be expressed as simple explicit functions of the IP coefficients. Wolovich et al. [11] also introduced a set of invariants from covariant conic decompositions of implicit polynomials.

Curve Registration. In prior literatures [6, 9], global shape registration is performed through a single (non-iterative) computation using the central and oriented information extracted from the polynomial coefficients of two algebraic curves. Recently, an iterative method for aligning partially matched curves that uses the distance measurement of the polynomial gradient field together with a fast polynomial transformation has been introduced [12].

Algebraic Surface

Bo Zheng

Computer Vision Laboratory, Institute of Industrial Science, The University of Tokyo, Meguro-ku, Tokyo, Japan

Synonyms

Implicit polynomial surface

Related Concepts

► Algebraic Curve

Definition

Similar to an algebraic curve, an *algebraic surface* is determined by a 3-D *implicit polynomial* (IP) of degree n :

$$\begin{aligned} f_n(\mathbf{x}) &= \sum_{0 \leq i, j, k: i+j+k \leq n} a_{ijk} x^i y^j z^k \\ &= \underbrace{(1 \ x \ y \ z \dots z^n)}_{\mathbf{m}^T} \underbrace{(a_{000} \ a_{100} \ a_{010} \ a_{001} \dots a_{00n})^T}_{\mathbf{a}} \\ &= 0, \end{aligned} \quad (1)$$

where $\mathbf{x} = (x, y, z)$ is a 3-D point on a surface, that is, the surface is always represented by f_n 's zero level set: $\{\mathbf{x} | f_n(\mathbf{x}) = 0\}$. The polynomial function can be denoted by an inner product of two vectors: monomial vector \mathbf{m} and coefficient vector \mathbf{a} . For the entries in these vectors, indices $\{i, j, k\}$ can be arranged in different orders, such as *lexicographical order* or *inverse lexicographical order*. In addition, the *homogeneous binary polynomial* of degree r in x, y , and z , $\sum_i i + j + k = r$ $a_{ijk} x^i y^j z^k$, is called the *r-th degree form* of the IP. The n -th form is also called *leading form*. The degree of algebraic surface is the degree of polynomial: n . An algebraic surface of degree 2 is called a quadric surface, degree 3 a cubic surface, degree 4 a quartic surface, and so on.

Background

In computer vision, representing 3-D surface data sets with algebraic surfaces has been also well studied. It is attractive for vision applications such as 3-D object recognition, pose estimation, and registration. In contrast to other surfaces represented by the functions such as Splines, Fourier, Rational Gaussian, and radial basis function, algebraic surface is superior in

such areas as fitting efficiency, few parameters, convenience for calculating algebraic/geometric invariants, and robustness against noise and occlusion. Algebraic surface is also capable of modeling nonstar shapes, open curves, curves that contain gaps, and unordered curve data. However, algebraic surface representation still suffers from some major issues such as the lack of accuracy and stability when representing a complex 3-D shape. Figure 1 shows some examples of algebraic surfaces representing for 3-D surface data sets.

Application and Theory

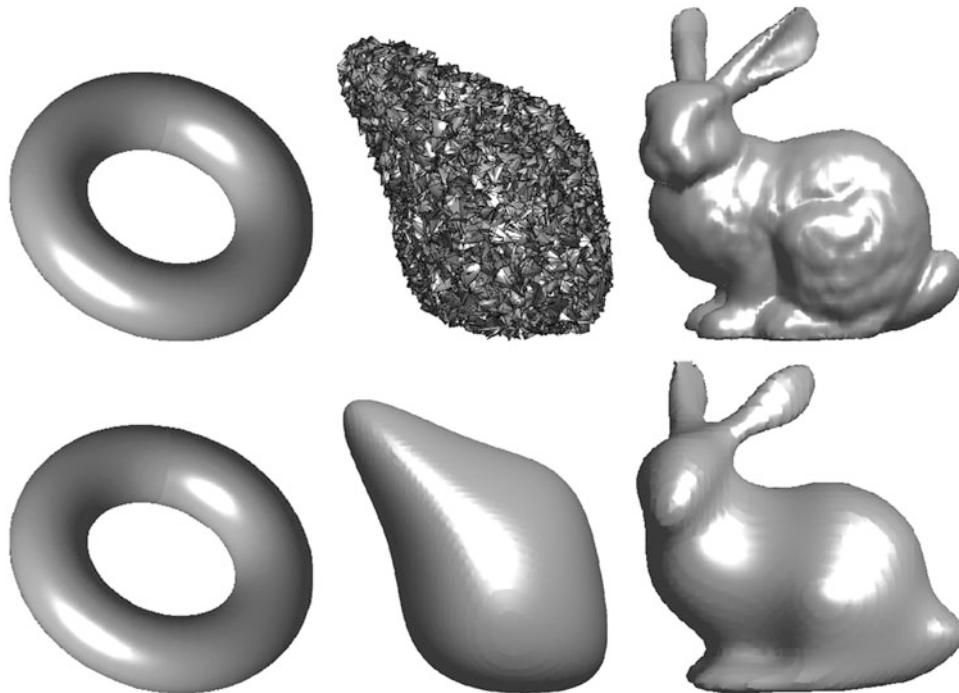

Algebraic surface representation is mainly attractive for vision applications such as 3-D object registration or pose estimation [2, 4, 8, 10, 11, 13] and recognition [3, 6, 8, 11]. To achieve those purposes, many efforts have been made in three topics: surface fitting, algebraic/geometric invariants, and 3-D object registration. The first topic faces the problem of how to fit an algebraic surface to a complex 3-D shape accurately and stably; the second topic focuses on the problem of how to extract algebraic or geometric invariants from a 3-D shape-representing polynomial; and the third topic concentrates on the task of how to estimate the rigid transformation relationship between two algebraic surfaces representing the same object in different positions.

Surface Fitting

There have been great improvements concerning algebraic surface fitting with its increased use during the late 1980s and early 1990s [10]. Recently, new robust and consistent fitting methods such as 3L fitting [1], gradient-one fitting with Rigid regression [5, 9], and degree-adaptive fitting [14] have been proposed to make the algebraic surface representation more feasible for vision applications.

Algebraic/Geometric Invariants

The main advantage of algebraic surfaces for recognition is the existence of algebraic/

Algebraic Surface, Fig. 1 Examples of algebraic surfaces. *Top row*: original 3-D data sets of torus, simple shape with noise, and bunny; *bottom row*: resulting algebraic surface fits of degree 4, 4, and 8, respectively

geometric invariants, which are functions of the polynomial coefficients that do not change after a coordinate transformation. The algebraic/geometric invariants that are found by Taubin and Cooper [11], Teral and Cooper [8], and Keren [3] are global invariants and are expressed as simple explicit functions of the coefficients. Another set of invariants that have been mentioned by Wolovich et al. is derived from the covariant conic decompositions of implicit polynomials [12].

3-D Object Registration

In prior literatures such as [7, 11], the global shape registration is performed through single (non-iterative) computation after obtaining the central and oriented information extracted from polynomial coefficients. An iterative method in [13] is proposed by using the distance metric generated from polynomial gradient field and fast polynomial coefficient transformation.

Animat Vision

Dana H. Ballard

Department of Computer Sciences, University of Texas at Austin, Austin, TX, USA

Synonyms

[Active vision](#); [Purposive vision](#)

Definition

Animat vision is the computational study of the visual systems used by animals, with special

attention to the binocular systems used by humans. For human vision, the goal is to show how the characteristics of the human eye movement system can be used to make the computation of needed information more efficient.

Background

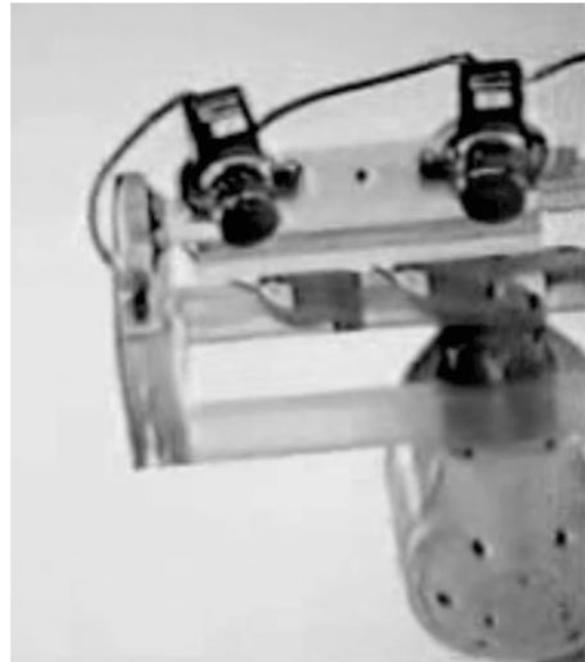

The field of computer vision was given an enormous impetus by the publication of Rosenfeld's seminal book *Picture Processing by Computer* [28] in 1969, but in the 1970s the research focus shifted to human vision with the exciting new formulations of *early vision* that recognized that the human visual system devoted enormous resources to extracting cues such as binocular disparity, color, and motion from their composite representation in the initial image. Two groups were especially influential: the group at MIT headed by David Marr and Tomas Poggio [21] and the group at SRI headed by Harry Barrow and Martin Tanenbaum [8]. David Marr in particular had an enormous effect on the field and his book, *Vision*, is a classic [20].

While the early vision paradigm had a wonderful impact of defining computation in vision, by the early 1980s it was apparent that the computations defined on static images were mathematically delicate and could only be tamed with exceptional ingenuity. Thus the idea evolved that perhaps a moving camera, with known movement parameters, would help. An early effort was undertaken at MIT, but the first complete working system was built at the University of Pennsylvania by Ruzena Bajcsy who coined the term *active perception* to describe it [5]. That system was unveiled at a computer vision conference in northern Michigan run by Avi Kak and had an instantaneous acceptance among the researchers present.

Very shortly afterwards, Christopher Brown and the author built a similar system that had a significant advantage. Brown was tracking video processing pipeline computers and realized that this evolving computer architecture, when combined with a servo-driven binocular camera system, would allow the new computations to be

A

realized in real time. The complete system is shown in Fig. 1. Subsequently the appearance of video-rate graphics cards capable of doing real-time image operations served to spur progress. Originally driven by the needs of the computer games industry, researchers quickly realized that now a large amount of the expensive visual calculations could be done in real time. The net result is that animat/active vision moved to lower-cost mobile robotic platforms with the result that robots using a moving cameras on mobile platforms are now commonplace.

Along the mainstream path of robotic animats, Rodney Brooks at MIT, perhaps inspired by Shimon Ullman’s concept of *visual routines*, realized that the jobs that vision had to do now became preeminent and built MIT’s humanoid robot *Cog* to focus on task-based vision. The particular architecture advocated may not have caught on, but the point was made and the system has been enormously influential. Two diverse communities – robotics and psychology – have been working on cognitive architectures for managing complex tasks that take a more integrated approach to vision and action, and both have recognized that the ultimate model architecture will have a hierarchical structure, e.g., [3, 11,

12, 16, 23]. Robotics researchers have gravitated to a three-tiered structure that models strategic, tactical, and detailed levels in complex behavior [10].

Theory

Animat vision, like its larger cousin active vision, is a paradigm with a huge number of important papers outstanding, with the consequence that it is only possible to provide the barest of outlines here. The interested reader is referred to some of the early papers [2, 6, 32]. Here we will demonstrate the impact on the calculation of early vision and introduce some more recent developments.

Consequences for Early Vision

Consider the problem of computing just one of the useful early vision representations, that of *optic flow*. Three-dimensional motion due to a moving observer induces the projection of two-dimensional motion on the retina. If the time-varying image function $f(x, y, t)$ represents only this effect, then the differential equations that represent the relationship between optic flows ($u(x, y, t), v(x, y, t)$) can be related to changes

in photometric intensities $\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y}, \frac{\partial f}{\partial t}$ with the equation, captured at the sensor to the image intensity M by

$$\frac{\partial f}{\partial x}u + \frac{\partial f}{\partial y}v + \frac{\partial f}{\partial t} = 0 \quad (1)$$

The conundrum of early vision can be easily apparent: At each point in the image x, y at time t , there is a single equation in two unknowns u, v . Poggio famously characterized this as an “ill-posed problem.” A plethora of solution methods were tried, but they almost all involved integrating information across the optic array, a very delicate process. In contrast, moving the camera view point immediately solves this problem. If the motion is under the control of the human observer, then, say for the case of horizontal motion, to a first approximation one can assume a reliable estimate for u , and of course the system reduces to a well-behaved two equations in two unknowns. This kind of simplification surfaces again and again in early vision, and many novel instances of this kind of constraint still remain to be discovered.

The Importance of Eye Fixations

Yarbus’s original work in gaze recordings [37] in the 1950s and 1960s revealed the enormous importance of gaze in revealing the underlying structure of human cognition. From this perspective, it is somewhat surprising that the first significant computational theory of vision [20] postponed the study of gaze as well as any influence of cognition of the extraction of information from the retinal array. In his “principle of least commitment,” Marr argued the case for the role of the cortex in building elaborate goal-independent descriptions of the physical world. Perhaps as a consequence, when researchers took on the task of defining the mechanisms for directing gaze deployment, these turned out to be predominantly image based [18, 19, 36]. These theories have been compelling, but have many drawbacks. They usually cannot predict the exact landing points and typically leave more than 30% of the fixations unaccounted for.

Recent experiments show that fixations are extracting very specific information needed by the human subject’s ongoing task [14, 34]. The task context introduces enormous economies into this process that are very obvious: If a subject needs to pick up a red object, the search for that object can be limited to just red portions of the image; vast amounts of extraneous detail can be neglected. The visual information-gathering specificity of almost every portion of every task will introduce similar economies. Knowledge of task also has the promise of interpreting a substantial literature devoted to “change blindness.” Subjects fail to notice large changes between successive images or movie frames. While the exact reason for this has been the subject of controversy [22], the problem may be resolvable if one has access to the viewer’s cognitive agenda. On agenda changes are noticed and off agenda changes are not.

Theoretical Breakthroughs in Task Modeling

What experiments testing the information extracted during a fixation have lacked is a theory that accounts for the role of the cognitive processes that are controlling the subject’s behaviors. What form should such a theory take? There have been several enormous theoretical advances, mostly from the fast emerging field of machine learning, that promise to have an enormous impact on quantitatively testable theories of cognition. The requirements of animat vision suggest that such a cognitive theory will have three important elements: (1) probabilistic representations, (2) the use of reward in learning, and (3) embodied cognitive architectures.

1. *Probabilistic methods.* There is rapidly increasing recognition that the brain is a probabilistic device and maintains a variety of mechanisms for calculating the statistical model of the world around it and its actions upon that world. To handle this a major new representational formalism has been developed that goes under the name *graphical models*. Originally developed by Pearl [26], such models have seen refinement as a general

way to factor complex statistical interdependencies into locally calculable quantities. The result is that the maintenance of elaborate statistical dependencies has become practical. Furthermore, Bayesian models of these interdependencies have proven their worth in characterizing many different observations in visual perceptions [35, 38].

2. *Reinforcement Learning.* A second breakthrough has been the development of model-making algorithms that are programmed by reward. It has long been appreciated that the brain must have mechanisms to learn complex behaviors and that these mechanisms must be steered by some scalar affinity signal. For the dominant effects the neurotransmitter dopamine has been implicated as the major signaling mechanism. Schultz, Glimcher, and others have made the connection between dopamine and reinforcement learning algorithms [17, 27, 33], the latter which by themselves have seen rapid development [1, 9]. Reinforcement learning algorithms are in their infancy but hold the promise of being an integral part of a comprehensive theory of animat vision learning.
3. *Embodied Cognition.* As emphasized by a number of researchers, the brain cannot be understood in isolation as so much of its structure is dictated by the body it finds itself in and the world that the body has to survive in [7, 13, 24, 25, 29]. This has special important implications, particularly for the cognitive architectures, because the brain can be dramatically simpler than it could ever be without these encasing milieus. The reason is that the brain does not have to replicate the natural structure of the world or the special ways of interacting with it taken by the body but instead can have an internal structure that implicitly and explicitly anticipates these commitments. The brain just has to have an interface that allows successful interactions with the world, but does not have to explicitly model all the detailed consequences of the actions taken. This realization opens up a way to address the challenge of making the leap from the apparent simplicity of the observed

behaviors to the complexity of the brain-body-world system that produces them and that is to see the behaving body itself as a laboratory instrument. From this vantage point, the momentary disposition of the eyes, head, and hands during the course of behavior reveals essential details about the underlying cognitive program that is making those choices.

Open Problems

Although the importance of body in cognition has been stressed at least since Merleau-Ponty, until the middle of 1980s, it was only practical to study very controlled circumstances such as those made by an experimental subject seated in front of a small display.

The research program at Rochester pioneered the study of embodied, visually driven behaviors by the development of innovative laboratory equipment and techniques. With Pelz at the Rochester Institute of Technology [4], they were the first laboratory that were able to track the eyes inside a head-mounted display. This capability allowed the exploitation of another recent development: Virtual Reality(VR). It is now straightforward to render scenes in real time from a moving observer's vantage point that are extraordinarily close to the real thing. Thus a person can have the compelling illusion of being in a fictional world that at the same time is under experimental control. This capability, in turn, has allowed researchers to address many new experimental questions for the first time. For example, one can study a person's disposition of visual resources in these virtual worlds by using the eye trackers inside the head-mounted display to manipulate the information that is available at each fixation [14, 30, 34].

Now flexible portable instrumentation can be attached to the body during the course of extended natural behaviors. Eye tracking capability that started out requiring subjects to be restrained in a bite bar has evolved to the point where portable trackers can be worn during a squash match. Head, hand, and body

movements, even those of the facial muscles during expressions, can be reliably captured at high data rates during tea making, athletics, and everyday conversation. The new instrumentation opens up the possibility of acquiring large amounts of such data at millisecond time scales during these natural behaviors and thus provides access to the essential choices made in directing behavior under natural circumstances.

Obtaining such data from behavior and modeling it has led to another new question: How does one become confident that the models one builds are accurate? Answering this question has led to another new development and that is simulated human modeling. It is now possible to create models of humans that have the degrees of freedom of the skeletal system and also the capabilities of the binocular vision system [15, 31]. Thus one can build a human avatar that acts out the cognitive models obtained by fitting human data. A bonus is that one can test the models in completely new situations that were not part of the original human data gathering and observe their performance. This in turn can lead to an iterative refinement of the models and new experiments. However the most important aspect of this animat vision research avenue is the testing of the embodied cognition hypothesis with a suitably rich model. Our everyday experience and introspection as to the nature of the execution of everyday tasks has proven very misleading as to the brain's underlying representations owing to the artfulness of conscious experience.

Definition

Human detection may be seen as a classification problem with two classes: human and nonhumans, in which the latter class is composed of background samples containing anything but humans. When the appearance-based human detection is employed, a large number of examples of human and nonhumans are considered to capture different poses, backgrounds, and occlusion situations through the extraction of feature descriptors so that a machine learning method can be used to classify samples as belonging to either one of the classes.

Background

Due to the large number of applications that require information regarding people's location, such as autonomous vehicles, surveillance, and robotics, finding people in images or videos presents large interest of the community. Even though widely studied in recent years [1], the human detection problem is still a challenge due to the wide variety of poses, clothing, background, and partial occlusions, which generate a large number of person's appearances.

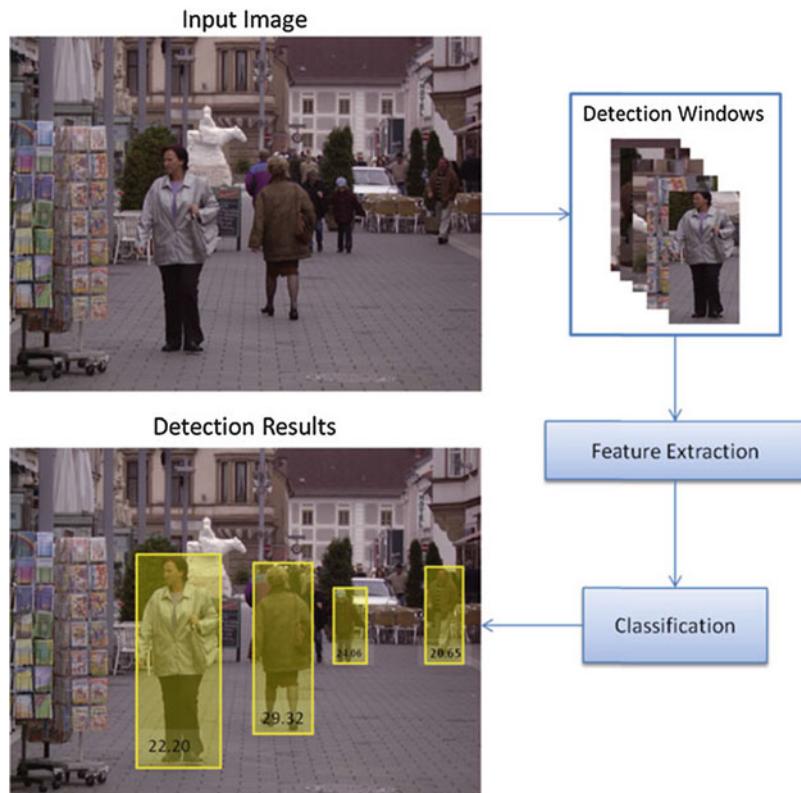

Two main approaches have been explored in the human detection literature. The first class of methods consists of a generative process that combines detected parts of the human body according to a model. The second class considers statistical analysis through the use of machine learning techniques to classify a feature vector composed of low-level feature descriptors extracted from a detection window. This approach, also referred to as appearance-based, captures the appearance information and focuses on the discrimination between human and nonhuman samples.

Theory

Appearance-based human detection presents two important aspects: feature extraction and classification. Once both aspects have been considered, the training and test (detection) steps can be performed.

Appearance-Based Human Detection, Fig. 1

Example of the human detection process. Image sample extracted from the INRIA Person dataset [3]

The feature extraction is responsible for capturing the visual information from the scene, such as the presence of strong vertical edges, homogeneous textured clothing, or color constancy in the face. Such characteristics, useful for human detection, will be extracted using low-level feature descriptors. It has been shown that the combination of these characteristics improves detection results [2]. Among the most used feature descriptors are the histograms of oriented gradients (HOG) [3], local binary patterns (LBP) [4], and Haar wavelet-based features [5].

The second relevant aspect is the choice of a machine learning method capable of classifying between humans and non-humans by giving higher importance to those descriptors that best distinguish between the two classes. Among the most employed methods are the linear discriminant analysis (LDA), neural networks (NN), support vector machines (SVM), and partial least squares (PLS).

The training step is responsible for learning parameters of the machine learning methods such that the differences between the two classes can be properly captured. For that, features are extracted from multiple samples from both classes, and the descriptors are stored in feature vectors. It is important to emphasize that a good training set is important to assure that variations of the human appearances are captured. Each classification method presents a different way of learning the differences. For example, while SVM finds support vectors that maximize the margins between both classes, PLS will give more weight to those dimensions of the feature vector that best discriminate between the classes. In addition, it is important to note that a good training set is also important to assure that variations of the human appearances are captured.

Once the training has been performed, a sliding window is passed in the image at multiple scales to locate humans at different locations and scales. For each location, features are extracted and stored in a feature vector, which is then presented to the classifier. The output for each detection window is a value that reflects the probability or confidence in which a human is located inside the detection window. Figure 1 illustrates the detection process of a typical appearance-based human detection method.

Application

In general, the human detection is of interest in any application that falls inside the *Looking at People* [6] (domain which focuses primarily in analyzing images and videos containing humans). For example, a human detector can be used to provide the location of each agent in a scene so that tasks such as tracking, re-identification, action, and activity recognition can be executed by a surveillance system. In addition, a human detector can be executed in the domain on autonomous navigation, where the location of the pedestrians will be used as information for path planning. Furthermore, the use of human detection systems embedded in vehicles may be very useful to assure pedestrian safety [7].

Human appearance modeling and tracking; Human body tracking

Related Concepts

► [Human Pose Estimation](#)

Definition

Appearance-based human tracking is the task of tracking the areas that belong to a person over a

set of consecutive frames in a video, where the measurements are made based on the appearance of the human body such as color, intensity, edge, gradient, texture, shape, and their combination.

Background

Various human tracking algorithms have been proposed so far, but the focus of each algorithm is different. Appearance-based human tracking is an algorithm to track human based on the similarity between the current appearance model and the observation from an input image; the control and search algorithms in tracking are arbitrary. Several different features have been employed including color, edge, gradient, texture, shape, etc., and multiple features are often integrated together for more robust observations. The appearance of human based on the features is represented by density function, histogram, template, and feature descriptors. For the representation of human body, the spatial layout of the features is typically considered to model the appearance of human. The appearance models can be constructed for the entire human body, a few subregions of the human body, or the individual articulated human body parts, depending on the target state spaces and tracking algorithms.

Generic tracking algorithms can be employed to track a blob-based human with a simple appearance model in a low-dimensional state space. However, in case of articulated human body tracking, the dimensionality of target state space is typically very high, and the inference procedure of the complex human body configuration is generally complex; more efficient and specialized tracking algorithms are required.

Theory

Methodologies of Appearance Models

Two aspects—integrated features and mathematical representation techniques—are considered to characterize the appearance-based human tracking.

Features Integrated

The appearance for human tracking is modeled with color [6, 9, 11], silhouette [3, 13], shape [5, 7, 14], edge [3, 10, 12], or texture.

Representation Methods

Some appearance modeling techniques assume that the appearance of human body is consistent horizontally. With the assumption, the human body is represented with multiple histograms [9] or density functions [6] based on a cylinder model as in the left subfigure in Fig. 1. Another method is a path-length model [15], where the spatial variations are modeled by the distance from the head along the shape of the person as shown in the right subfigure in Fig. 1 and feature-spatial distribution is constructed for appearance modeling [4]. Template is also frequently used [2, 8, 12], and probabilistic template is integrated in [1].

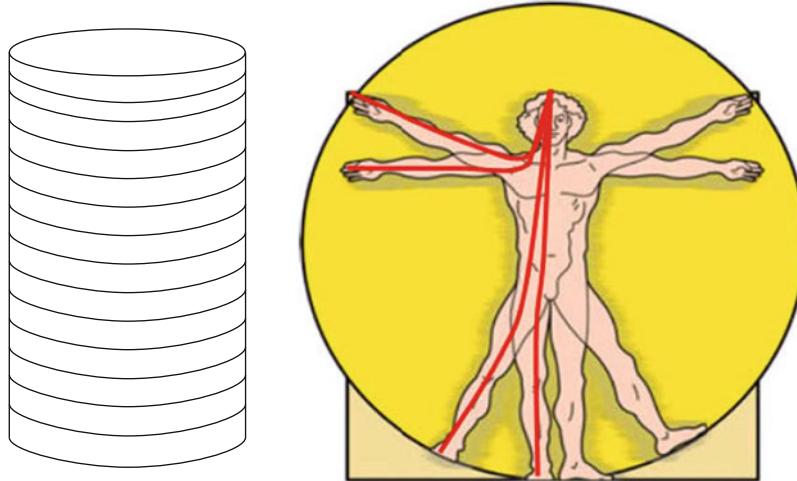

With the assumption, the human body is represented with multiple histograms [9] or density functions [6] based on a cylinder model as in the left subfigure in Fig. 1.

Acquisition and Maintenance of Appearance Models

The appearances may be fixed throughout the sequence or adaptive to the variations of human body appearance. The initialization of the appearance can be performed based on (manual or automatic) human detection. In [8, 12], the appearance of each body part of human is learned in an online manner based on simple features obtained in off-line process.

Tracking Control and Search

Human tracking can be classified into two types based on the description method of human body; one is blob-based tracking, and the other is articulated human body tracking. In case of blob-based tracking, tracking algorithm is simple, and the state space of the target is typically low dimensional. The algorithms in this type have no big difference from generic tracking algorithms for other objects; a major difference is that human tracking algorithms often divide target into a few subregions based on appearance consistency to improve measurement accuracy. However, the

A

Appearance-Based Human Tracking: Traditional Approaches, Fig. 1 Some examples to model spatial layout of a person in human appearance modeling. (*Left*) The appearance model is developed for each height slice

of a person. (Fig. 2 in [9]) (*Right*) The path length is the distance from the *top* of the head to a given point on the path (Fig. 2 in [15])

articulated human body tracking involves very high-dimensional state space (typically more than 20 dimensions) and complicated probabilistic inference procedures; efficient tracking control and search algorithms are required to handle the challenges such as annealing [1, 3], message passing [8], and covariance sampling [13] in particle filter framework.

Application

Appearance-based human tracking has a lot of potential applications such as in activity recognition, event detection, video understanding, visual surveillance, autonomous driving, and vision-based user interface in computer games.

Definition

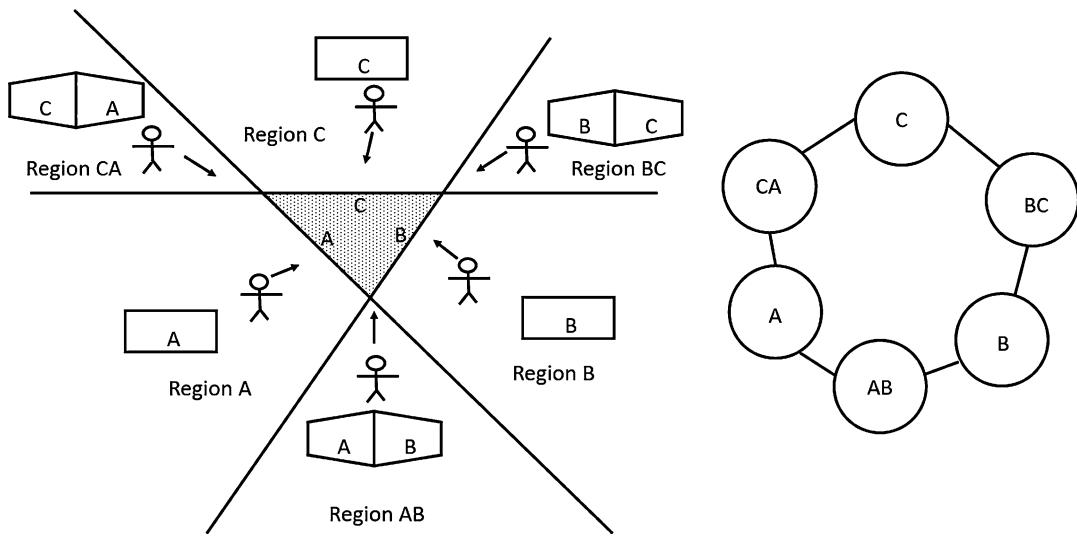

An aspect is defined as a set of topologically equivalent views of a three-dimensional object. An aspect graph of an object is a graph that contains all aspects of the object as nodes with edges connecting to adjacent aspects. It describes transitions, referred to as visual events, between aspects of the object in a three-dimensional viewer's space.

Theory

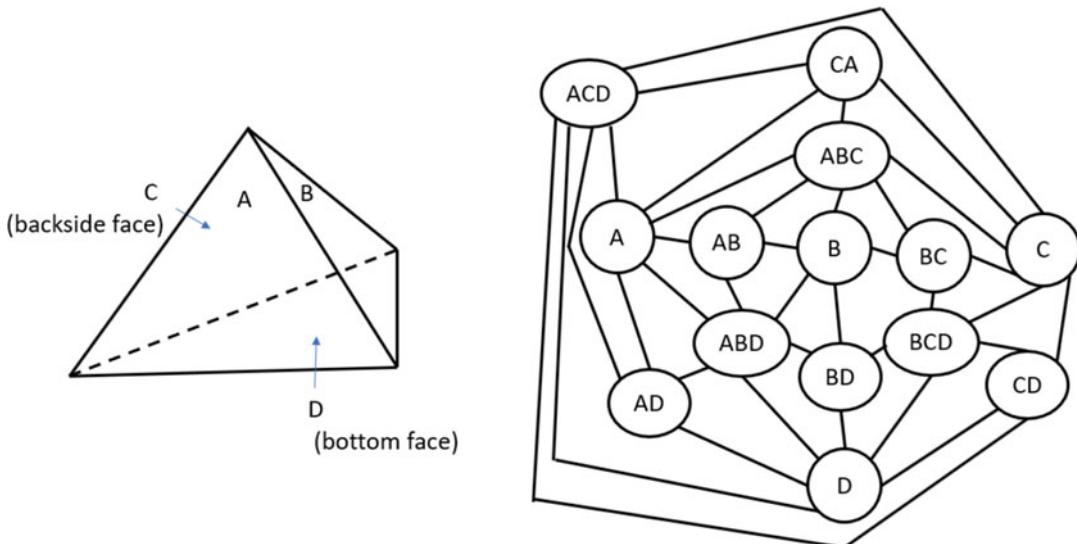

An aspect graph denotes segmentation of the possible view space into regions based on the topology of views of the object. Koenderink and van Doorn originally proposed the concept of aspects [11, 12]. A similar idea can be found in the work of J. J. Gibson [5] and M. Minsky [14]. The work of Chakravarty and Freeman employs a similar concept, referred to as characteristic views [3].

For the sake of a simple explanation, let's consider the two-dimensional case of view-space segmentation of a triangle (a convex polygon), which consists of three edges (2-dimensional faces), A, B, and C as shown in Fig. 1. A two-dimensional observer in the view-space can only move on the same two-dimensional plane of the triangle and cannot depart from the plane. This infinite 2D plane of the view-space is divided into seven regions. One region is the original triangle, with six additional regions defined by extending the lines of the three edges as shown in Fig. 1.

Each region is characterized by the edges (two-dimensional faces) visible from that region. For example, from any point inside region A, the observer can only see the edge A, while from any point inside of region AB, the observer can see both edge A and edge B. Each region corresponds to one aspect of the triangle, defined as a view-space sharing topologically equivalent views. A graph that connects the nodes corresponding to those aspects is referred to as the aspect graph of the triangle. Each edge of the graph corresponds to a visual event, defined as a transition between two different regions [1].

Aspect Graph, Fig. 1 Two-dimensional view-space segmentation and 2-dimensional aspect graph

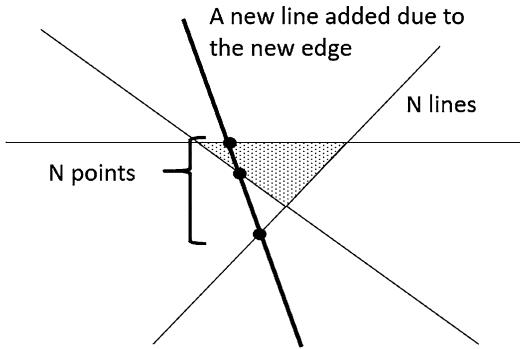

Aspect Graph, Fig. 2 A tetrahedron and its three-dimensional aspect graph

We can extend this idea into the three-dimensional view-space of a convex polyhedron. In the three-dimensional view-space, each view region is divided by the infinite planes of the extensions of three-dimensional polyhedral faces. Figure 2 shows the aspect graph of a tetrahedron with face A, B, C, and D.

Researchers' investigations have found a way to estimate the number of aspects of an object by counting the number of view-space regions.

Again, for the sake of a simple explanation, let's start with a two-dimensional convex polygon with n edges. As in the previous discussion, the possible viewpoints are located on the same infinite plane as the polygon. The n edges of the polygon generate $F(n)$ regions on this plane by extending those n edges. Let us modify the n -polygon into $(n + 1)$ -polygon by adding a new edge in this n -polygon. This new edge forms a new infinite straight line, which intersects the

Aspect Graph, Fig. 3 View-space segmentation with a $n + 1$ polygon. A newline intersects previous n lines with n intersection points and adds $n + 1$ new regions.

previous n lines with n points. See Fig. 3. As a result, the infinite line is divided into $(n + 1)$ segments. Each segment divides one previous region into two new regions. Thus, $F(n + 1) = F(n) + (n + 1)$. Apparently, $F(3) = 7$ regions, including the original polygon as one region. Thus, $F(n) = \frac{(n+1)n}{2} + 1 \sim O(n^2)$.

Let us suppose that we have a n -polyhedron in the view-space which is divided into $G(n)$ three-dimensional regions with the extended planes formed by n faces. When we add a new infinite plane as the extension of a new face of the $n+1$ polyhedron, this new plane intersects the original n planes with n intersection lines on the plane. On this plane, $F(n)$ two-dimensional regions exist between n intersection lines. One two-dimensional region divides one previous three-dimensional region into two new three-dimensional regions at each two-dimensional region on the plane. As a result, it generates $F(n)$ two-dimensional regions. Thus, $G(n + 1) = G(n) + F(n)$. Thus, $G(n) = \frac{n(n^2+5)}{6} + 1 \sim O(n^3)$.

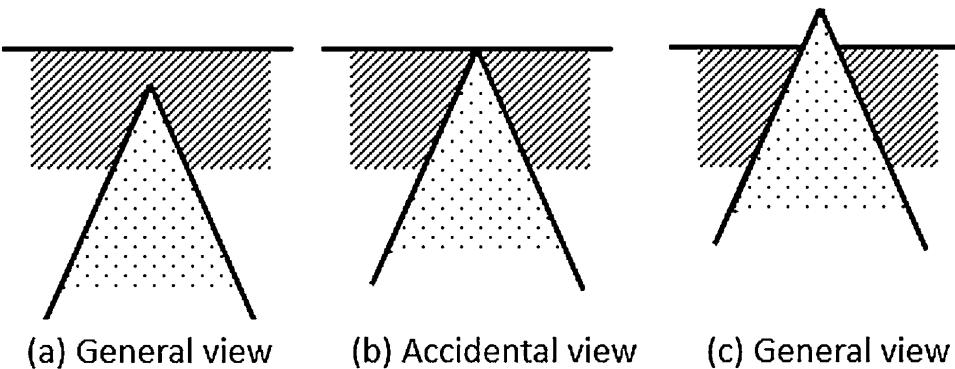

The aspect graph of a non-convex polyhedron requires introducing two view classes: general and accidental views. A general view is defined as a viewing point where any infinitesimal movement around that viewing position preserves the topology of views; the view is locally stable within the neighborhood. An accidental view is defined as a singular viewing point where even infinitesimal movement changes the topology of the view; the view only exists within an infinitely

small region. For example, in Fig. 4b one viewing point's vertex is aligned on the edge, making this is an accidental view. In contrast, Fig. 4a, 4c shows viewing points with vertexes that do not project to that edge, making them correspond to general views. While accidental viewing positions of a convex polyhedron exist on an infinite plane dividing the view space, the view itself is included in one of the two views along the plane. Plantinga's work shows non-convex objects have $O(n^6)$ regions under orthographic projection and $O(n^9)$ regions under perspective projection [17].

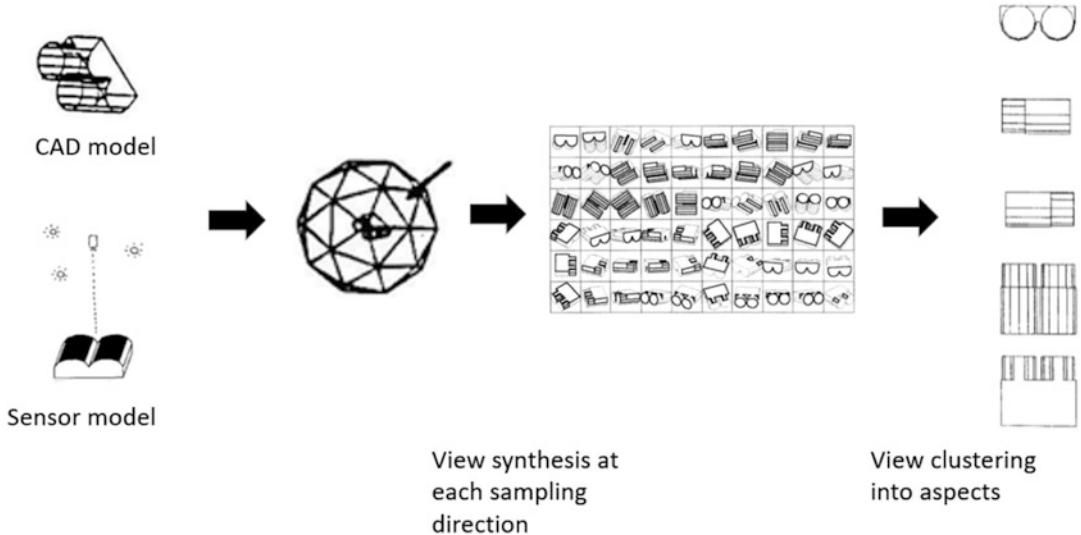

Algorithms for automatically computing the aspect graph of a non-convex polyhedron typically start by extracting accidental viewpoints [6, 17, 20]. This step corresponds to the drawing of infinite planes in the view space when handling a convex polyhedron. The difference between the convex and non-convex case is the latter requires more operations to compute the regions. Then, all the visual events across the accidental viewpoints are enumerated by examining the regions. Finally, the aspect graph is obtained by traversing the partitions between the regions in the viewpoint space.

We can also define the aspect graph of a curved-surface object [2, 13, 16, 18, 19]. The main flow of a graph generation process follows the same steps as polyhedral objects: accidental view extraction and segmentation of the viewing space into regions based on the accidental views and then generating the graph by traversing the region partitions. However, contour generator(s) on a curved-surface object move(s) over the object surface along the transition in the viewing direction. Thus, the first and second steps require more complicated analysis than is required for a polyhedral object.

In practical applications such as robotic object manipulation or navigation, it often occurs that it is not necessary to consider unstable accidental views. First, they rarely occur. Secondly, even if they occur, we can avoid them by adding small active motions to the robot's behavior during observation and using only stable non-accidental views. For such applications, several researchers propose dividing the viewing directions into a certain number of sampling directions based on

Aspect Graph, Fig. 4 Accidental and general views

Aspect Graph, Fig. 5 View-direction sampling and aspect generation by the approximation method [8]

a higher degree of a semi-regular geodesic dome and then generating appearances of an object at the center of each mesh by using a CAD model of the object [7, 8]. See Fig. 5. Once views from all sampling directions are obtained, the algorithm groups those views into clusters based on given visible features and handles those clusters as a set of aspects.

This approximation method can be extended to include views from a particular sensor by applying a model of the sensor to the view generation process [10]. In this case, even using the same viewing directions, views are different from each other due to the physical characteristics of the sensor. Views from a Lidar sensor are differ-

ent from those captured by a common RGB or IR camera and thusly, they extract different features. As a result, aspect graphs generated using Lidar view data are different from those generated by RGB or IR camera views [10]. The approximation method can handle such cases by generating views that consider the sensor model used from each sampling direction and enumerating those views into clusters.

Open Problems

Some researchers consider aspect graphs to be non-practical [4]. Their arguments are based

on their experiences and efforts to obtain complete aspect graphs from the analysis of line-drawings of an object. It is well-known that it is extremely difficult to extract complete line-drawings from images. As a result, generating aspect graphs based on complete line-drawings becomes impractical. However, this problem may be overcome by relaxing the definition of aspects to include views that share a common set of features observable by a particular sensor. For example, matching visible face color combinations or numbers of visible regions detected by a particular sensor could be included in the relaxed definition of an aspect. Further, the approximation method can be used to help achieve practicality with relaxed aspect definitions. Going forward in this direction, it is necessary to consider which visible features are effective for the object recognition task at hand in order to enumerate and classify the views.

The concept of the aspect graph indicates that object recognition consists of two different kinds of operations, aspect determination and linear shape-change determination [9]. Aspect determination conducts a labeling operation to choose one particular aspect among all possible aspects based on feature-matching within the set of visible features. Linear shape-change determination conducts localization of the viewer's position and orientation by distorting the appearance of model features to match the current sensed appearance. In a human brain, it is believed that the labeling operation is performed in the inferior temporal cortex along the ventral system from the parvocellular layer through V2 and V4 to areas of the inferior temporal lobe [15]. The localization operation is done along the dorsal system from the primary visual cortex (V1) into the parietal lobe. In parallel to this discussion, it is of interest to analyze how recent convolutional neural networks (CNN) handle aspect determination and linear shape-change determination in their network structures.

Asperity Scattering

S. C. Pont

Industrial Design Engineering, Delft University of Technology, Delft, The Netherlands

Synonyms

Surface scattering; Velvety reflectance

Related Concepts

- ▶ Retroreflection
- ▶ Lambertian Reflectance
- ▶ Surface Roughness

Definition

The “asperities” can be of various nature, hair-tips, dust, “fluff”, local high curvature spots or ridges (the term derives from scattering by powdered materials where the “asperities” are sharp edges like on broken glass).

Background

The reflectance of natural, opaque, and rough surfaces [1, 2] can be described by the Bidirectional Reflectance Distribution Function (BRDF) [6]. BRDFs that are common and well-known are those of Lambertian, perfectly diffusely scattering surfaces and of specular surfaces. Such surfaces scatter light in all directions (diffuse scattering) or primarily in the mirror direction (specular reflection). However, natural surfaces can scatter light in many other ways. Asperity scattering adds a “surface lobe” to the usual diffuse, backscatter, and specular lobes of rough surfaces. It is an important effect in many materials that are covered with a thin layer of sparse scatterers such as dust or hairs. In the common case that single scattering predominates, asperity scattering adds important contributions to the structure of the occluding contour and the edge

of the body shadow. This is the case because the BRDF is inversely proportional to the cosines of both illumination and viewing angles. The BRDF is generally low (and typically negligible), except when either the illuminating rays or visual directions graze the surface.

Because asperity scattering selectively influences the edges in the image of an object, it has a disproportionately (as judged by photometric magnitudes) large effect on (human) visual appreciation. It is a neglected but often decisive visual cue in the rendering of human skin. Its effect is to make smooth cheeks to look “velvety” or “peachy” (the appearances of both velvet and “peachy” skin are dominated by asperity scattering), that is to say, soft. This is a most important aesthetic and emotional factor that is lacking from Lambertian (looks merely dullish, paperlike), “skin type” BRDF (looks like glossy plastic), or even translucent (looks “hard”, vitreous) types of rendering.

Theory

Asperity scattering is due to scattering by a sparse “cloud cover” of the surface with essentially point scatterers. In sparse distributions of scatterers, one may assume that single scattering predominates. Then parameters of interest are the geometry of the cloud and the nature of the single scatterers. For this case, a physical, geometrical optical model was derived [3] and experimental data gathered [5].

It is also possible to fit asperity scattering characteristics in a convenient, simplified formula (note that basic physical constraints should hold, e.g., non-negativity, energy conservation, and Helmholtz reciprocity) [4]. For instance, for a surface element with unit (outward) normal n , irradiated from the direction (unit vector) i and viewed from the direction (unit vector) j , the following BRDF model

$$V(\mathbf{i}, \mathbf{j}, \mathbf{n}, a) = \frac{1}{\pi} \frac{a}{a + (\mathbf{i} \cdot \mathbf{n})(\mathbf{j} \cdot \mathbf{n})}, \quad (1)$$

describes a “surface lobe” such as one observes in black velvet cloth or peach skin. The parameter

a determines the width of the lobe. (A similar behavior results if one substitutes $(\mathbf{i} \cdot \mathbf{n}) + (\mathbf{j} \cdot \mathbf{n})$ for $(\mathbf{i} \cdot \mathbf{n})(\mathbf{j} \cdot \mathbf{n})$.) The albedo is found to be

$$A_V(\mathbf{i}, \mathbf{n}, a) = \frac{2a}{(\mathbf{i} \cdot \mathbf{n})^2} \left(\mathbf{i} \cdot \mathbf{n} + a \log \frac{a}{a + \mathbf{i} \cdot \mathbf{n}} \right), \quad (2)$$

which has a lowest value

$$2a \left(1 + \log \left(\frac{a}{1+a} \right)^a \right) \approx 2a + 2 \log aa^2 + \dots \quad (3)$$

at normal incidence and rises monotonically to unity at grazing incidence. (For black velvet $a \ll 1$.) Other possibilities for simplified formulations may be found in graphics as so-called velvet shaders. However, care should be taken that many of these rendering applications do not fulfill the above mentioned basic physical constraints.

Open Problems

BRDFs of natural surfaces can probably be categorized into about a dozen different modes. Currently, only the forward, backward, diffuse, and surface scattering modes have been described by formal optical models.

Reflectance estimation from images suffers from image ambiguities. Prior knowledge on the reflectance statistics of natural materials plus formal descriptive models for the common modes of natural BRDFs can constrain this problem.

Definition

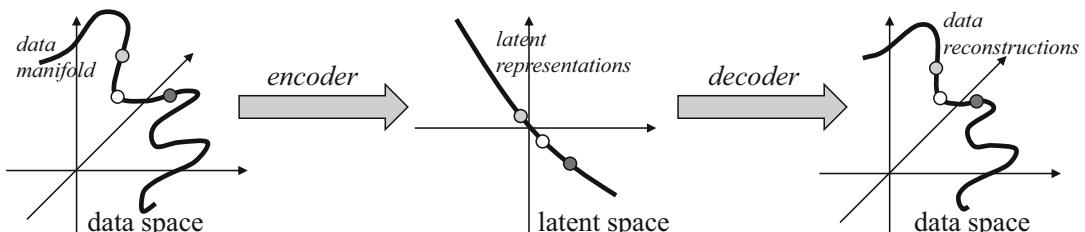

An autoencoder is a deep neural architecture comprising two parts, namely, (1) an *encoder* network that maps each input data point to a point in a different (*latent*) space and (2) a *decoder* network that maps the points in the latent space back to the data space. The two components are trained jointly in an unsupervised way, so that their composition approximately preserves points from a given training dataset.

Background

Autoencoders are a very popular deep architecture for unsupervised learning going back to at least 1980s [1, 2]. Similar to other unsupervised learning methods such as principal component analysis [3], the objective of autoencoder learning is to find some latent representation of the points in a training dataset that preserves the information contained in the data points, while simplifying the data in a certain way. In the case of autoencoder, the mapping from the data points to their latent representations is parameterized by a deep feedforward network (an encoder). The learning also aims to recover an approximate inverse mapping of the encoder that is also parameterized as a deep network (a decoder). Training the encoder and the decoder in parallel ensures that the discovered latent representation of the data preserves most of the information contained in the data. To uncover the latent (hidden) structure of the dataset (or the underlying distribution), certain constraints are usually imposed on the architecture of the encoder and/or the decoder. Once the autoencoder is trained, its components or the discovered latent representations can be used in various ways. In particular, the latent representations of data points can often be used as features for different machine learning tasks.

Theory

Autoencoders are deep architectures trained in an unsupervised way for a dataset x_1, x_2, \dots, x_N

Autoencoder, Fig. 1 The autoencoder architecture comprises the encoder that maps data to latent space and the decoder that is trained in parallel with the encoder to approximately invert it on the data points. The goal of the

in a certain data space X . In a probabilistic setting, we may think of the dataset as a sample from some underlying distribution p_X defined on X . Alternatively, we may think of the training dataset as a set of samples from some manifold (the *data manifold* M) that lies within the data space and forms the support of the distribution p_X . Autoencoder learning can then be seen as a way to find a suitable parameterization of the data manifold and is thus related to manifold learning methods.

An autoencoder (Fig. 1) includes an encoder \mathbf{e}_ϕ with learnable parameters ϕ that maps each example x to its latent representation $z = \mathbf{e}_\phi(x)$ from a certain latent space Z . The structure of X and Z may be arbitrary, e.g., X may contain images of a certain size, and Z may correspond to a Euclidean space of a certain dimensionality.

The second part of the autoencoder, the decoder \mathbf{d}_θ with learnable parameters θ operates in the reverse direction to the encoder. The decoder thus maps points $z \in Z$ to the data space X . The full autoencoder network then corresponds to the composition of the encoder and the decoder:

$$\mathbf{a}_{\phi,\theta} = \mathbf{d}_\theta \circ \mathbf{e}_\phi \quad (1)$$

The exact structure of the encoder and the decoder can also be arbitrary. In modern computer vision, it is common to use convolutional architectures [4] with multiple layers for both networks.

An autoencoder is trained by approximating the identity mapping on the dataset X . The

learning is to obtain a latent representation of the data that is in a certain way simpler or more amenable for further processing than the original data representation

training loss is therefore defined as:

$$L(\phi, \theta) = \frac{1}{N} \sum_{i=1}^N \Delta(x_i, \mathbf{a}_{\phi, \theta}(x_i)) \quad (2)$$

where the function Δ measures the dissimilarity between its arguments. In the simplest case, one may use the squared Euclidean distance $\Delta(x, y) = \|x - y\|_2^2$, though more sophisticated variants, such as perceptual dissimilarity [5], are often used in recent works. The choice of Δ plays an important role, since the autoencoders are usually designed in a way that the training loss cannot be minimized to zero, leaving some mismatch between the training data points x_i and their reconstructions. The choice of the dissimilarity measure Δ thus determines which kind of dissimilarities between data points and reconstructions are penalized more and which are penalized less.

The training process of an autoencoder corresponds to the minimization of the loss (2) using some variant of stochastic gradient descent. As with many other unsupervised learning techniques, the goal of the training is to learn some latent representation of data that uncovers some latent (hidden) structure in the data. This means that the dataset z_1, z_2, \dots, z_N , where $z_i = e_\phi(x_i)$ (and the underlying distribution $p_Z = \mathbf{e}_\phi(p_X)$), should have a form that is simpler in some sense than the original dataset and the original distribution.

From the manifold viewpoint, learning autoencoder essentially amounts to finding the parametrization of the data manifold. One indicator of success here (which is often used by researchers to evaluate the quality of an autoencoder) is the plausibility of interpolation in the latent space. Thus, given two data samples x_1 and x_2 and their latent representation z_1 and z_2 , the latent points lying on the line segment that connects z_1 and z_2 in the latent space should be mapped by the decoder onto the data manifold, i.e., $\forall \lambda \in [0; 1] \mathbf{d}_\theta(\lambda z_1 + (1 - \lambda)z_2) \in M$. When data are images of a certain kind, e.g., face images, this condition can be verified by looking at the reconstructions $\mathbf{d}_\theta(\lambda z_1 + (1 - \lambda)z_2)$ and checking whether they look like face images.

Note that a line segment connecting x_1 and x_2 in the original data space would typically not lie on the data manifold M , as most data manifolds have highly non-convex shape in the embedding space.

Types of Autoencoders

Given enough capacity of the networks \mathbf{e} and \mathbf{d} as well as large enough space Z , the autoencoder is likely to learn to copy the data points into the latent space (potentially with some trivial injective transformation T) and then to copy it back to the original space (while reverting the transformation T). This is because such solution achieves lowest possible (zero) loss. In this case, the latent representation will not be in any ways simpler than the original data representation, and the data manifold will not be properly parameterized. Below, we discuss several ways how autoencoders can be encouraged to learn simplified data representation.

Autoencoders as architectures for nonlinear dimensionality reduction. In this approach, the dimensionality of Z is taken to be substantially smaller than the dimensionality of X . In this situation, learning an autoencoder effectively amounts to dimensionality reduction, as the learning process seeks to identify the most important factors of variation in the data in order to preserve them within the latent representations.

Regularized autoencoders Alternatively, or in addition to having Z of small dimensionality, it is common to impose certain regularization on the learning process. For example, one may penalize a certain norm of the latent vectors z_i [6] and/or penalize a certain norm of the network parameters ϕ and θ [7]. Adding such regularization effectively prevents the autoencoder from learning the identity function and forces it to learn a simplified latent representation of data.

Denoising autoencoders Alternatively, or in addition to the above approaches, one can regularize the training process by injecting (adding) noise or performing some structured corruption process on the training points, so that

the autoencoder receives the corrupted versions \tilde{x}_i of the data points x_i during training. In this scenario, the autoencoder needs to combine reconstruction with restoration, as the loss function still computes the difference between the reconstruction obtained from the corrupted data and the original data points:

$$L(\phi, \theta) = \frac{1}{N} \sum_{i=1}^N \Delta(x_i, \mathbf{a}_{\phi, \theta}(\tilde{x}_i)) \quad (3)$$

Once again, denoising autoencoder cannot attain low training loss by simply copying the data from the input to the output via the latent space, since such copying will not remove the corruption effect. Instead, the autoencoder has to learn to project the corrupted examples onto the manifold containing the original distribution [8] and therefore has to uncover the latent representation of data, from which the original data points can be reconstructed.

Variational autoencoders Variational autoencoders (VAEs) [9, 10] combine several of the above ideas and do so in a probabilistic setting. In a variational autoencoder, the encoder and the decoder are thought as stochastic functions. The encoder maps each data point to a distribution in the latent space (which is usually taken to be Gaussian with diagonal covariance matrix, so that both the mean vector and the covariance parameters are predicted by the encoder). The decoder is also designed to map points in the latent space to the (usually Gaussian) distribution in the data space (though the covariance matrix is often fixed and only the mean vector is predicted). The autoencoding process inside VAE corresponds to mapping a training data sample to the distribution in the latent space, sampling from the resulting distribution and mapping the sample back to the data space. The minus log-likelihood of the input data sample w.r.t. the resulting distribution is then minimized. The learning is regularized by penalizing the Kulback-Leibler divergence between the encoding of each data sample and the unit zero-mean Gaussian. When the regularization coefficient equals one, the

total learning objective can be interpreted as the maximization of the so-called evidence lower bound on the log-likelihood of the data points.

Related Models

Autoencoders have deep connections to a number of models and tasks. Some of these connections are discussed below.

Principal component analysis (PCA) PCA [3] can be regarded as a particular type of an autoencoder with the encoder and the decoder having the fully connected single-layer architecture under additional constraints on the matrices and biases of the layers and more efficient training algorithms (namely, singular value and eigenvalue decompositions). The usage patterns discussed below are thus common to autoencoders and PCA, though autoencoders with multiple convolutional layers in most circumstances attain much better performance for image datasets.

Data compression When the dimensionality of the latent space is lower than the original space or if the latent representation of the dataset is more amenable for compression algorithms, training an autoencoder can be used for lossy data compression [11].

Generative adversarial networks (GANs) GANs [12] are another kind of latent models learned to approximate the data manifold/distribution. In their original form, GANs allow to map points from latent space to data space (as do decoders within autoencoders), but not vice versa. Multiple hybrid models that combine autoencoders with GANs exist [13, 14].

Generative latent optimization (GLO) The recently proposed GLO model [15] is another deep latent model learned to parameterize the data manifold. GLO can be regarded as a simplification of the autoencoder model, where only the decoder network is trained and reused after training.

Applications

Autoencoders have a number of applications, and below we provide examples of the most common patterns of usage.

Feature extraction Once an autoencoder is trained, its encoder part \mathbf{e}_ϕ can be used as a feature extractor for various machine learning tasks including supervised learning. In the semi-supervised training scenario, a large amount of unlabeled data $\{x'_i\}$ can be used to train an autoencoder, and a small amount of labeled data $\{x_i, y_i\}$ (where y_i is a label of x_i) can then be used to train a predictor (e.g., a classifier) \mathbf{c}_ψ with learnable parameters ψ in the latent space, so that $y_i \approx \mathbf{c}_\psi(\mathbf{e}_\phi(x_i))$. Assuming that the training of the autoencoder is successful, and the distribution in the latent space has a simpler form than in the data space, training such predictor in the latent space Z will lead to better generalization than training a predictor in the original data space X . Note that the decoder \mathbf{d}_θ is effectively discarded in such a scenario.

Pretraining generator networks It is common to use the decoder part of a pretrained autoencoder for conditional sampling/synthesis. In more detail, consider a scenario when a limited amount of *aligned* data $\{(x_i, y_i)\} \subset X \otimes Y$ (e.g., images from the image space X and their text descriptions from the description space Y) and a large amount of *unaligned* samples $\{x'_j\} \subset X$ (e.g., images without descriptions) are given. In order to learn image synthesis conditioned on text description, one may first learn an autoencoder on unaligned data $\{x'_j\}$ with latent space Z and then learn a mapping \mathbf{f}_τ from Y to the latent space Z with learnable parameters τ , such that its composition with the pretrained decoder \mathbf{d}_θ maps x_i close to y_i (i.e., $x_i \approx \mathbf{d}_\theta(\mathbf{f}_\tau(y_i))$). The composition of the mapping \mathbf{f}_τ and the decoder will thus provide a mapping from Y to X (text-to-image in our example) that is trained both on aligned and unaligned data. Such mapping is likely to generalize to unseen data better than the mapping learned solely on aligned data.

Disentangling of factors Under certain circumstances, the latent distribution learned by an autoencoder has some factor disentangling properties so that a certain factor of variation affects all or almost all dimensions in the original space X but only a small subset of dimensions in the latent space Z . For example, when autoencoder is trained for face images, certain latent dimensions may correspond to person identity, while being invariant to expression (and vice versa). Such disentangling is most common to observe in a variational autoencoder (VAE) due to the diagonal covariance structure imposed on the latent distributions within VAE.

Data manipulation in latent space Even if factors of variation are not disentangled in the latent space, it often happens that high-level (semantic) editing is easier in the latent space than in the data space. For example, given a dataset of face images, it often happens that a change of a certain attribute (e.g., changing neutral face expression to smiling expression) can be easily modeled in the latent space. Sometimes, such transformation that is very complex in the data space can be well approximated by a simple translation by a certain vector in the latent space. The parameters of the transformation in the latent space can be learned from a small amount of extra annotation (e.g., in the example above, the translation vector can be learned as a difference between the mean of the latent representations of several smiling faces and the mean of the latent representations of several neutral faces).

Unsupervised restoration and anomaly detection The ability of autoencoders to project data on the data manifold can be used to restore corrupted data as well as to identify outlier samples that do not belong to the data manifold [16, 17].

Definition

Members of the equivalence class of convex Lambertian surfaces that produce the same set of orthographic images under arbitrary combinations of distant point light sources

are related by elements of a three-parameter subgroup of $GL(3)$, called generalized bas-relief (GBR) transformations. This inherent ambiguity in determining the three-dimensional shape of an object from shading and shadow information is called the bas-relief ambiguity.

Background

For a surface $f(x, y)$, the GBR-transformed surface is given by $f(x, y) = \mu x + \nu y + \lambda f(x, y)$, where $\mu, \nu \in \mathbb{R}$ and $\lambda \in \mathbb{R}_{++}$. The orthographic image of an object with Lambertian reflectance, illuminated by an arbitrary set of distant point light sources, remains unchanged when the object shape is transformed by a GBR, with an inverse transformation applied on the set of light sources and a corresponding pointwise transformation on the albedos. Further, any continuous transformation that preserves the shading and shadowing configuration for a convex surface must belong to the GBR group [1].

Thus, for a Lambertian surface, any reconstruction or recognition algorithm based on shading and shadow information alone can at best enunciate the shape, albedo, or lighting up to a “bas-relief ambiguity.” The ambiguity derives its name from the corresponding low-relief sculpture technique (Italian: *basso rilievo*), which can be understood as a special case of the GBR, where $\lambda < 1$.

Theory

Under orthographic projection, each point on a surface may be represented as $[x, y, f(x, y)]^\top$, where $(x, y) \in \mathbb{R}^2$ is a point on the image plane and f is a piecewise differentiable function. The unit surface normal is given by

$$\hat{\mathbf{n}} = \frac{[-f_x, -f_y, 1]^\top}{\sqrt{f_x^2 + f_y^2 + 1}}. \quad (1)$$

A GBR transformation that maps a surface $f(x, y)$ to $\bar{f}(x, y) = \mu x + vy + \lambda f(x, y)$ and the corresponding inverse GBR transformation may be represented as 3×3 linear transformations:

$$\mathbf{G} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \mu & v & \lambda \end{bmatrix}, \mathbf{G}^{-1} = \frac{1}{\lambda} \begin{bmatrix} \lambda & 0 & 0 \\ 0 & \lambda & 0 \\ -\mu & -v & 1 \end{bmatrix}. \quad (2)$$

Under the matrix product operation, the set of GBR transformations forms a subgroup of $G L(3)$, the group of 3×3 invertible linear transformations. The unit surface normals of the GBR-transformed surface \bar{f} are $\frac{\mathbf{G}^{-\top} \hat{\mathbf{n}}}{\|\mathbf{G}^{-\top} \hat{\mathbf{n}}\|}$.

Shadows and Shading

The image formation equation at a point $\mathbf{p} = [x, y, f(x, y)]^\top$ on a Lambertian surface is given by

$$I(x, y) = \mathbf{n}^\top \mathbf{s} \quad (3)$$

where I is the intensity, \mathbf{n} is the product of albedo a and unit surface normal $\hat{\mathbf{n}}$, while \mathbf{s} is the light source direction, scaled by its strength. The point \mathbf{p} lies in an attached shadow if $\mathbf{s}^\top \hat{\mathbf{n}} < 0$, while it lies on a cast shadow boundary if there exists a point \mathbf{p}' on the surface, with unit normal $\hat{\mathbf{n}'}$, such that

$$\mathbf{s}^\top \hat{\mathbf{n}'} = 0, \mathbf{p} - \mathbf{p}' = k\mathbf{s}, \text{ for some } k \in \mathbb{R}_{++}. \quad (4)$$

A point $\mathbf{p} = [x, y, f(x, y)]^\top$ lies in an attached shadow or on a cast shadow boundary in an image produced by the light source \mathbf{s} if and only if the

point $\bar{\mathbf{p}} = \mathbf{G}\mathbf{p}$ does so in an image produced by the light source $\bar{\mathbf{s}} = \mathbf{G}\mathbf{s}$, where \mathbf{G} is a GBR transformation given by Eq. (2). Further, the image of a surface $f(x, y)$ with albedo $a(x, y)$, when illuminated by a light source \mathbf{s} , is equivalent to the image under the light source $\bar{\mathbf{s}} = \mathbf{G}\mathbf{s}$ of the GBR-transformed surface \bar{f} , with a pointwise albedo transformation given by

$$\bar{a} = \frac{a}{\lambda} \left(\frac{(\lambda f_x + \mu)^2 + (\lambda f_y + \mu)^2 + 1}{f_x^2 + f_y^2 + 1} \right)^{\frac{1}{2}}. \quad (5)$$

It follows that the set of images of a Lambertian surface-albedo pair $\{f, a\}$, under all possible combinations of distant light sources, is identical to that of any GBR-transformed surface-albedo pair $\{\bar{f}, \bar{a}\}$ [1] (see Fig. 1). Thus, the illumination cones of surfaces related by a GBR transformation are identical [2].

Existence and Uniqueness

It is shown in [1] that any two convex, smooth surfaces with visible occluding contours that produce the same set of attached shadow boundaries must be related by a GBR transformation. Thus, the GBR transformation is the only one that preserves the set of all images of an object.

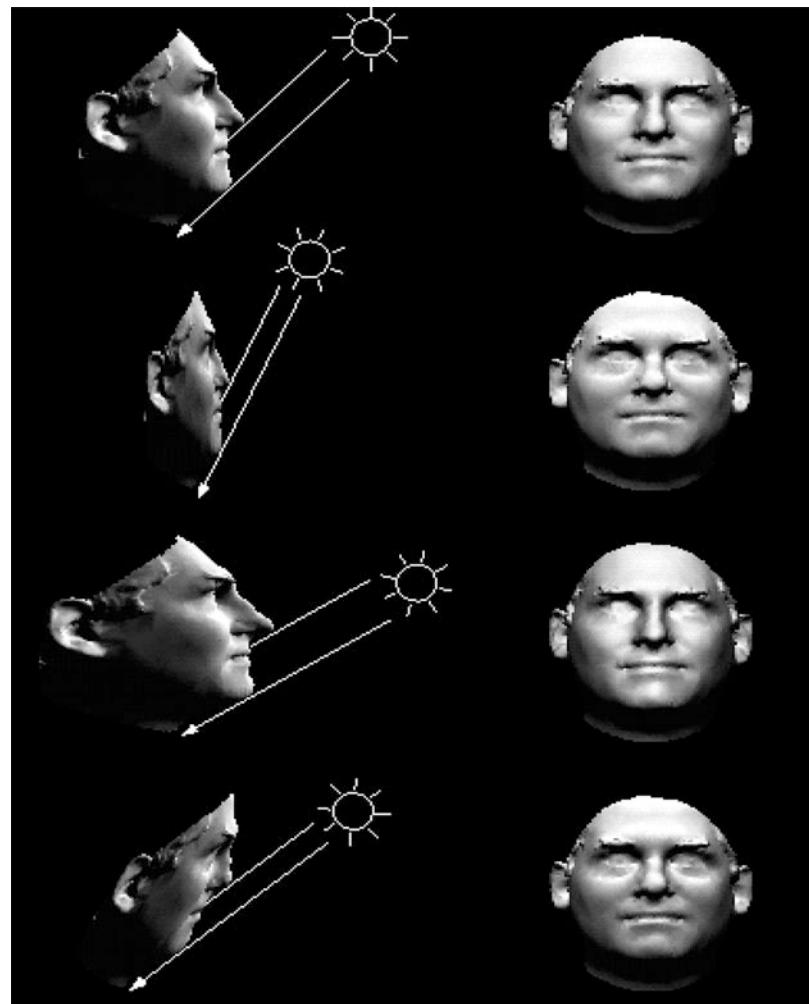

While the existence result for the bas-relief ambiguity does not explicitly require convexity of the surface, in practice, the image formation model for concave regions must account for interreflections. It has been shown that modeling diffuse interreflections uniquely determines the shape and lighting [3].

Integrability

In traditional photometric stereo, given images of a point \mathbf{p} under three or more known light sources, one may recover its surface normal $\hat{\mathbf{n}}$ using Eq. (3). However, in uncalibrated photometric stereo where the light sources are unknown, the surface normal and the light sources can be recovered only up to an arbitrary, invertible 3×3 linear transformation, since $\mathbf{n}_* = \mathbf{A}^\top \mathbf{n}$ and $\mathbf{s}^* = \mathbf{A}^{-1} \mathbf{s}$ satisfy Eq. (3) for any $\mathbf{A} \in GL(3)$.

Bas-Relief Ambiguity

Fig. 1 The left column shows various GBR transformations applied to a surface, with the corresponding inverse transformation applied to the light source direction. The top row is the true shape. The right column shows that the shading and shadows produced in an orthographic image of the surface are identical for any GBR transformation. (Figure reproduced in part from [1], courtesy of the authors)

For the recovered normal field to correspond to a surface, it must satisfy the integrability constraint [4]:

$$\frac{\partial}{\partial y} \left(\frac{n_1^*}{n_3^*} \right) = \frac{\partial}{\partial x} \left(\frac{n_2^*}{n_3^*} \right). \quad (6)$$

It is shown in [1] that requiring the recovered normal field to be integrable restricts \mathbf{A} to lie in the group of GBR transformations.

Generalizations

Under perspective projection, the shadows produced by an object under distant or proximal point light sources are the same as those produced

by a surface transformed by a generalized perspective bas-relief (GPBR) transformation, with an inverse transformation applied on the light sources [5]. The GPBR is a three-dimensional elation [6] and, in the limiting case of orthographic projection, reduces to the definition of GBR in Eq. (2).

Under orthographic projection from an unknown viewpoint, there exists an ambiguity that corresponds to the group of three-dimensional affine transformations, called the Klein generalized bas-relief (KGBR) ambiguity, such that the set of images of an object is preserved under the action of a KGBR transformation on the shape, lighting, albedos,

and viewpoint [7]. In the limiting case of a fixed viewpoint, the KGBR ambiguity reduces to the bas-relief ambiguity.

Application

The bas-relief ambiguity in computer vision explains psychophysical observations of similar unresolved ambiguities in human visual perception [8]. An important consequence of the existence of the bas-relief ambiguity is that any image-based computer vision algorithm, relying on inference based solely on shading and shadow information, can only describe the object up to an arbitrary GBR transformation. Further, it has been established that for any infinitesimal motion of a surface f , there exists a motion for the GBR-transformed surface \bar{f} that produces the same motion field [1]. Thus, an infinitesimal motion does not provide additional cues for disambiguation.

Surface reconstruction up to a GBR transformation can be performed by imposing integrability in uncalibrated photometric stereo [9]. The bas-relief ambiguity may be resolved in practice by incorporating additional information, for instance, priors on albedo distribution [10, 11]. Alternatively, the presence of non-Lambertian effects – such as specular highlights [12], a Torrance-Sparrow reflectance [13], or a spatially unvarying, isotropic, additive non-Lambertian reflectance component [14] – eliminates the GBR ambiguity.

- ▶ [Texture Recognition](#)

Definition

In the context of computer vision, texture often refers to a variation of image intensity or color, where the variation exhibits some type of repetition. The terms *2D texture* and *3D texture* provide a more precise definition of texture. A *2D texture* may be a color or shade variation such as a paisley print or zebra stripes. A textured surface can also exhibit geometric variations on the surface such as gravel, grass, or any rough surface. This type of texture is termed *3D texture* [1, 2]. Algorithms developed for 2D texture are generally not useful for 3D texture because appearance varies as a function of viewing and illumination direction.

The difference between 2D and 3D texture is readily apparent when considering photometric effects due to illumination direction and geometric effects due to viewing direction. Consider Fig. 1 with four images of the same surface under different surface tilt angles. The surface geometry

does not change, but the illumination and viewing direction is different in each of the images. With a 2D texture model, these changes could be misinterpreted as changes in the texture class. As shown in Fig. 2, the appearance of the texture also changes significantly over the surface of a 3D object. The photometry of 3D texture causes shading and shadowing that vary with illumination direction. The geometry of 3D texture causes a variation in foreshortening and occlusions along the imaged surface. Consider Fig. 3 which illustrates oblique viewing of a 3D-textured surface patch. A similar oblique view of a 2D-textured surface patch gives a uniformly compressed or downsampled version of the frontal view. However, for an obliquely viewed 3D-textured surface patch, there is a non uniform resampling of the frontal view. Consequently, some texture features are compressed in the oblique view, while others expand. Computer graphics algorithms for texture mapping traditionally characterize the texture with a single image. To synthesize oblique views, these texture-mapping algorithms apply a uniform resampling which clearly cannot account for the spatially varying foreshortening and occlusions.

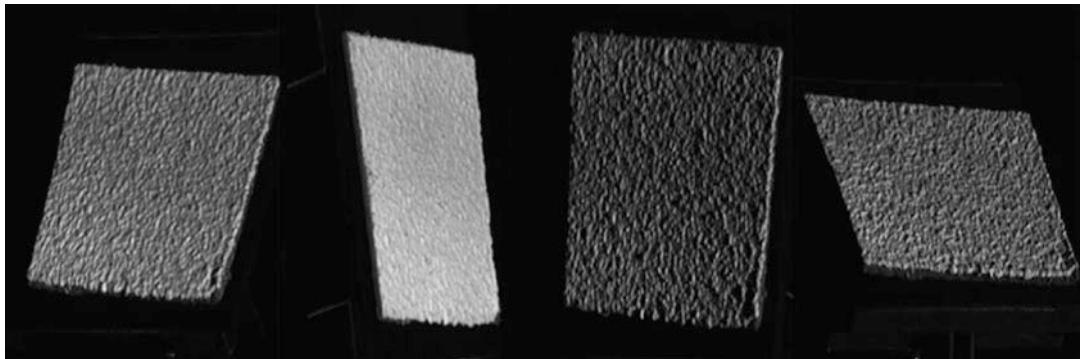

Background

Measurement of 3D texture with a bidirectional texture function (BTF) was introduced in [1, 2]. This work created a database of 3D texture called the CURET database (Columbia-Utrecht Reflectance and Texture database). This publicly available collection of measurements from real-world surfaces served as a starting point for subsequent work in 3D texture.

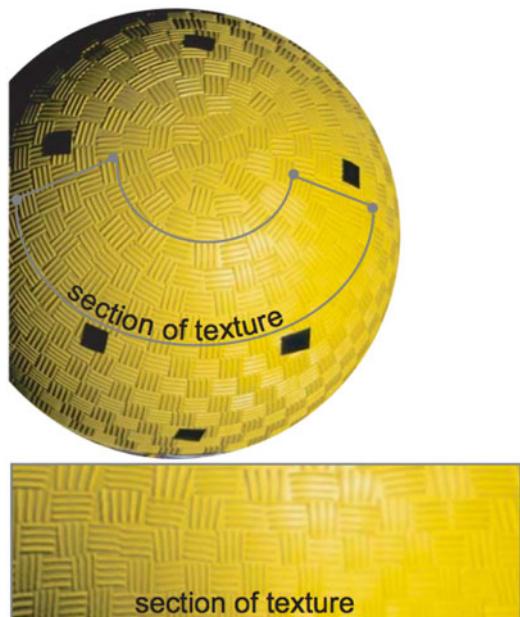

Theory

Histogram Models for 3D Texture

Numerous texture models for 2D texture have been developed since the early 1970s and are used in areas like texture mapping,

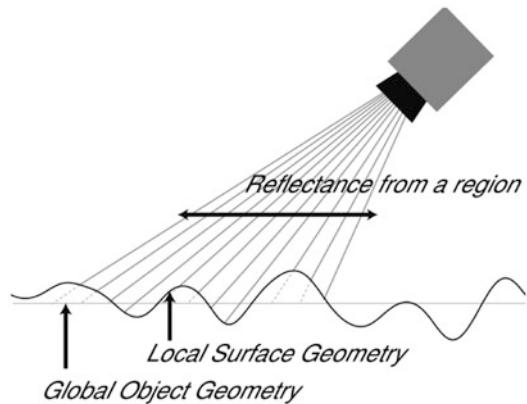

Bidirectional Texture Function and 3D Texture, Fig. 1 Four images of the same 3D-textured surface. As the surface tilt and illumination direction varies, surface appearance changes

The local appearance of a 3D-textured object. Notice that local foreshortening, shadowing, and occlusions change across the texture because of the differences in global surface orientation and illumination direction

texture synthesis, shape-from-texture, and texture classification and segmentation. These representations include co-occurrence matrices, histograms, power spectra, Gabor filter outputs, textons, wavelets, and Markov random fields. In the late 1990s, the emphasis of texture research expanded to include 3D textures. Analytical models of intensity histograms of 3D-textured

Geometry of 3D texture. For oblique views of a 3D-textured surface, the sampling rate of the surface depends on the local geometry

surface are developed in [3] and [4]. Intensity histograms are a very basic tool to represent texture but are too simple for most computer vision tasks. A standard framework for texture representations consists of a primitive and a statistical distribution (histogram) of this primitive over space. Intensity is the simplest primitive; however, image features are better primitives to characterize the spatial relationship of pixels. In order to account for changes with imaging parameters (view/illumination direction), either the primitive or the statistical distribution should be a function of the imaging parameters. Two methods to represent 3D texture are the bidirectional feature histogram (BFH) [5]

and the 3D texton method [6]. In the 3D texton method, the primitive is a function of imaging parameters, while in the BFH method, the histogram is a function of imaging parameters. The advantage of the BFH approach is that there is no need for aligning images obtained under different imaging parameters.

Appearance-Based Representations

In computer vision, the precise surface geometry that comprises a 3D texture is often unknown. Instead, images of the 3D texture, i.e., appearance, are used to represent the textured surface. The term bidirectional texture function (BTF) is the appearance of texture as a function of viewing and illumination direction. BTF is typically captured by imaging the surface at a set of possible viewing and illumination directions. Therefore, measurements of BTF are collections of images. The term BTF was first introduced in [2, 7], and similar terms have since been introduced including BSSRDF [8] and SBRDF (spatial BRDF) [9]. SBRDF has a very similar definition to BTF, i.e., BTF is also a spatially varying BRDF.

BTF measurements can be very large because the measurements typically consist of a high-resolution image for every possible viewing and illumination direction. Dense sampling of the illumination and viewing space results in extremely large datasets to represent the surface. For example, if a 3 Mb image is captured for each of the 100 sampled viewing directions and 100 illumination directions, the resulting dataset is 30 Gb. Compact representations of the BTF are clearly important for efficient storage, rendering, and recognition. Methods for compact representations and compression of the BTF are presented in [10–13].

Geometry-Based Representations from Computer Graphics

In computer vision, image-based representations are standard because the surface geometry is typically unknown. However, in computer graphics, the precise geometry of the 3D-textured surface may be known. Rendering 3D textures using a volumetric representation of surface geometry

is a common approach. Many of the rendering packages such as OpenGL and Blender use the term 3D texture to refer to volumetric texture. In this definition, the 3D texture is defined by opacity in a volume, instead of the definition here which refers to a surface height variation. In recent work [14], a volumetric representation is used for texture rendering, where the volume is a stack of semitransparent layers obtained using measured BTF data. Historically, volumetric texture methods are also referred to as solid texturing [15–18].

Application

The main applications for 3D texture representations are in recognition, synthesis, and rendering. While many applications use image-based representations, or assume a known geometric model, other applications need to capture the local geometry of 3D texture. Digital archiving of art is an example of such an application where fine-scale surface detail can enhance geometric models. Often the 3D texture is not easily captured with standard laser scanning devices. For example, in capturing the geometry of sculptures, researchers devised ways to capture high-resolution 3D texture such as tool marks [19–21]. An additional method for capturing high-resolution 3D texture geometry uses a specialized texture camera based on the optical properties of curved mirrors [22]. For texture recognition, 3D texture methods have been used in material recognition [6, 23–25]. One of the popular recognition tasks is the recognition of materials from the CURET database. Another real-world recognition task is the measurement and recognition of skin texture [26–28]. For texture synthesis and rendering, the main problem is to synthesize the appearance of 3D texture. Several authors have developed methods to synthesize and render 3D-textured surfaces using the BTF representation [29–35]. Other authors used an image-based approach to capture and render complex surfaces by direct photography of the full object under various illumination and viewing directions, simultaneously capturing object shape and surface light

fields [36–38]. Synthesizing 3D textures via texture morphing enables creating and rendering novel 3D texture [39]. In computer graphics, 3D-textured surfaces were traditionally rendered by bump mapping [40], albeit with limited realism. In more recent years, several new methods have been developed that can efficiently render 3D texture detail. These include view-dependent displacement mapping [41], relief texture mapping [42], the polynomial texture map [43], and a Blender-based rendering method [44].

Definition

Binocular stereo refers to the task of recovering depths of a static scene using a pair of overlapping images captured from different viewpoints. Binocular stereo systems usually use two identical parallel cameras that are horizontally separated by a certain distance, referred to as the *baseline*. The task of binocular stereo amounts to finding dense pixel correspondences between the image pair along horizontal scan lines (called *epipolar lines*) or estimating the *disparity* for each pixel of the stereo images. The outcome of binocular stereo takes a form of a depth map that can be computed from disparity given the

baseline and focal length of a stereo system or instead of a disparity map itself.

Background

Binocular stereo is one of the oldest topics in computer vision. Similar to the mechanism of human depth perception, the principle of binocular stereo is triangulation, which is mathematically formulated based on the epipolar geometry. However, due to ambiguous pixel correspondences, binocular stereo typically becomes ill-posed when scenes have no textures or show repetitive patterns.

Wide baseline stereo refers to a particular setting of binocular stereo where the two cameras are widely separated. This leads to a more difficult task because of larger disparity ranges, lesser overlaps between image pairs, and a higher likelihood of occlusions.

Occlusion is an inevitable problem in binocular stereo, which occurs when a part of an object in one view is not present in the other view because it is occluded by another object or is out of the field of view in the other view. Since occluded regions have no true visual correspondence, they produce incorrect depth estimates unless properly handled.

Binocular stereo can be seen as special or simplified cases of other related computer vision tasks. For example, multiview stereo uses two or more images captured from calibrated but possibly irregular viewpoints. In principle, multiview stereo can achieve higher accuracy than binocular stereo, because the use of multiple images can reduce matching ambiguities and can also lead to fewer occluded surfaces (as each surface point has a better chance of being visible from at least two views). However, multiview stereo is a more complicated task, because images from irregular viewpoints may contain low-overlapping image pairs that have to be excluded from matching via viewpoint selection. Also, surface patches often undergo more significant distortions across views, which makes accurate evaluations of patch similarity difficult.

Optical flow is also a visual correspondence estimation task between two images but involves estimating more general motions of a dynamic scene between two different temporal frame images captured by a possibly moving monocular camera. While pixel motions in binocular stereo (disparities) are induced by factors of object positions and the left-to-right camera motion, optical flow involves more complicated motion factors of object positions, an unknown camera motion, and dynamic object movements. Because of this complexity, estimation of pixel motions in optical flow requires a 2D search space, which is wider than 1D search spaces for disparities and depths in binocular and multiview stereo. The presence of dynamic object movements also makes the occlusion reasoning more complicated than stereo.

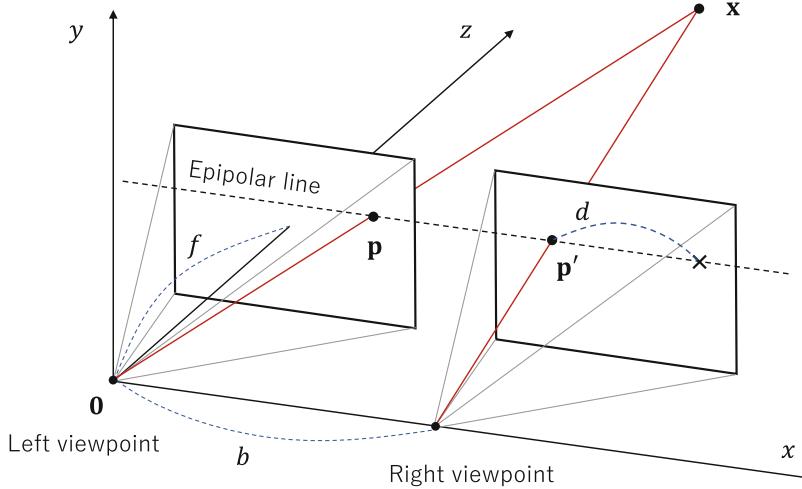

Binocular stereo can thus be considered as the most fundamental dense visual correspondence estimation task, which is built upon notions from a wide range of computer vision areas such as camera calibration, image filtering, and combinatorial optimization as explained in following sections.

Theory and Application

We first discuss the mathematical foundation of binocular stereo based on the epipolar geometry. We then review classical methodologies of binocular stereo and also review recent learning-based methodologies using neural networks.

a) Mathematical Principle

In this section, we explain how a 3D point can be triangulated from a pair of corresponding pixels, using a typical *rectified* setting of binocular stereo shown in Fig. 1. Here, two identical pinhole cameras, both directed along the z axis in the 3D world coordinate system, are positioned at the origin $(0, 0, 0)^T$ (left viewpoint) and a horizontally shifted place $(b, 0, 0)^T$ (right viewpoint) where b is baseline. Both cameras are calibrated and have the following intrinsic parameter matrix:

B

Binocular Stereo, Fig. 1 Rectified setting of binocular stereo where two parallel cameras are horizontally placed

$$K = \begin{bmatrix} f & 0 & c_u \\ 0 & f & c_v \\ 0 & 0 & 1 \end{bmatrix}, \quad (1)$$

where (c_u, c_v) is the principal point and f is the focal length. Note that in reality it is difficult to setup such an ideally rectified stereo capturing system. However, given a calibrated stereo system (i.e., the relative pose and intrinsic parameters of the two cameras are known), we can transform unrectified stereo image pairs into rectified ones using a technique of stereo image rectification.

In this rectified setting, suppose there is a surface shown at a pixel $\mathbf{p} = (u, v)^T$ in the left view image (reference image). Its unknown 3D coordinate $\mathbf{x} = (x, y, z)^T$ in question can be represented as

$$\mathbf{x} = K^{-1}(z\bar{\mathbf{p}}), \quad (2)$$

where $\bar{\mathbf{p}}$ is the homogeneous coordinate of \mathbf{p} . This 3D point \mathbf{x} can be projected to the right view image at the following 2D location $\mathbf{p}' = (u', v')^T$.

$$\mathbf{p}' = \pi(K [R \ t] \bar{\mathbf{x}}). \quad (3)$$

Here, R is the identity rotation matrix, $\mathbf{t} = (-b, 0, 0)^T$ is the translation representing horizontal baseline, and π is a function $\pi(x, y, z) =$

$(x/z, y/z)^T$. Thus, by plugging Eqs. 2 into 3, we obtain an expression for the point corresponding to \mathbf{p} in the right image as

$$\mathbf{p}' = \mathbf{p} - \begin{bmatrix} fb/z \\ 0 \end{bmatrix}. \quad (4)$$

This result shows that for each pixel \mathbf{p} in the left image, its correspondence \mathbf{p}' in the right image should be found at a horizontally shifted position of \mathbf{p} by shifting the pixel by the following amount to the left.

$$d = fb/z. \quad (5)$$

This horizontal shifting amount d is called *disparity*. As shown by Eq. 5, once we obtain a disparity d for a pixel (or obtain its correspondence \mathbf{p}'), we can obtain its depth z from the disparity given the baseline b and focal length f of the considered stereo system.

b) Classical Methodologies

Scharstein and Szeliski [11] provide a well-known taxonomy of classical stereo algorithms based on the following four steps of algorithms: matching cost computation (photo-consistency), cost aggregation, disparity computation and optimization, and disparity refinement. In this section, we discuss classical stereo algorithms in

terms of design and minimization of the following objective function:

$$E(\mathbf{D}) = \sum_{\mathbf{p}} C_{\mathbf{p}}(D_{\mathbf{p}}) + R(\mathbf{D}). \quad (6)$$

Here, \mathbf{D} represents a disparity map that we estimate for an input stereo image pair. $C_{\mathbf{p}}(D_{\mathbf{p}})$ is a matching cost term that evaluates a given disparity estimate $D_{\mathbf{p}}$ for a pixel \mathbf{p} by measuring photo-consistencies between the two images. $R(\mathbf{D})$ is a regularization term that enforces some notion of smoothness on the disparity map \mathbf{D} .

The disparity map \mathbf{D} often takes a discrete variable form $\mathbf{D} \in \{d_1, d_2, \dots, d_K\}^{H \times W}$, and thus the objective function $E(\mathbf{D})$ is optimized using discrete (combinatorial) optimization algorithms. This is because objective functions of stereo are usually highly non-convex, and continuous optimization methods can be easily trapped at poor local minima.

Stereo algorithms can be broadly divided into local and global methods. Local methods rely only on the matching cost term and minimize the objective function by a simple winner-takes-all strategy. Global methods use a more complicated objective function with explicit regularizers, which involve computationally more expensive optimization procedures. Below we review important components and techniques of those local and global stereo methods.

Photo-consistency As a critical component of the matching cost term, photo-consistency $\rho(\mathbf{p}, \mathbf{p}')$ is a scalar function that evaluates dissimilarity between two pixels or image patches at respective locations \mathbf{p} and \mathbf{p}' in a given image pair $\{\mathbf{I}, \mathbf{I}'\}$. The simplest photo-consistency measure is SAD (sum of absolute difference) that evaluates $\rho(\mathbf{p}, \mathbf{p}') = |I_{\mathbf{p}} - I'_{\mathbf{p}'}|$, but directly comparing image intensities is not robust to illumination changes. As a more robust measure, normalized cross correlation (NCC) is used to compare two image patches. Zabih and Woodfill [18] propose the CENSUS transform that encodes an image patch into a binary feature vector, whose dissimilarity can be efficiently computed as the Hamming distance.

Cost aggregation Cost aggregation refers to a technique to refine noisy raw photo-consistency measures $\rho(\mathbf{p}, \mathbf{p}')$ by summing them over pixels in a patch around \mathbf{p} as

$$C_{\mathbf{p}}(d) = \sum_{\mathbf{s} \in W_{\mathbf{p}}} \omega_{\mathbf{ps}} \rho(\mathbf{s}, \mathbf{s}'_d). \quad (7)$$

Here, $W_{\mathbf{p}}$ is a support window centered at \mathbf{p} in the reference image, $\omega_{\mathbf{ps}}$ is some weight function, and $\mathbf{s}'_d = \mathbf{s} - (d, 0)^T$. Cost aggregation is often referred to as *cost volume filtering*, because if we precompute raw matching costs $\rho(\mathbf{p}, \mathbf{p}'_d)$ for all pixels \mathbf{p} and for all pre-defined disparities $d \in \{d_1, d_2, \dots, d_K\}$ as a 3D cost volume $V(\mathbf{p}, d)$, then cost aggregation is carried out by applying an image filter on 2D cost map slices $V_d(\mathbf{p}) = V(\mathbf{p}, d)$ with a filter kernel of $\omega_{\mathbf{ps}}$. Although a naive implementation of cost aggregation requires $O(|W_{\mathbf{p}}|)$ of computations for each term $C_{\mathbf{p}}(d)$, the notion of cost volume filtering can allow $O(1)$ of computations when using a constant-time filter (e.g., a box filter $\omega_{\mathbf{ps}} = 1$).

Cost aggregation relies on an assumption that the support pixels \mathbf{s} in a window $W_{\mathbf{p}}$ have the same disparity. However, as discussed in [3], this assumption often breaks down in two cases: (1) when there are depth boundaries in the window and (2) when the window region shows a highly slanted surface that has significantly varying disparities.

The first issue causes boundary-flattening artifacts in resulting disparity maps, but it can be well handled by adaptive window approaches [17] that use soft support window weights $\omega_{\mathbf{ps}}$ for cost aggregation. Yoon and Kweon [17] propose to use the joint bilateral filtering for cost aggregation as illustrated in Fig. 2.

The second issue causes staircase artifacts at slanted surfaces especially when large support windows are used. For this, Bleyer et al. [3] propose a slanted patch-matching technique, which approximates a surface in a support window by linearly varying disparities (parameterized by a disparity plane $d = au + bv + c$) instead of a constant disparity and can thus relax the fronto-parallel window bias. This approach imposes a complicated inference task of pixelwise 3D

continuous variables (a, b, c), which is solved by inference techniques explained later in a section on continuous disparity estimation.

Regularization Local methods that only rely on the matching cost term often produce inaccurate disparities due to low-feature regions or noises of matching costs. Therefore, global methods add a regularization term $R(\mathbf{D})$ in the objective function that is minimized by an optimization algorithm.

A widely adopted regularization is the truncated linear model

$$R(\mathbf{D}) = \sum_{(\mathbf{p}, \mathbf{q}) \in N} \omega_{\mathbf{pq}} \min\{\tau, |D_{\mathbf{p}} - D_{\mathbf{q}}|\}, \quad (8)$$

where N is the set of neighboring pixel pairs, $\omega_{\mathbf{pq}}$ is a contrast-sensitive weight for preserving edges, and τ is a user-defined threshold parameter for allowing depth jumps at object boundaries. Because of its simple pairwise function form, adopting this model can keep the optimization quite tractable [13]. However, it is known to have the fronto-parallel bias causing staircase artifacts at slanted surfaces [16].

A variety of regularizers have been proposed to handle the fronto-parallel bias. Woodford et al. [16] propose a second-order smoothness term, which evaluates $|D_{\mathbf{q}} - 2D_{\mathbf{p}} + D_{\mathbf{r}}|$ instead of $|D_{\mathbf{p}} - D_{\mathbf{q}}|$ for three consecutive pixels ($\mathbf{q}, \mathbf{p}, \mathbf{r}$). However, it imposes complicated optimization due to the higher-order form of the objective function and treatment of continuous disparities. Olsson et al. [10] propose a powerful curvature regularization term, which requires pixelwise continuous disparity plane estimation but allows an efficient pairwise function form. Scharstein et al. [12] propose a scheme to encode pre-estimated surface orientation priors into regularization without increasing computational costs of optimization.

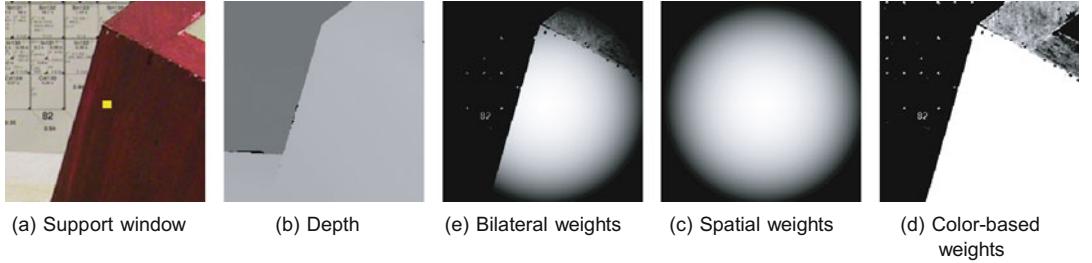

Optimization Optimization is a necessary step in global methods to minimize their objective function with pairwise or higher-order interaction terms for enforcing regularization.

When disparities are discrete variables and the objective function has only up to their pairwise interactions, then its optimization is well established [13]; we can directly apply discrete optimizers such as message-passing algorithms (belief propagation) and the expansion move algorithm using graph cuts to approximately solve the combinatorial optimization problem. A commonly used practical optimization method is the semi-global matching (SGM) [5], which has a good trade-off property between accuracy and efficiency for real-time applications. It has been shown to be a variant of message-passing techniques [4].

Continuous disparity estimation Because disparities inherently reside in a continuous space, we need to infer continuous disparities for a more accurate representation of 3D scenes.

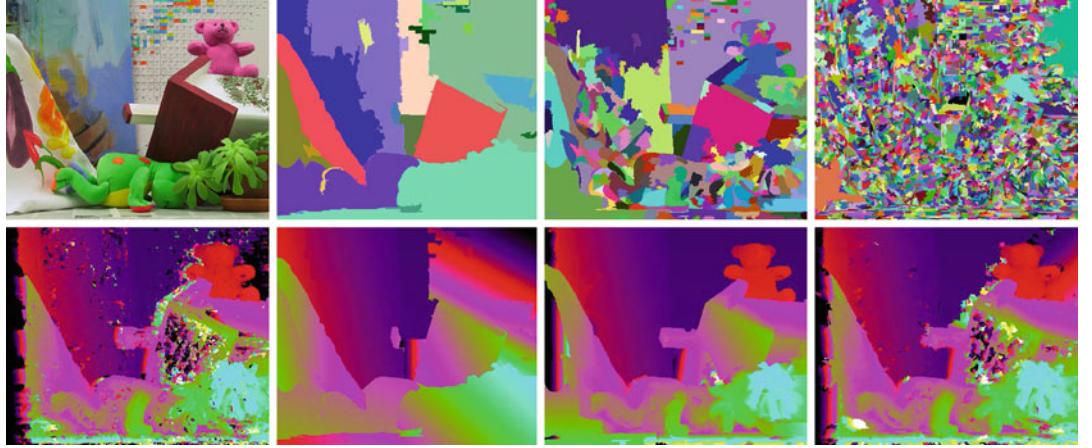

One type of approaches to continuous disparity estimation seeks continuous disparities during optimization. Since discrete optimizers cannot be directly applied for this purpose, discrete-continuous optimization strategies are often employed. For example, segment-based stereo [2] optimizes the assignment of pre-estimated disparity plane labels to each of superpixel regions, which produces continuous-valued but piecewise planar disparity maps (Note that in segment-based methods, the objective function in Eq. 6 is modified so that each node \mathbf{p} and variable $\mathbf{D}_{\mathbf{p}}$ represents a superpixel and its disparity plane assignment, respectively.). Fusion-based methods [16] fuse many continuous-valued disparity map proposals to produce a better solution by solving a combinatorial optimization task using graph cuts, where proposals are generated, e.g., by segment-based methods using various patterns of superpixels (see Fig. 3 for an illustration). PatchMatch stereo [3] estimates pixelwise continuous disparity planes using a randomized search scheme, which no longer requires pre-estimated proposals. Its variants using belief propagation [1] or graph cuts [14] further add regularization into this randomized search scheme.

Another type of approaches estimates continuous disparities as post-processing by refining

Binocular Stereo, Fig. 2 Adaptive support windows. For (a) an support window with (b) depth boundaries, the adaptive window method [17] computes (e) bilateral

support weights by combining (c) spatial weights and (d) color-based weights

Binocular Stereo, Fig. 3 Segment-based disparity map proposals for fusion. (The image courtesy of Woodford et al. [16])

initial discrete disparity estimates. Since it is usually used to refine initial disparities at integer pixels, this refinement process is often called *sub-pixel refinement*. For example, techniques based on gradient descent [8] or curve (parabola) fitting [5] are often employed.

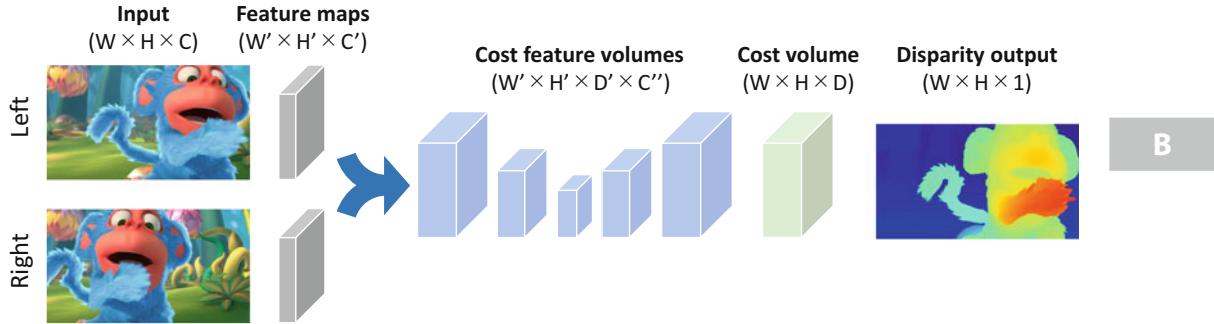

Occlusion handling Occlusion handling in binocular stereo is usually done either as post-processing using left right consistency check [3, 5] or during optimization by incorporating a occlusion model into the objective function [7, 15]. While the former approach can be adopted for both local and global methods, the latter can be only employed by global methods at the cost of producing complicated higher-order interactions in the matching cost term.

c) Learning-Based Methodologies

As an emerging trend in this field, learning-based approaches to binocular stereo have been gathering great interest. In particular, end-to-end learning approaches using deep neural networks are popular, which directly learn a mapping function f from an image pair to a disparity map as

$$\mathbf{D} = f(\mathbf{I}, \mathbf{I}'; \Theta). \quad (9)$$

The function f is implemented as convolutional neural networks (CNN), whose parameters Θ are optimized so as to minimize some loss function $\ell(\mathbf{D})$ over a large amount of training data. The loss is evaluated using ground-truth disparities in supervised learning or using a criteria similar to

Binocular Stereo, Fig. 4 Basic neural network architecture for end-to-end learning of binocular stereo

the classical objective function in Eq. 6 without using ground truth in self-supervised learning.

Such learning-based methods are often advantageous over classical methods in that they can automatically handle difficulties of stereo such as image patch distortions, illumination changes, occlusions, rectification and calibration errors, by data-driven approaches. Because computations of CNNs are massively parallelizable on GPUs, CNN based methods can perform quite efficiently even for continuous disparity inference.

Analogously to the taxonomy of classical stereo algorithms [11], we identify four stages that neural network architectures for binocular stereo often perform: feature extraction, volume construction, cost volume learning, and disparity computation and refinement. An example architecture of such neural networks is shown in Fig. 4. Based on this view, below we review existing works on learning-based methods.

Feature extraction Early works on learning-based methods use a neural network to compute stereo matching costs. MC-CNN by Zbontar and LeCun [19] extracts feature vectors from image patches and computes matching costs using the cosine distance (fast version) or fully connected layers (accurate version). Learned matching costs are then fed into classical stereo pipelines (SGM [5]) for disparity estimation. Later, this feature extraction is taken as the first stage of network architectures in end-to-end learning approaches [6, 9, 20], e.g., using feed-forward CNNs [9],

ResNet-like networks [6], spatial pyramid pooling (SSP) layers, or 2D hourglass networks [20], with the following subsequent stages.

Volume construction A seminal work by Mayer et al. [9] proposes DispNetC, which constructs a matching cost volume and regresses out a continuous disparity map for end-to-end learning. Volume construction is initially done in [9] by correlating left and traversed right feature maps, but it is later extended to concatenate feature maps [6] or combine concatenation and group-wise correlation.

Cost volume learning Kendall et al. [6] propose GC-Net, which processes a concatenation-based cost feature volume (4D tensor) by a 3D hourglass network using 3D Conv layers for cost volume learning. Zhang et al. [20] propose semi-global aggregation and local-guided aggregation layers for cost volume learning, analogously to classical techniques of SGM [5] and adaptive window-based cost aggregation [17].

Disparity computation and refinement In early works [9, 19], computing disparities is not explicitly done in classification-based methods [19] or done by treating a 3D cost volume as a 2D feature map for a scalar-map regression CNN in DispNetC [9]. Kendall et al. [6] propose the soft-argmin operator that can more effectively output a continuous disparity map from a 3D cost volume. Regressed disparity maps are often

further processed by a shallow 2D CNN for refinement.

Open Problems

Benchmarks and Datasets

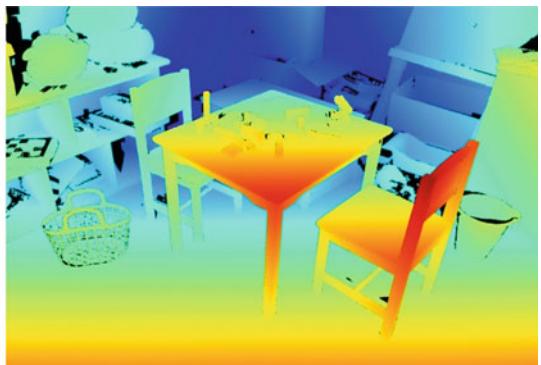

As there is an increasing demand for large-scale binocular stereo datasets for data-driven approaches, we introduce benchmarks and datasets that are popularly used in this area.

Middlebury benchmark (version 3) (<http://vision.middlebury.edu/stereo/>) provides high-resolution (1 to 6 MPix) stereo image pairs of 10 testing and 23 training indoor scenes with highly accurate dense ground-truth disparities obtained by using structured light scanning. An example is shown in Fig. 5. The benchmark is designed to contain some challenges such as different exposures or illumination conditions

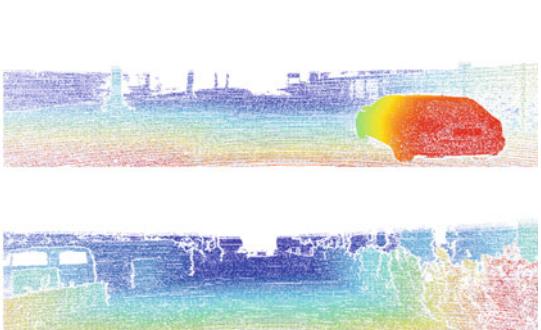

between image pairs and the presence of vertical displacements due to imperfect rectification.

KITTI 2015 benchmark (http://www.cvlibs.net/datasets/kitti/eval_scene_flow.php?benchmark=stereo) provides 200 stereo image pairs of 376×1242 pixels (0.5 MPix) for each of training and testing sets, recorded by a synchronized stereo camera mounted on a vehicle running on public roads. An example is shown in Fig. 6 (top). The training set images are provided with ground-truth disparities for background (using sparse depths measured by a LiDAR sensor) and foreground regions (using 3D CAD models of vehicles manually registered to the scenes).

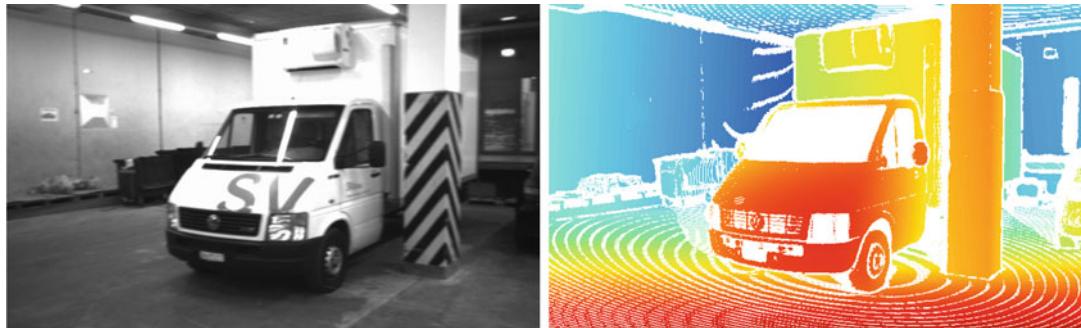

KITTI 2012 benchmark (http://www.cvlibs.net/datasets/kitti/eval_stereo_flow.php?benchmark=stereo) provides stereo image pairs of 194 training and 195 testing scenes. The images and ground-truth disparities are provided similarly to

Binocular Stereo, Fig. 5 Middlebury benchmark (an example scene image and its ground-truth disparity map)

Binocular Stereo, Fig. 6 KITTI 2015 and 2012 benchmarks

Binocular Stereo, Fig. 7 ETH3D benchmark

Binocular Stereo, Fig. 8 SceneFlow dataset

the 2015 version. An example is shown in Fig. 6 (bottom).

ETH3D benchmark (low-res two-view) (<https://www.eth3d.net>) provides 27 training and 20 testing stereo image pairs, covering both indoor and outdoor scenes. Each image has about 0.4 MPix. Training images are provided with ground-truth disparities obtained by a laser scanner. An example is shown in Fig. 7.

SceneFlow dataset (https://lmb.informatik.uni-freiburg.de/resources/datasets/SceneFlowDatasets_en.html) is a synthetic large scale dataset for neural network training. It provides stereo image pairs of totally 35,454 training and 4,370 testing scenes, where each image has 960×540 pixels (0.5 MPix), and is provided with the ground-truth disparities for all the pixels. Both sets contain randomly generated 3D scenes named *FlyingThings3D* (see Fig. 8 for an example) and the training set further contains additional *Monkaa* (see Fig. 4) and *Driving* subsets.

Definition

A blackbody is an idealized object that absorbs all electromagnetic radiation incident on it. The absorbed energy is incandescently emitted with a spectral power distribution that is a function of its temperature. It is called a blackbody partly because it appears black to the human observer when it is cold, as it emits mostly infrared radiation.

Background

Blackbody radiation, in general, stood as a major challenge to the scientists in the nineteenth century as they were pushing the limits of classical physics. Several physicists studied blackbody radiators, including Lord Rayleigh, James Jeans, Josef Stefan, Gustav Kirchhoff, Ludwig Boltzmann, Wilhelm Wien, and finally, Max Planck, who arguably broke the way for quantum physics.

Wien's approximation is used to approximately describe the spectral content of radiation from a blackbody. This approximation was first derived by Wilhelm Wien in 1893 [8]. This law was found to be accurate only for short wavelengths of emission spectra of blackbody radiators and is used today only as an approximation. Wien stated that the radiant exciteance of a blackbody may be given by

$$M_e(\lambda, T) = \frac{2\pi h\nu^3}{c^2} \exp - \frac{h\nu}{kT} \quad (1)$$

$$= \frac{2\pi hc^2}{\lambda^5} \exp - \frac{hc}{kT\lambda} \quad (2)$$

The above equation holds in the specific case when $\exp - \frac{hc}{kT\lambda} \gg 1$, which typically occurs when the wavelength is short. The work by Wien was soon replaced by the findings of Max Planck, in 1901.

Another important finding regarding blackbody radiators was made by Josef Stefan in 1879 and later formalized by Ludwig Boltzmann. Known as the *Stefan-Boltzmann law*, it states that the total radiant exciteance of a blackbody radiator is proportional to the fourth power of its absolute temperature. In other words,

$$\int_{\lambda} M_e(\lambda, T) = \sigma T^4, \quad (3)$$

where $\sigma = 5.674 \times 10^{-8} W \cdot m^{-2} \cdot K^{-4}$ is known as the Stefan-Boltzmann constant.

Max Planck, in 1901, stated a more general law, known as *Planck's radiation law*. This describes the spectral distribution of radiant exciteance M_e as a function of wavelength (These equations are often given in terms of frequencies instead of wavelength, as shown in this article. This is easily converted back and forth using $\nu \cdot \lambda = c$, where ν denotes frequency, λ the wavelength, and c the speed of light in vacuum.) λ and temperature T and is given by

$$M_e(\lambda, T) = \frac{c_1}{\lambda^5 \left[\exp \left(\frac{c_2}{\lambda T} \right) - 1 \right]} \quad (4)$$

where $c_1 = 2\pi hc^2 = 3.74183 \times 10^{-16} W \cdot m^{-2}$, $c_2 = h \cdot c/k = 1.4388 \times 10^{-2} m \cdot K$ (c is the speed of light in vacuum: $2.99792458 \times 10^8 m \cdot s^{-1}$, h is Planck's constant: $6.62606896 \times 10^{-34} J \cdot s$, k is Boltzmann's constant: $1.38065 \times 10^{-23} J \cdot K^{-1}$) [4], and the exciteance is defined in units of $W \cdot m^{-3}$ [3, 5, 6, 9].

Figure 1 shows the spectral power distribution of various blackbody radiators from 1,000 to 10,000 K, with all spectral power distributions normalized to unity at 560 nm. As the blackbody gets hotter (T increases), one can see that the red content in the spectrum reduces and the blue content increases – an indication of the color as would be seen by the human observer. Both Wien's approximation and the Stefan-Boltzmann law can be derived from Planck's law.

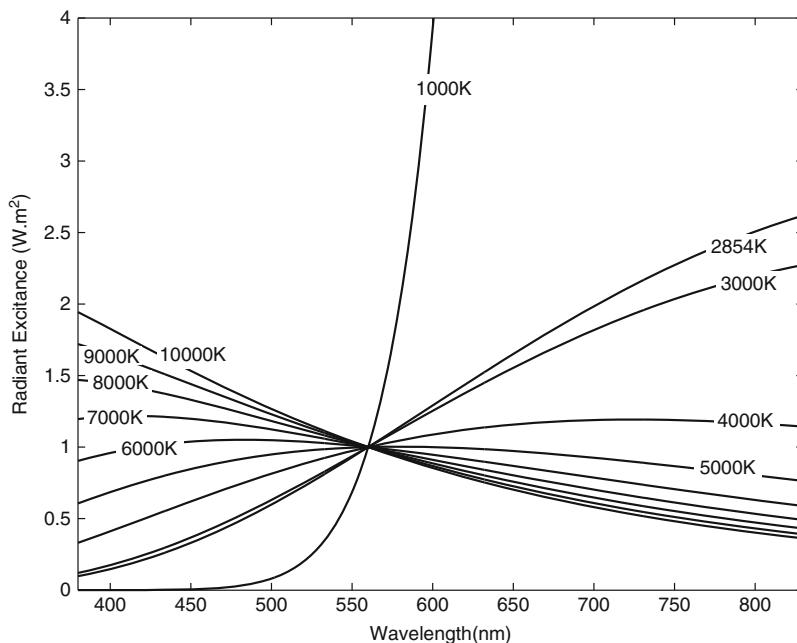

Wien's displacement law may be derived by differentiating the equation for Planck's law Eq.(4) with respect to wavelength λ and equating the result to zero to find the maximum. It states that the spectral distribution of the spectral exciteance of a blackbody reaches a maximum at a wavelength λ_m and that the product of the this maximum wavelength and the temperature of a blackbody is a constant, given by:

$$\lambda_m \cdot T = \frac{h \cdot c}{4.965114 k} = 2.8977685 \times 10^{-3} \quad (5)$$

where h denotes the Planck constant, c denotes the speed of light in vacuum, and k denotes the Boltzmann constant. The corresponding value of the spectral exciteance is given by:

$$M_{e\lambda_m} = T^5 1.286673 \times 10^{-5} Wm^{-3} \quad (6)$$

Blackbody radiators are the select few sources of illumination that match “standard illuminant” spectral power distributions – this may be seen as valid in the case of the equivalence of standard illuminant “A” and a blackbody with a temperature 2,856 K.

Definition

Blind image deconvolution is the problem of recovering a sharp image (such as that captured by an ideal pinhole camera) from a blurred and noisy one, without exact knowledge of how the image was blurred. The unknown blurring operation may result from camera motion, scene motion, defocus, or other optical aberrations.

Background

A correct photographic exposure requires a trade-off in exposure time and aperture setting. When illumination is poor, the photographer can choose to use a long exposure time or a large aperture. The first setting results in motion blur when the camera moves relative to objects in the scene during the exposure. The second setting results in out-of-focus blur for objects at depths away from the focal plane. Furthermore, these effects may be exacerbated by the user due to camera shake, incorrect focus settings, or other distortions such as atmospheric turbulence.

Blind Deconvolution, Fig. 1 Example of blind deconvolution using the method in [1] where a single image on a plane has been captured by a defocused camera.

Under local approximations, these processes can be modeled as convolution operations between an ideal “sharp” image and a *kernel* or point spread function (PSF). This PSF represents how a point of light in the scene would be imaged onto the camera’s sensor. In general, the PSF may be space-varying or depth-varying, such that each point in 3D space has its own response in the kernel function. In general, the effect of the kernel is to blur and remove information from the image (see Fig. 1).

When the PSF is known, deconvolution algorithms can be used to remove the effect of these degradations. Deconvolution may be performed using direct (e.g., Fourier-based) or iterative (e.g., gradient descent or conjugate gradient-based) algorithms. Essentially, a large linear system must be inverted to recover the sharp image, and depending on the conditioning of the matrix representing the blurring, the solution may be obtained to a greater or lesser accuracy. Observation noise also hinders exact invertibility, and for these reasons, *regularization* of the solution is required. Such regularization typically imparts prior knowledge about the expected statistics of the sharp image, such as smoothness, sparseness of its gradients, or compressibility in some domain, and is typically key to obtaining well-behaved solutions.

In practice, the PSF is rarely known from calibration, and in a practical scenario, it must be estimated from the blurred image itself. While many algorithms have been proposed to tackle the

(a) Photographed out-of-focus image (on a plane). (b) Estimated PSF. (c) Restored image. (d) Actual in-focus image for comparison

blind deconvolution problem with some success, a universal solution is not yet available, and it is still an active area of research. The difficulty owes in part to the dimensionality of the unknowns in the problem, and its extreme ill-posedness, with the potential for multiple local solutions arising from non-convex optimization problems. Progress has been made in both priors to describe images and blurs and better constrain the solution and estimation methods to better approximate the intractable inference problems.

There exist also methods to recover the sharp image from multiple observations, e.g., a blurred image and a sharp, but noisy image, or multiple blurred images. In these cases, the problem is much more well-posed, and the solution is more readily obtained; this is also closely related to the problem of super-resolution, where the sharp image is estimated at a higher resolution than the input images.

Theory

Imaging Model

The following linear spatially varying (LSV) observation model represents the formation of a general blurred image on the camera sensor:

$$g(\mathbf{x}) = \sum_{\substack{s \in S_f, \\ \text{with } (\mathbf{x}, s) \in S_H}} h(\mathbf{x}, s) f(s) + w(\mathbf{x}), \quad (1)$$

where $\mathbf{x} \in S_g$, $f(s)$ is the *true* or *sharp* image, $g(\mathbf{x})$ the observed blurred image, $w(\mathbf{x})$ is additive noise, and $h(\mathbf{x}, s)$ is the kernel function describing the blur. The position \mathbf{x} lies in the blurred image support $S_g \subset \mathbb{R}^2$, while the position s lies in the true image support $S_f \subset \mathbb{R}^2$. Notice that $S_H \subset \mathbb{R}^4$ denotes the support of the kernel h . In case the blur does not vary with position s in the true image and the depth is constant, the kernel may be reduced to a stationary PSF, $h(\mathbf{x}, s) = h(\mathbf{x} - s)$. Then the image model becomes a convolution (denoted \star):

$$g(\mathbf{x}) = [h \star f](\mathbf{x}) + w(\mathbf{x}). \quad (2)$$

With discretization and appropriate *lexicographic ordering* or raster scanning of the images into vectors, either Eq.(1) or Eq.(2) may also be expressed in matrix-vector form:

$$\mathbf{g} = \mathbf{H}\mathbf{f} + \mathbf{w}, \quad \text{or equivalently,} \quad (3)$$

$$\mathbf{g} = \mathbf{F}\mathbf{h} + \mathbf{w}. \quad (4)$$

With the spatially invariant degradation model, the matrices \mathbf{F} and \mathbf{H} acquire a special structured block form, termed block Toeplitz with Toeplitz blocks (BTTB), with constant block entries on each block diagonal and constant diagonals within each block. Sometimes these matrices are approximated as circulant, implying circular convolution of the sharp image, and then they may be diagonalized using the discrete Fourier transform (DFT), enabling fast calculations to be performed.

Probabilistic Formulation

With uncertainty in the observation model (3), it is natural to estimate the most likely solution for the sharp image using a probabilistic approach. The Bayesian framework provides a unified way to tackle such ill-posed inverse problems. Here a *likelihood* $p(\mathbf{g} | \cdot)$ is specified from the imaging model and combined with a *prior* $p(\mathbf{f}, \mathbf{h} | \cdot)$ on the image and blur to be estimated, ensuring that only plausible solutions are obtained. The resulting posterior distribution

$$\begin{aligned} p(\mathbf{f}, \mathbf{h} | \mathbf{g}, \Omega) \\ = \frac{p(\mathbf{g} | \mathbf{f}, \mathbf{h}, \Omega) p(\mathbf{f} | \Omega) p(\mathbf{h} | \Omega)}{p(\mathbf{g})} \end{aligned} \quad (5)$$

is used for inference of the unknowns, where Ω denotes *hyperparameters* of the model, such as noise variances or regularization parameters; these are usually considered known, but correctly estimating them is often critical for accurate blind deconvolution. The additive noise \mathbf{w} is commonly assumed to be Gaussian or sometimes Poisson distributed. In the independent white Gaussian noise (WGN) case with variance σ_w^2 , the distribution is $p_w(\mathbf{w}) = \mathcal{N}(\mathbf{w} | 0, \sigma_w^2 \mathbf{I})$. Thus, the likelihood of \mathbf{g} conditioned on \mathbf{h}, \mathbf{f} is given by:

$$\begin{aligned} p_G(g | f, h, \sigma_w^2) &= p_W(g - Hf) \\ &= (2\pi\sigma_w^2)^{-\frac{L_g}{2}} \exp\left[-\frac{1}{2\sigma_w^2}\|g - Hf\|^2\right], \end{aligned} \quad (6)$$

where L_g is the size of the vector g .

Bayesian Inference Methods

Due to the complexity of the chosen prior models, it may not be possible to obtain an exact analytic solution of Eq. (5). A common approximation is to compute a point estimate of the unknowns f and h via an optimization procedure. However, these estimates work well only with highly peaked distributions. With more uncertainty in the parameters, it is better to estimate the whole parameter *distribution*. Unfortunately, strategies that do so in the Bayesian framework are typically more computationally demanding [2–4]. Finally, as the estimated posterior distribution of the parameters must have a finite representation, further approximations or simulations must be introduced.

Maximum a Posteriori and Maximum Likelihood

The *maximum a posteriori* (MAP) solution is one common point estimate where it is possible to prescribe our prior knowledge about the unknowns. It is defined as the values \hat{f} , \hat{h} , and $\hat{\Omega}$ that maximize the posterior probability density (5):

$$\begin{aligned} \{\hat{f}, \hat{h}, \hat{\Omega}\}_{\text{MAP}} &= \underset{f, h, \Omega}{\operatorname{argmax}} p(g | f, h, \Omega) p(f | \Omega) \\ &\quad p(h | \Omega) p(\Omega). \end{aligned} \quad (7)$$

A very related method is *maximum likelihood* (ML), where one looks for

$$\{\hat{f}, \hat{h}, \hat{\Omega}\}_{\text{ML}} = \underset{f, h, \Omega}{\operatorname{argmax}} p(g | f, h, \Omega). \quad (8)$$

Notice that the ML method is essentially the MAP method, where the prior distributions are uniform (uninformative). Despite this equivalence, the ML is usually referred to as a non-Bayesian method. The advantage of using the MAP approach is that

we can also encode the case where parameters are entirely or partly known by using degenerate distributions (Dirac deltas), that is, $p(\Omega) = \delta(\Omega - \Omega_0)$. Then, the MAP and ML formulations become, respectively,

$$\begin{aligned} \{\hat{f}, \hat{h}\}_{\text{MAP}} &= \underset{f, h}{\operatorname{argmax}} p(g | f, h, \Omega_0) p(f | \Omega_0) \\ &\quad p(h | \Omega_0) \end{aligned} \quad (9)$$

$$\{\hat{f}, \hat{h}\}_{\text{ML}} = \underset{f, h}{\operatorname{argmax}} p(g | f, h, \Omega_0). \quad (10)$$

Moreover, this formulation allows to easily incorporate important constraints on the unknowns, e.g., that the PSF is nonnegative and that it integrates to 1, which have been shown to play a fundamental role in the solution of blind deconvolution [5].

The Bayesian framework can be used to describe several deconvolution methods and to emphasize their differences in terms of choice of likelihood, priors on the image, blur, and hyperparameters. Further differences can be found in how the maximization problem is solved.

A typical example of methods that can be formulated in the Bayesian framework is regularized approaches based on the L_2 norm. One such method is Tikhonov regularization, where a linear system is solved in least-squares sense by introducing an additional L_2 constraint on the unknowns. More in general, the blind deconvolution task is formulated as a constrained minimization where several regularization constraint terms are added.

A common choice is to always use a term in the form of $\|g - Hf\|^2$, called *data fidelity term*. The additional regularization terms encode the constraints on the unknowns. For example, one may want to impose smoothness of the image and the blur. To do so, a term that penalizes small variations of the image and the blur can be used. The regularization parameters are then used to adjust the relative importance between the data fidelity term and the regularization terms in the solution.

An important example that illustrates this procedure is [6]. In that work, the classical regularized image deconvolution formulation [7, 8] was extended to the *blind image deconvolution* (BID) case by adding regularization on the blur parameters. The problem is formulated as

$$\begin{aligned}\hat{\mathbf{f}}, \hat{\mathbf{h}} = \operatorname{argmin}_{\mathbf{f}, \mathbf{h}} & \left[\|\mathbf{g} - \mathbf{H}\mathbf{f}\|_{\mathbf{Q}_w^{-1}}^2 \right. \\ & \left. + \lambda_1 \|\mathbf{L}_f \mathbf{f}\|^2 + \lambda_2 \|\mathbf{L}_h \mathbf{h}\|^2 \right],\end{aligned}\quad (11)$$

where \mathbf{Q}_w^{-1} are local weights for the data fidelity term, λ_1 and λ_2 are the Lagrange multipliers for each constraint, and \mathbf{L}_f and \mathbf{L}_h are the regularization operators. To avoid oversmoothing the edges, each \mathbf{L} operator is the Laplacian multiplied by space-varying weights. These weights are obtained from the local image variance as in [8–11].

Alternating Minimization or Iterated Conditional Modes

One of the main difficulties in MAP is to simultaneously recover both \mathbf{f} and \mathbf{h} . The problem can be already observed in the image model Eq. (1), which is bilinear in both \mathbf{f} and \mathbf{h} . One common way to address this challenge is *alternating minimization* (AM). When applied to Eq. (11), it performs the minimization by working on one variable at a time, while the others are fixed. As a result, the minimization of Eq. (11) becomes a sequence of least-squares problems, whose solutions can be computed in closed form by solving linear systems. A related method is *iterated conditional modes* proposed by Besag [12].

Minimum Mean-Squared Error

As mentioned earlier on, the MAP estimate is only a point estimate of the whole posterior PDF. While this is not a problem when the posterior is highly peaked about the maximum, in the case of high observation noise or a broad (heavy-tailed) posterior, this estimate is likely to be unreliable (as chances of obtaining values that are different from the maximum are very likely). Indeed, in a high-dimensional Gaussian distribution, most of

the probability *mass* lies away from the probability *density* peak [13].

One way to correct for this shortcoming is to use the *minimum mean-squared error* (MMSE) estimate. The rationale is to find the optimal parameter values as those that minimize the expected mean-squared error between the estimates and the true values. This requires to compute the mean value of $p(\mathbf{f}, \mathbf{h}, \Omega | \mathbf{g})$. However, computing MMSE estimates analytically is generally difficult. A more practical solution is to use sampling-based methods (see next paragraph).

Markov Chain Monte Carlo Sampling

A general technique to perform inference is to simulate the posterior distribution in Eq. (5), by drawing samples. Provided that we have obtained enough independent samples, this strategy allows us to deal with arbitrarily complex models in high-dimensional spaces, where no analytic solution is available. *Markov chain Monte Carlo* (MCMC) sampling methods approximate the posterior distribution by the statistics of samples generated from a Markov chain. Widely used MCMC algorithms are the Metropolis-Hastings or Gibbs samplers (see, e.g., [2, 14–16]).

The samples can then be used in Monte Carlo integration to obtain point estimates or other distribution statistics. For instance, in the BID problem, the MMSE estimate of the \mathbf{f} can be readily obtained by taking the mean of the samples, $\frac{1}{n} \sum_{t=1}^n \mathbf{f}^{(t)}$.

MCMC can provide better solutions than AM or any other method. However, there are some limitations. First, they are very computationally intensive in comparison to the point estimate methods. Second, convergence to the posterior can be theoretically guaranteed, but in practice, it can be hard to tell when this has occurred, and it may require a long time to explore the parameter space.

Marginalizing Hidden Variables

In the discussion so far, the aim was to recover all the unknowns. However, in most cases, one is interested in recovering only the sharp image \mathbf{f} . This leads to another approach to the BID problem where undesired unknowns are marginalized

and inference is performed on the remaining variables (i.e., a subset of \mathbf{f} , \mathbf{h} , and $\boldsymbol{\Omega}$). Therefore, one can approach the BID inference problem in two steps. First, one can calculate

$$\hat{\mathbf{h}}, \hat{\boldsymbol{\Omega}} = \underset{\mathbf{h}, \boldsymbol{\Omega}}{\operatorname{argmax}} \int_{\mathbf{f}} p(\mathbf{g} | \boldsymbol{\Omega}, \mathbf{f}, \mathbf{h}) p(\mathbf{f}, \mathbf{h} | \boldsymbol{\Omega}) p(\boldsymbol{\Omega}) d\mathbf{f} \quad (12)$$

and, second, one selects the sharp image

$$\hat{\mathbf{f}}|_{\hat{\mathbf{h}}, \hat{\boldsymbol{\Omega}}} = \underset{\mathbf{f}}{\operatorname{argmax}} p(\mathbf{g} | \hat{\boldsymbol{\Omega}}, \mathbf{f}, \hat{\mathbf{h}}) p(\mathbf{f} | \hat{\boldsymbol{\Omega}}). \quad (13)$$

Alternatively, one can also marginalize \mathbf{h} and $\boldsymbol{\Omega}$ to obtain

$$\hat{\mathbf{f}} = \underset{\mathbf{f}}{\operatorname{argmax}} \int_{\mathbf{h}, \boldsymbol{\Omega}} p(\mathbf{g} | \boldsymbol{\Omega}, \mathbf{f}, \mathbf{h}) p(\mathbf{f}, \mathbf{h} | \boldsymbol{\Omega}) p(\boldsymbol{\Omega}) d\mathbf{h} \cdot d\boldsymbol{\Omega}. \quad (14)$$

Deconvolution Under a Gaussian Prior (MAP)

If the PSF is known and assuming a Gaussian prior $p(\mathbf{f} | \boldsymbol{\Sigma}_f) = \mathcal{N}(\mathbf{f} | 0, \boldsymbol{\Sigma}_f)$ for \mathbf{f} , with a given covariance matrix $\boldsymbol{\Sigma}_f$, the posterior for \mathbf{f} is found as

$$p(\mathbf{f} | \mathbf{g}) \propto p(\mathbf{g} | \mathbf{f}) p(\mathbf{f} | \boldsymbol{\Sigma}_f) \quad (15)$$

$$\begin{aligned} &\propto \exp \left(-\frac{1}{2} [\mathbf{f}^T (\sigma_w^{-2} \mathbf{H}^T \mathbf{H} + \boldsymbol{\Sigma}_f^{-1}) \right. \\ &\quad \left. \mathbf{f} - 2\mathbf{f}^T (\sigma_w^{-2} \mathbf{H}^T \mathbf{g}) + \sigma_w^{-2} \mathbf{g}^T \mathbf{g}] \right) \end{aligned} \quad (16)$$

which is a Gaussian

$$p(\mathbf{f} | \mathbf{g}) \propto \mathcal{N}(\mathbf{f} | \boldsymbol{\mu}_{\hat{\mathbf{f}}}, \boldsymbol{\Sigma}_{\hat{\mathbf{f}}}) \quad (17)$$

$$\begin{aligned} &\propto \exp \left(-\frac{1}{2} [\mathbf{f}^T \boldsymbol{\Sigma}_{\hat{\mathbf{f}}}^{-1} \mathbf{f} \right. \\ &\quad \left. - 2\mathbf{f}^T \boldsymbol{\Sigma}_{\hat{\mathbf{f}}}^{-1} \boldsymbol{\mu}_{\hat{\mathbf{f}}} + \boldsymbol{\mu}_{\hat{\mathbf{f}}}^T \boldsymbol{\Sigma}_{\hat{\mathbf{f}}}^{-1} \boldsymbol{\mu}_{\hat{\mathbf{f}}}] \right). \end{aligned} \quad (18)$$

By comparing Eq. (16) to Eq. (18), we find that the parameters are given as

$$\boldsymbol{\Sigma}_{\hat{\mathbf{f}}}^{-1} = \sigma_w^{-2} \mathbf{H}^T \mathbf{H} + \boldsymbol{\Sigma}_f^{-1} \quad (19)$$

$$\boldsymbol{\mu}_{\hat{\mathbf{f}}} = \boldsymbol{\Sigma}_{\hat{\mathbf{f}}} (\sigma_w^{-2} \mathbf{H}^T \mathbf{g}). \quad (20)$$

The mean of this distribution, which is also the maximum, is just

$$\hat{\mathbf{f}} = \boldsymbol{\mu}_{\hat{\mathbf{f}}} = (\mathbf{H}^T \mathbf{H} + \sigma_w^2 \boldsymbol{\Sigma}_f^{-1})^{-1} \mathbf{H}^T \mathbf{g}. \quad (21)$$

In practice, as solving the above equation involves inverting a large linear system, one employs iterative methods.

B

Application

Blind deconvolution methods are commonly used to restore images that have been distorted by motion blur, out-of-focus blur, and turbulence. As these methods provide an estimate of blur, other uses include digital refocusing, that is, digitally changing the focus setting of a camera after the snapshot, changing the camera bokeh, and obtaining a 3D model of the scene (from the out-of-focus blur).

Definition

Blur estimation is a process to estimate the blur kernel (a.k.a. point spread function) from blurry images so that it can facilitate the high-quality sharp image restoration or evaluate the quality of images.

Background

Blur usually occurs when taking a photo with long exposure time or with wrong focal length. This is because the lights captured for a pixel are mixed with the lights captured for the other pixels within a local neighborhood during the exposure period. Such effect is modeled by the point spread function which describes how the lights are mixed during the exposure period.

In motion blur, the point spread function describes the relative motions between the camera and the scene. In the defocus blur, the point spread function is related to the distance of a scene point from the focal plane of the camera. Blur often leads to information loss, and the resulting image blur is usually undesirable. Estimating blur from blurry images is an important step for the restoration of high-quality images.

Theory

The Image Formation Model

Mathematically, the blur process can be modeled by:

$$B(x) = \sum_{y \in \mathcal{N}(x)} I(x - y)k_x(y) + n(x), \quad (1)$$

where B denotes a blurry image, I denotes a sharp image, k_x denotes the blur kernel at pixel x , n denotes image noise, and $\mathcal{N}(x)$ denotes a

local neighborhood centered at pixel x . If the blur kernel k_x is spatially variant, the blur model (1) is usually used to approximate those cases when the camera exhibits rotational motion or the scene has large depth disparity or contains a moving object during exposure period.

While the blur kernel is spatially varying, the variation of the blur kernel is spatially smooth. Lots of previous works simplify the problem by assuming that the blur kernel is spatially invariant to model the camera motion blur. Thus, the blur model will reduce to a convolution operation:

$$B = I \otimes k + n, \quad (2)$$

where \otimes denotes the convolution operator.

As (2) cannot effectively model the blur caused by camera rotation, several methods [1,2] assume that the blurry image is the sum of lots projectively transformed versions of sharp image:

$$B(x) = \sum_{\theta} I(\mathbf{H}_{\theta}x)k(\theta) + n(x), \quad (3)$$

where \mathbf{H}_{θ} denotes the homography induced at the camera pose θ .

Methodology

Estimating a blur kernel from a blurry image is highly ill-posed because only blurry image B is available and many different pairs of I and k give rise to the same B . To solve this problem, existing algorithms usually explore additional information of blur kernels and sharp images and can be categorized into hardware-based, prior-based, and data driven-based methods.

Hardware-based methods If the effect of blur is caused by the internal camera setting, such as lens aberration, the blur kernel can be calibrated.

For example, the simplest method is to capture an image of a spotlight in a dark room. When there is no blur, the image of the captured spotlight (ideally) should occupy only one pixel. When there is blur, the image of the captured spotlight will occupy more than one pixel, and the shape of the recorded spotlight is the blur kernel. Similarly, for the defocus blur, the focal length of

the camera can be adjusted in order to obtain a set of defocus blur kernel [3].

For the motion blur, Ben-Ezra and Nayer [4] and Tai et al. [5] propose a hybrid camera system which estimates the blur kernel through integration of optical flows from the auxiliary high-speed camera. In [6], Levin et al. develop prototype camera to estimate spatially variant blur kernels. The inertia sensors of cameras have also been explored to facilitate the blur kernel estimation [7–9].

Another line of research tackles blur kernel estimation by exploring additional information. For example, the noisy/blurry image pair by Yuan et al. [10] and two consecutively captured blurred images by Chen et al. [11]. Using specific devices or additional information is able to simplify the blur kernel estimation process and achieves favorable performance. However, designing specific devices or experimental settings is often expensive.

Prior-based methods As blur kernel estimation is ill-posed, lots of methods explore the kinds of priors to make the problem well-posed. Chan and Wang [12] develop the total variation regularization to constrain both blur kernels and sharp images. This method is further explored by [13]. Fergus et al. [14] and Whyte et al. [2] propose a multi-scale variational Bayesian framework to estimate the uniform blur kernels and non-uniform blur kernels, respectively. Shan et al. [15] use a parametric model to model the heavy-tail property of image gradients and develop an alternating optimization method to estimate the blur kernel. Levin et al. [16] show that the variational Bayesian inference method [14] is able to avoid trivial solutions, while naive maximum a posterior based methods may not [15]. They propose an improved maximum a posterior for the blur kernel estimation [16]. In addition, as the variational Bayesian approach is computationally expensive, Levin et al. [17] propose an efficient marginal likelihood optimization for blur kernel estimation.

As the maximum a posterior based methods are likely to converge to trivial solution [16], some edge prediction-based methods [18–21]

have been proposed for blur kernel estimation. As one of the earliest edge-based approach, Jia [22] use alpha mattes to help blur kernel estimation. In [23], Dai and Wu propose a new motion blur constraint based on alpha matte. This constraint is further extended by [24] for the motion blur estimation in dynamic scenes. In addition, the alpha mattes have been integrated into the maximum a posterior-based deblurring framework to help blur estimation in depth aware deblurring [25] and dynamic scenes deblurring [26] problems.

Cho and Lee [18] develop an effective edge-prediction method using heuristic filters and the blur estimation can be solved efficiently. Xu and Jia [19] develop an edge selection method to remove small-scale edges for blur kernel estimation. In [20], Sun et al. use a patch prior to refine edges for blur kernel estimation. As demonstrated by [27], these edge prediction-based methods have been proven to be effective in real cases.

To overcome the limitations of the naive maximum a posterior-based methods and avoid the heuristic edge-prediction step, some effective image priors have also been introduced for blur kernel estimation, e.g., normalized sparsity prior [28], L0-regularized prior [29–31], internal patch recurrence [32], sparsity of dark channel prior [33], blur normalization [34], logarithmic image prior [35], and so on. Lai et al. [36] evaluate the performance of some aforementioned algorithms and show that using the intensity information is able to help blur kernel estimation [31].

Data driven-based methods The data driven approach is developed for blur estimation. In [37], Zuo et al. develop a discriminative learning approach to adaptive learn priors for blur kernel estimation. Motivated by the success of shrinkage fields in image restoration [38], Xiao et al. [39] extend [38] to blur kernel estimation in the text image deblurring. The deep learning approach is also employed to estimate blur kernels. In [40], Sun et al. develop a deep convolutional neural network to estimate the probabilistic distribution of motion blur at the patch level. Gong et al. [41] directly estimate the motion flow from the blurred image through a fully convolutional deep neural

network and use the estimated optical flow as the motion blur. Schuler et al. [42] and Pan et al. [43] develop deep convolutional neural networks to learn the key components that are used for blur kernel estimation. In spite of achieving decent results, the generalization ability of these methods is worth further investigation.

Application

Blur estimation has been an active research effort in the vision and graphics communities within the last decade due to its application on deblurring. Since blur is a common artifact in imaging system, its applications range from astronomy telescope to satellite imaging, medical imaging, and the common consumer-level cameras or mobile phones. In addition to deblurring, the estimated point spread function can also be used to evaluate image quality and to identify moving objects from a scene.

Definition

Boosting is an ensemble meta-learning algorithm for supervised learning such as classification and regression problems. In the boosting algorithm, weak hypotheses are sequentially learned at each stage and aggregated into a single highly accurate hypothesis.

Background

Boosting is an important branch of ensemble learning in machine learning. In the paradigm of ensemble learning, many hypotheses learned from observed samples are aggregated into a single accurate hypothesis. The ensemble learning includes popular learning methods such as bagging and random forest as well as boosting. Boosting is, however, thought of as one of the most promising ensemble methods for classification and regression problems.

The study of boosting has started from the following question: Is it possible to boost “weak learner” into “strong learner”? which was given by Kearns and Valiant in 1988. The weak learner intuitively denotes a learning algorithm that yields a classifier with prediction accuracy better than the coin flip, and the strong learner produces a high accurate classifier. Two years later, Schapire cracked this conjecture by proposing “boosting by filtering” [1] in binary classification problems. After Schapire’s pioneering work, some boosting algorithms were proposed by some researchers. In 1997, eventually, Freund and Schapire proposed Adaboost as an efficient online learning algorithm with weighting sampling scheme [2]. Soon after the appearance of Adaboost, statisticians gave an intuitive interpretation to Adaboost [3], i.e., Adaboost is regraded as an optimization algorithm to find an approximate maximum likelihood estimator using generalized additive models. This accessible interpretation had opened the door to the flood of boosting-like learning algorithms and wide applications to the analysis of real-world data.

Let us introduce the problem setup. The purpose of statistical learning is to produce a hypothesis $f(\mathbf{x})$ based on samples consisting of input-output pairs $S = ((\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n))$. In binary classification problems, the hypothesis is trained such that the sign of $f(\mathbf{x}_i)$ matches the binary output $y_i \in \{+1, -1\}$ for most samples. In regression problems, $f(\mathbf{x}_i)$ should approximate the real-valued output $y_i \in \mathbb{R}$ to achieve highly accurate prediction.

Algorithm

In this section we introduce boosting algorithms according to [4]. The boosting algorithm constructs the hypothesis f_T by the linear combination of T weak hypotheses, $h_1(\mathbf{x}), \dots, h_T(\mathbf{x}) \in \mathcal{H}$, where \mathcal{H} is a set of weak hypotheses. Commonly used weak hypotheses are the decision stumps and regression trees implemented by rpart and CART [5]. The hypothesis is updated in the sequel manner, i.e., f_T is determined from f_{T-1} and h_T . Weak hypotheses are chosen so that a loss function is approximately minimized.

Let us define $\ell_y(f(\mathbf{x})) = \ell(f(\mathbf{x}), y)$ as the loss function of the hypothesis $f(\mathbf{x})$ on the sample (\mathbf{x}, y) , and let the empirical loss be $\widehat{L}(f) = \frac{1}{n} \sum_{i=1}^n \ell_{y_i}(f(\mathbf{x}_i))$. In binary classification problems, $y_i f(\mathbf{x}_i)$ should take a large value. Thus, the logistic loss $\ell_y(f) = \log(1 + e^{-yf})$ or the exponential loss $\ell_y(f) = e^{-yf}$ is commonly used. In multiclass classification, the vector-valued hypothesis and the corresponding logistic loss are used. For regression problems, the squared error $\ell_y(f) = (y - f)^2$ is the standard choice. The

detailed formulation is provided in Section 4.6 of [4]. Taylor expansion of the empirical loss $\widehat{L}(f + \alpha h)$ for $\alpha \geq 0$ is given by j

$$\widehat{L}(f + \alpha h) = \widehat{L}(f) - \frac{\alpha}{n} \sum_{i=1}^n d_i h(\mathbf{x}_i) + o(\alpha),$$

where the weight d_i is defined as the negative derivative $-\ell'_{y_i}(f(\mathbf{x}_i))$. From the above expansion, a preferable weak hypothesis h is given by the minimizer of the second term. Once the preferable hypothesis h is determined, the coefficient α is found by solving the one-dimensional problem $\min_{\alpha \geq 0} \widehat{L}(f + \alpha h)$. This is the generic boosting algorithm. The learning algorithm of weak hypothesis over \mathcal{H} is denoted as $\text{WeakLearn}_{\mathcal{H}}$. For the input-output pairs $S = ((\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n))$ with the weight $\mathbf{d} = (d_1, \dots, d_n)$, $\text{WeakLearn}_{\mathcal{H}}$ is regarded as the function mapping to \mathcal{H} , i.e., $\text{WeakLearn}_{\mathcal{H}}(S, \mathbf{d}) \in \mathcal{H}$. The generic algorithm of the gradient boosting is shown in Algorithm 1.

Some examples of loss functions, hypotheses sets, and WeakLearn are shown below.

Adaboost The problem is the binary classification. For $\mathcal{H} \subset \{h : \mathcal{X} \rightarrow \{+1, -1\}\}$, $\ell_y(f) = e^{-yf}$ and $d_i = y_i e^{-y_i f(\mathbf{x}_i)}$, the equality

$$\sum_{i=1}^n d_i h(\mathbf{x}_i) = \sum_{i=1}^n |d_i| (1 - 2 \cdot \mathbf{1}[h(\mathbf{x}_i) \neq y_i])$$

holds, where $\mathbf{1}[\cdot]$ is the indicator function. WeakLearn is the learning algorithm with weighted misclassification error:

Algorithm 1 Boosting with $\text{WeakLearn}_{\mathcal{H}}$

Require: input-output paired samples $S = ((\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n))$

- 1: $f_0 = 0$
- 2: **for** $t = 1$ to T **do**
- 3: $d_i = -\ell'_{y_i}(f_{t-1}(\mathbf{x}_i))$, $i = 1, \dots, n$ and $\mathbf{d} = (d_1, \dots, d_n)$.
- 4: $h_t = \text{WeakLearn}_{\mathcal{H}}(S, \mathbf{d})$
- 5: $\alpha_t = \operatorname{argmin}_{\alpha \geq 0} \widehat{L}(f_{t-1} + \alpha h_t)$
- 6: $f_t = f_{t-1} + \alpha_t h_t$

▷ Initialization

$$\begin{aligned} \text{WeakLearn}_{\mathcal{H}}(S, \mathbf{d}) \\ = \operatorname{argmin}_{h \in \mathcal{H}} \sum_{i=1}^n |d_i| \cdot \mathbf{1}[h(\mathbf{x}_i) \neq y_i]. \end{aligned}$$

The decision trees or decision stumps, i.e., decision trees with depth one, are often used as \mathcal{H} .

Gradient boost Gradient boost is applicable to both classification and regression problems. Let us define $\mathcal{H} \subset \{h : \mathcal{X} \rightarrow \mathbb{R}\}$ and $d_i = -\ell'_{y_i}(f(\mathbf{x}_i))$. WeakLearn is defined as

$$\text{WeakLearn}_{\mathcal{H}}(S, \mathbf{d}) = \operatorname{argmin}_{h \in \mathcal{H}} \sum_{i=1}^n (h(\mathbf{x}_i) - d_i)^2.$$

Note that the weak hypothesis $h(\mathbf{x}_i)$ that approximates d_i over all samples maximizes $\sum_{i=1}^n d_i h(\mathbf{x}_i)$ under the norm constraint. One can incorporate the regularization term to the above mean squared error. The regression trees is used as \mathcal{H} .

Implementation: Gradient Boosted Decision Trees

An algorithmic bottleneck of boosting is to find a weak hypothesis. A straightforward method searches over all hypotheses in \mathcal{H} , which takes $O(|\mathcal{H}|n)$, which is prohibitive when the set \mathcal{H} is exponentially large, e.g., the set of all decision trees with fixed size.

In this section we introduce XGBoost [6] which is an efficient implementation of the gradient boosted regression tree (GBRT). Learning algorithm to learn weak hypotheses is implemented by the decision tree,

$$h_w(\mathbf{x}) = \sum_{u=1}^U w_u \mathbf{1}[\mathbf{x} \in \mathcal{X}_u],$$

where $\{\mathcal{X}_u; u = 1, \dots, U\}$ is the partition of the domain $\mathcal{X} = \mathbb{R}^d$ and w_u is the prediction value of the output at each region \mathcal{X}_u . To learn the decision tree, the loss function $\ell_y(\hat{y})$ with the regularization term $\lambda \sum_u w_u^2 / 2$ is minimized. Let

us define $f_T = f_{T-1} + h$ and $\hat{y}_i = y_i - f_{T-1}(\mathbf{x}_i)$. Taylor expansion of the regularized loss $R(w) := \hat{L}(f_{T-1} + h_w) + \frac{\lambda}{2} \sum_u w_u^2$ yields

$$\begin{aligned} R(w) &\approx \sum_i \left(\ell_{y_i}(\hat{y}_i) + \ell'_{y_i}(\hat{y}_i)h(\mathbf{x}_i) \right. \\ &\quad \left. + \frac{1}{2} \ell''_{y_i}(\hat{y}_i)h(\mathbf{x}_i)^2 \right) + \frac{\lambda}{2} \sum_u w_u^2 \\ &= \sum_u \left(r_u w_u + \frac{s_u + \lambda}{2} w_u^2 \right) + \sum_i \ell_{y_i}(\hat{y}_i), \end{aligned}$$

where $r_u = \sum_{i \in k\text{-th leaf}} \ell'_{y_i}(\hat{y}_i)$, $s_u = \sum_{i \in k\text{-th leaf}} \ell'_{y_i}(\hat{y}_i)$. Hence, the optimal prediction value at each region is $w_u^* = -r_u/(s_u + \lambda)$. Additional regularization term such as $\lambda' U$, $\lambda' > 0$ works to determine the size of the decision tree. Concerning the partition of the domain, the one that minimizes $R(w^*)$ is preferable. Instead of searching infinite possible partitions, one can grow the tree greedily; (i) start from root node, (ii) each leaf is split so as to maximize the gain, i.e., the change of objective $R(w^*)$ by adding the split.

For high-dimensional large-scale data, the XGBoost is still unsatisfactory. The time-consuming part is the learning of decision trees. To reduce the computational cost, the weighted subsampling and exclusive feature bundling are implemented in the LightGBM [7]. Besides LightGBM, efficient implementation of WeakLearn is possible when \mathcal{H} is intervals, bookean conjunctions [8], subgraphs for graph instances [9, 10], and substrings for text instances [11].

Theory: Generalization Error

This section describes generalization bounds related to boosting for binary classification problems. The generalization ability of boosting can be explained in terms of the “margin” of the combined hypothesis. Suppose that $\mathcal{H} \subseteq \{h : \mathcal{X} \rightarrow [-1, 1]\}$ be a finite set of weak hypotheses. For the coefficient $\alpha \in \mathbb{R}^{|\mathcal{H}|}$ with the 1-norm $\|\alpha\|_1 = \sum_h |\alpha_h|$, the margin of a combined hypothesis $f_\alpha(\mathbf{x}) = \sum_{h \in \mathcal{H}} \alpha_h h(\mathbf{x})$

on an input-output pair $(\mathbf{x}, y) \in \mathcal{X} \times \{-1, 1\}$ is defined by

$$\frac{y \sum_{h \in \mathcal{H}} \alpha_h h(\mathbf{x})}{\|\boldsymbol{\alpha}\|_1}.$$

When $\|\boldsymbol{\alpha}\|_1 = 1$, the margin is given by $y f_{\boldsymbol{\alpha}}(\mathbf{x})$.

The margin has the geometric interpretation. Given the hypothesis $f_{\boldsymbol{\alpha}} = \sum_{h \in \mathcal{H}} \alpha_h h$, the label prediction of \mathbf{x} is given by +1 (resp. -1) when $\sum_h \alpha_h h(\mathbf{x}) > 0$ (resp. $\sum_h \alpha_h h(\mathbf{x}) < 0$) holds. Hence, the prediction boundary is the hyperplane $\{(g_h)_{h \in \mathcal{H}} \mid \sum_h \alpha_h g_h = 0\}$ in $\mathbb{R}^{|\mathcal{H}|}$. Then, the absolute value of the margin on the input-output pair (\mathbf{x}, y) , i.e., $|f_{\boldsymbol{\alpha}}(\mathbf{x})|/\|\boldsymbol{\alpha}\|_1$, corresponds to the ∞ -norm distance from the point $(h(\mathbf{x}))_{h \in \mathcal{H}} \in \mathbb{R}^{|\mathcal{H}|}$ to the decision boundary. Note that, for SVMs, the margin is defined in terms of 2-norm distance (Euclidean distance). See, e.g., [12] for more details.

We discuss the relation between the margin and the generalization performances of combined classifiers in the framework of the statistical learning theory. The generalization error of a combined classifier $f_{\boldsymbol{\alpha}}$ is defined as

$$\Pr_{\mathcal{D}}[\text{sign}(f_{\boldsymbol{\alpha}}(\mathbf{x})) \neq y] = \Pr_{\mathcal{D}}\{y f_{\boldsymbol{\alpha}}(\mathbf{x}) < 0\},$$

i.e., the probability that $f_{\boldsymbol{\alpha}}$ misclassifies an instance \mathbf{x} randomly drawn from unknown distribution \mathcal{D} over $\mathcal{X} \times \{-1, 1\}$.

Theorem 1 (Margin-based generalization bound [13–15]) Let us define S as n input-output pairs $S = ((\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)) \in (\mathcal{X} \times \{-1, 1\})^n$ that are independently and identically distributed from \mathcal{D} . Fix $\rho > 0$. Then, for any δ ($0 < \delta < 1$) with probability at least $1 - \delta$ over the samples, for any combined classifier $f_{\boldsymbol{\alpha}}$ such that $\|\boldsymbol{\alpha}\|_1 = 1$, it holds that

$$\Pr_{\mathcal{D}}\{y f_{\boldsymbol{\alpha}}(\mathbf{x}) < 0\} \leq \Pr_S\{y_i f_{\boldsymbol{\alpha}}(\mathbf{x}_i) < \rho\} + O\left(\sqrt{\frac{\log(|\mathcal{H}|) \log(n/|\mathcal{H}|)}{\rho^2 n}} + \sqrt{\frac{\log(1/\delta)}{n}}\right),$$

where $\Pr_S\{y_i f_{\boldsymbol{\alpha}}(\mathbf{x}_i) < \rho\}$ is the ratio of samples in S for which $f_{\boldsymbol{\alpha}}$ has margin less than ρ .

The right-hand side of the bound becomes small when $\Pr_S\{y_i f_{\boldsymbol{\alpha}}(\mathbf{x}_i) < \rho\}$ is small for large ρ . In other words, if the combined classifier has large margin on S , its generalization error is small with high probability. As shown in [13], aggregated hypotheses produced by Adaboost have such a property. Even when the size of the class \mathcal{H} is infinite, the bound above holds by replacing the term $\log |\mathcal{H}|$ with the VC dimension. For details, see, e.g., Mohri et al. [15].

B

Theory: Regularization

The margin-based generalization bounds motivate the following optimization problem:

$$\max_{\boldsymbol{\alpha}, \rho, \xi} \rho - \frac{1}{v} \sum_{i=1}^n \xi_i \quad (1)$$

sub. to

$$\begin{aligned} y_i \sum_{h \in \mathcal{H}} \alpha_h h(\mathbf{x}_i) &\geq \rho - \xi_i \quad (i = 1, \dots, n), \\ \sum_{h \in \mathcal{H}} \alpha_h &= 1, \quad \alpha_h \geq 0 \quad (h \in \mathcal{H}). \end{aligned}$$

The problem is called the soft margin optimization problem, which is about finding a convex combination of weak hypotheses by directly maximizing the margin on samples while allowing to have lower margins for some samples. The parameter v is fixed beforehand within the range $[1, n]$. Intuitively, the parameter v specifies the maximum number of samples for which one gives up to have large margins. More precise meaning will be explained later. Since the soft margin optimization problem is a linear programming problem, the following dual problem has the same optimal value,

$$\min_{d, \gamma} \gamma \quad (2)$$

sub. to

$$\sum_{i=1}^n y_i d_i h(\mathbf{x}_i) \leq \gamma \quad (\text{for } h \in \mathcal{H})$$

$$\sum_{i=1}^n d_i = 1, 0 \leq d_i \leq \frac{1}{\nu} \text{ (for } i = 1, \dots, n).$$

We define the edge of the weak hypothesis $h \in \mathcal{H}$ with respect to a distribution \mathbf{d} over the sample set S as $\sum_{i=1}^n y_i d_i h(x_i)$. The edge of h w.r.t. \mathbf{d} can be viewed as the weighted accuracy (whose range is $[-1, 1]$). The dual problem (2) is more intuitive. Note that the dual problem has a constraint that the edge of each weak hypothesis in \mathcal{H} to be less than γ w.r.t. the distribution. So, the dual problem is viewed as finding the “hardest” distribution so that the maximum edge w.r.t. the distribution is minimized. In addition, the dual problem has another constraints that $d_i \leq 1/\nu$. These constraints ensure that the obtained distribution does not put too much weight on a particular sample.

According to the KKT optimality conditions, the optimal solutions $(\alpha^*, \xi^*, \rho^*)$ and (\mathbf{d}^*, γ^*) satisfy

$$\begin{aligned} \alpha_h^*(\gamma^* - \sum_{i=1}^n y_i d_i^* h(x_i)) &= 0, \\ \alpha_h^* \geq 0, \sum_{i=1}^n y_i d_i^* h(x_i) &\leq \gamma^*, \\ d_i^*(y_i \sum_{h \in \mathcal{H}} \alpha_h^* h(x_i) - \rho^*) &= 0, \\ d_i^* \geq 0, y_i \sum_{h \in \mathcal{H}} \alpha_h^* h(x_i) &\geq \rho^* - \xi_i^*, \\ \xi_i^*(1/\nu - d_i^*) &= 0, \quad \xi_i^* \geq 0, \quad d_i^* \leq 1/\nu. \end{aligned}$$

These conditions imply that (i) if the edge of h on the distribution \mathbf{d}^* is less than γ^* , then its coefficient α_h^* is zero. (ii) If the final hypothesis f_{α^*} has margin larger than ρ^* on the sample (x_i, y_i) , then the corresponding weight d_i^* is zero. (iii) If $\xi_i^* > 0$, then $d_i^* = 1/\nu$. In particular, (iii) further implies that the number of samples whose margins are less than ρ^* is at most ν . This property makes the parameter setting of ν intuitive.

These characterizations of the optimal solution mean that, to solve the problem,

some samples with non-zero weights or some weak hypotheses with non-zero coefficients are sufficient. This motivates to solve smaller LP subproblems repeatedly by adding seemingly relevant hypotheses/samples, since in general, it is often time-consuming to solve large-scale soft margin optimization problems by standard LP solvers.

The LPBoost [16] in Algorithm 2 is an algorithm which approximately solves the soft margin optimization problem (1) by repeatedly solving the subproblems. Like standard boosting algorithms, the LPBoost assumes a subroutine which, when given a distribution \mathbf{d} over the sample set S , outputs a hypothesis $h \in \mathcal{H}$, we call WeakLearn. When \mathcal{H} is moderately large, e.g., a set of decision stumps, so that exhaustive search over \mathcal{H} is acceptable, let us define WeakLearn by

$$\text{WeakLearn}_{\mathcal{H}}(S, \mathbf{d}) = \arg \max_{h \in \mathcal{H}} \sum_{i=1}^n y_i d_i h(x_i). \quad (3)$$

This is nothing but the learning method with weighted misclassification rate. In some cases where the set \mathcal{H} is large such as decision trees or neural networks, however, the optimization problem (3) cannot be solved exactly. Suppose that WeakLearn returns a weak hypothesis whose edge is larger than some $\gamma > 0$ for any input distribution \mathbf{d} . Under this weaker assumption, it is possible to obtain a solution to (1) whose objective value is at least $\gamma - \varepsilon$ (see, e.g., [16–18] for the details).

LPBoost is often faster than solving the soft margin problem once by LP solvers. However, there is no known iteration bound for LPBoost (except the trivial upper bound $|\mathcal{H}|$). Moreover, in the worst case, it requires $\Omega(n/\varepsilon)$ iterations to find an ε -approximate solution [17]. The Entropy Regularized LPBoost [18], a modification of LPBoost where the objective contains an entropic regularization term, has an $O(\log n/\varepsilon^2)$ iteration bound. On the other hand, one has to solve an entropy maximization problem rather than LP at each trial, which requires more time than LP.

Algorithm 2 LPBoost

Input: Training samples $S = ((\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)) \in \mathcal{X} \times \{+1, -1\}$.

- 1: Let \mathbf{d}_1 be the uniform distribution over S and $\gamma_1 = -1$.
- 2: **for** $t = 1$ to ... **do**
- 3: $h_t = \text{WeakLearn}_{\mathcal{H}}(S, \mathbf{d}_t)$
- 4: Let $\hat{\gamma}_t = \sum_{i=1}^n y_i d_i h_t(\mathbf{x}_i)$.
- 5: **If** $\gamma_t > \hat{\gamma}_t - \varepsilon$ **then** $T = t - 1$ and break.
- 6: Solve the dual problem with $\mathcal{H}_t = \{h_1, \dots, h_t\}$:

$$(\mathbf{d}_{t+1}, \gamma_{t+1}) = \arg \max_{\mathbf{d}, \gamma} \gamma \quad (4)$$

sub. to

$$\sum_{i=1}^n y_i d_i h_t(\mathbf{x}_i) \leq \gamma \quad (\text{for } t = 1, \dots, T)$$

$$\sum_{i=1}^n d_i = 1, 0 \leq d_i \leq \frac{1}{v} \quad (\text{for } i = 1, \dots, n)$$

- 7: **end for**

8: **return** $f_T(\mathbf{x}) = \sum_{t=1}^T \alpha_t h_t(\mathbf{x})$, where each α_t is the Lagrange multiplier for h_t in the last optimization problem.

Algorithm 3 SelfieBoost for deep learning

Input: Training samples $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n) \in \mathcal{X} \times \{+1, -1\}$. Edge parameter $\rho \in (0, 1/4)$.

- 1: Initial network $f_0 = f(\mathbf{x}; \Theta_0)$ trained by a few SGD iterations ▷ Initialization
- 2: **for** $t = 1$ to T **do**
- 3: Resampling m training samples according to the probability p_i , $i = 1, \dots, n$ defined by

$$p_i \propto e^{-y_i f_{t-1}(\mathbf{x}_i)}.$$

- 4: Let S be the set of m resampled samples.
- 5: Use SGD or its variants to train the network $f(\mathbf{x}; \Theta)$ based on the empirical loss over S ,

$$\sum_{(\mathbf{x}, y) \in S} y_i (f_{t-1}(\mathbf{x}_i) - f(\mathbf{x}_i; \Theta)) + \frac{1}{2} \sum_{(\mathbf{x}, y) \in S} (f(\mathbf{x}_i; \Theta) - f_{t-1}(\mathbf{x}_i))^2$$

- 6: Let f_t be the trained network.

- 7: **end for**

8: **return** $f_T(\mathbf{x})$

Boosting for Deep Learning

Deep learning is one of the most significant developments in scientific community in the past few decades. The stochastic descent gradient (SGD) and its variants are commonly used to train deep neural networks. However, further improvement will be needed. In order to build computationally efficient algorithms, some boosting-like methods have been proposed. The SelfieBoost in Algorithm 3 is a boosting method for deep learning with a theoretical guarantee [19]. Let us briefly introduce SelfieBoost.

In boosting methods, weak hypotheses are combined to produce a single strong hypothesis. In DNN, however, such a property of boosting is not adequate, since the prediction using the ensemble of DNN is computationally demanding. In SelfieBoost shown below, a single network $f(\mathbf{x}; \Theta)$ with the parameter Θ for the binary classification problems is repeatedly trained using weighted samples.

The empirical loss in Step 5 of SelfieBoost algorithm is an upper bound of the difference of the exponential loss, $\log \left(\sum_i e^{-y_i f(\mathbf{x}_i)} \right) - \log \left(\sum_i e^{-y_i f_{t-1}(\mathbf{x}_i)} \right)$. Shalev-Shwartz [19]

derived an upper bound of the empirical error $e(f_T) := \frac{1}{m} \sum_{i=1}^m \mathbf{1}[y_i f_T(\mathbf{x}_i) < 0]$. Suppose that two conditions,

$$\begin{aligned} \sum_{i=1}^n p_i \left[y_i (f_t(\mathbf{x}_i) - f_t(\mathbf{x}_i)) \right. \\ \left. + \frac{1}{2} (f_t(\mathbf{x}_i) - f_{t-1}(\mathbf{x}_i))^2 \right] < -\rho, \\ |f_t(\mathbf{x}_i) - f_{t-1}(\mathbf{x}_i)| \leq 1, \quad i = 1, \dots, n, \end{aligned}$$

hold at every iteration of SelfieBoost. The first condition means the DNN is sufficiently trained in each step. The second condition implies that the outcome of the DNN does not drastically change from the one in the last step. Under these conditions, we have $e(f_T) \leq e^{-\rho T}$. The exponential decrease of the empirical error holds as well as Adaboost.

[Edge detection](#)

Definition

Boundary detection is the process of detecting and localizing salient boundaries between objects in a scene.

Background

Boundary detection is closely related to, but not identical with, edge detection. Edge detection is a classical problem in computer vision which aims at finding brightness discontinuities. Edge detection is usually viewed as a low-level process of feature extraction that works under the assumption of ideal edge models (such as step and ridge edges).

In comparison, boundary detection is usually viewed as a mid-level process of finding boundaries of (and between) objects in scenes, thus having close ties with both grouping/segmentation and object shape. A large-scale dataset of natural images with human-marked groundtruth boundaries, the *Berkeley Segmentation Dataset* (BSDS) [1, 2], was established in 2001 and quickly became the standard benchmark for both boundary detection and segmentation (see examples in Fig. 1). The Berkeley Segmentation Dataset helped defining the problem of boundary detection and clarifying several fundamental issues:

1. It directly addressed the complexities of real-world scenes by using a variety of photos from the Corel database.
2. It defined boundary detection as a perceptual problem by using human-marked boundaries as the groundtruth.
3. It showed that boundary detection is well defined by demonstrating that boundaries marked by human subjects are consistent.
4. It illustrated many challenges of boundary detection, including those of real-world tex-

ture, complex object appearance, and low-contrast boundaries.

By clarifying the task and establishing quantitative evaluation metrics, the Berkeley benchmark has witnessed and motivated large progresses in boundary detection in the recent years.

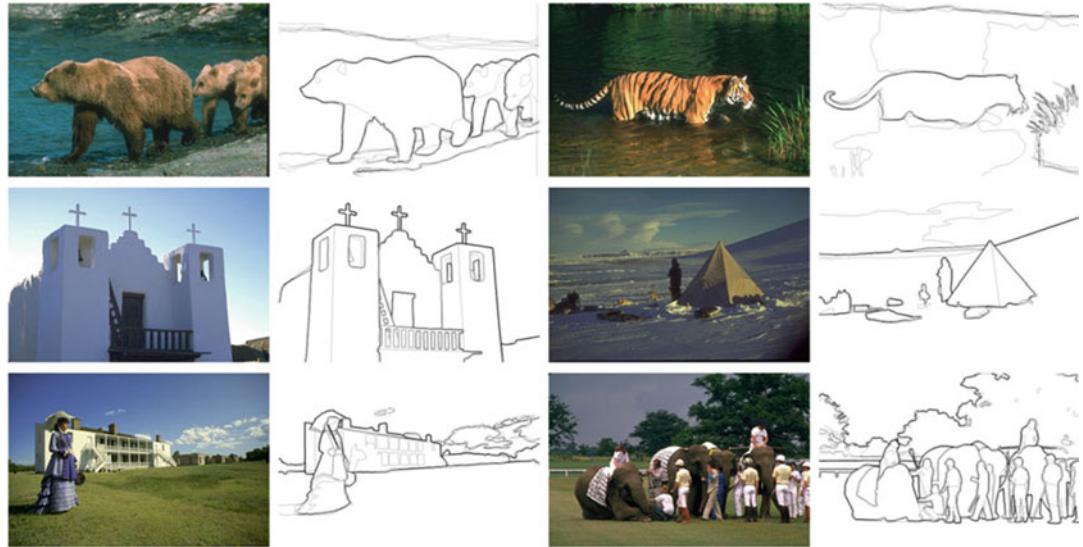

B

Local Boundary Detection

Early approaches to edge detection used local derivative filters such as the Roberts, Sobel, or Prewitt filters [3]. More advanced solutions included that of the zero crossing of Marr and Hildreth [4], the optimal filter design and non-maximum suppression in the Canny detector [5], and the use of quadrature filter pairs in oriented energy [6]. Scale (of the filter) is an important issue in edge detection and Lindeberg proposed a mechanism for automatic scale selection [7].

The key concept in boundary detection is that of *contrast*: regions on two sides of a boundary tend to have different appearances; consequently, there tends to be a high contrast at a boundary location. To a large extent, this contrast can be captured and measured locally in an image neighborhood (e.g., a disk with a fixed radius). Local contrast can be measured in a number of ways, such as using linear filters or computing distances between histograms. To handle real-world scenes, modern boundary detectors utilize contrast information from multiple channels (including brightness, color, and texture), multiple orientations, and multiple scales (see examples in Fig. 2). Good examples of these contrast operators can be found in the *Pb* work (probability-of-boundary) of Martin et al. [8] and the *gPb* work (global probability-of-boundary) of Arbelaez et al. [9] (Fig. 3).

Given the complexities of contrast cues and the availability of labeled images, local boundary detection is often formulated as learning a binary classifier of boundary vs. non-boundary, which will produce a soft boundary “likelihood” at each pixel. Such a dense boundary map can be used directly or converted to a sparse boundary map through non-maximum suppression. A number

Boundary Detection, Fig. 1 Examples of scenes in the Berkeley Segmentation Dataset [1]. Each photo is labeled by multiple human subjects, and the boundaries are shown

as being stacked together. There are variations across human subjects, but the marked boundaries are largely consistent especially for the salient ones

of supervised machine learning techniques were used and tested in [8] to combine a small set of handcrafted contrast cues. Others have taken a more direct learning approach, such as using boosting trees to combine thousands of simple features over patches [10].

Global Boundary Detection

Boundaries are not local phenomena that occur independently at pixels. In fact, boundaries are defined at the object level, and boundary pixels tend to form long, smooth contours, as evident from the examples in Fig. 1. Considerable efforts have been devoted to extracting boundaries globally, closely related to the classical problem of contour completion in perceptual organization. Algorithms for global boundary detection can be quantitatively evaluated based on their precision recall on the boundary detection task, same as for local boundary detection.

A variety of very different formulations have been proposed for global boundary detection and contour extraction, including classical works such as the Mumford-Shah functional [11].

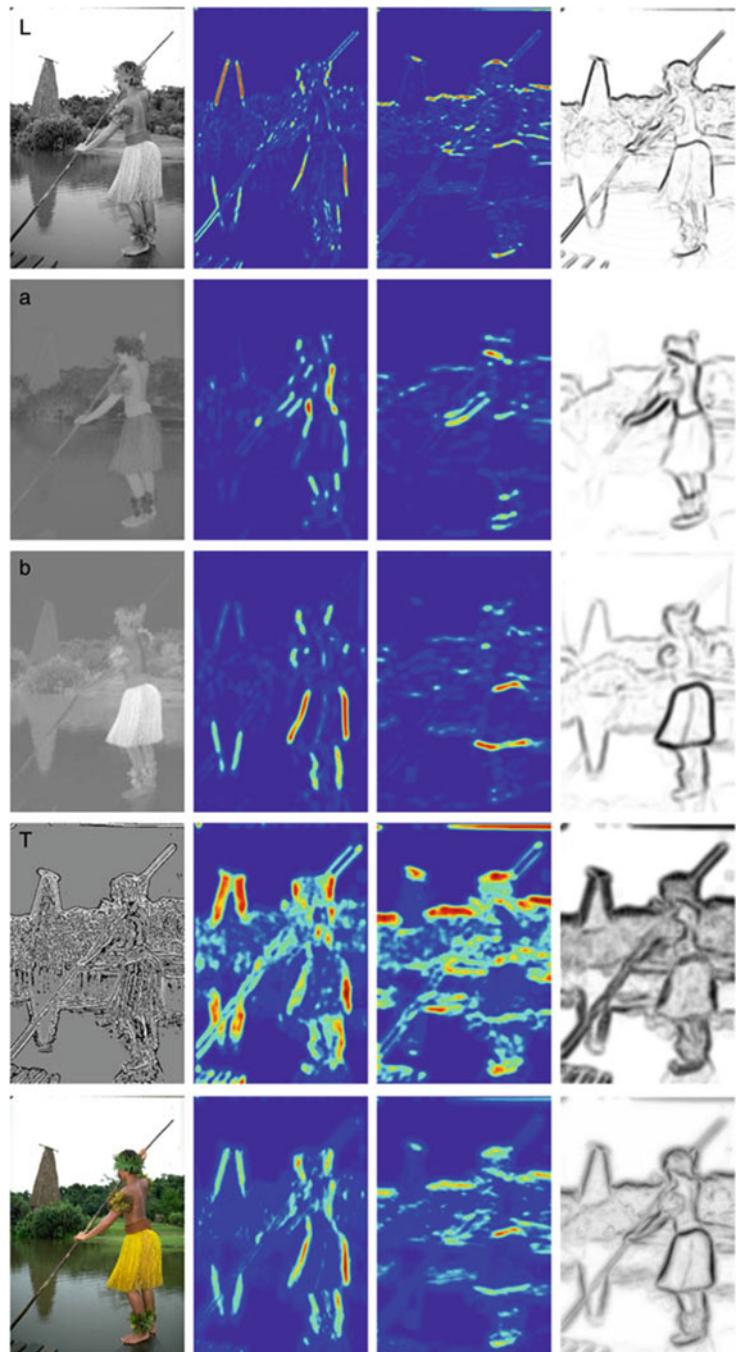

Several recent approaches have successfully demonstrated, through benchmarking, that globalization greatly improves boundary detection accuracy over local detectors. Ren et al. [12] applied constrained Delaunay triangulation (CDT) to decompose locally detected contours into pieces and used conditional random fields (CRF) and belief propagation to integrate local contrast cues through interactions at junctions. Zhu et al. [13] computed complex eigenvectors of a normalized random walk matrix, using circular embedding, to detect topologically closed cycles. In the *gPb* work of Arbelaez et al. [9], eigenvectors of the affinity matrix were first computed, as in Normalized Cuts [14], and then the gradients of these eigenvectors were added to the local contrast cues to produce a single contrast map.

[Optional]: One related but different form of global boundary detection can be found in the case of *top-down object segmentation* [15], where the algorithm has access to the knowledge (such as shape or texture) of the objects that are in the scene. It is beyond the scope of the discussion here, as boundary detection typically refers to the *bottom-up* case where no high-level object knowledge is needed.

Boundary Detection,

Fig. 2 Boundary detection combines multiple types of contrast. (Courtesy of [9], see details there).

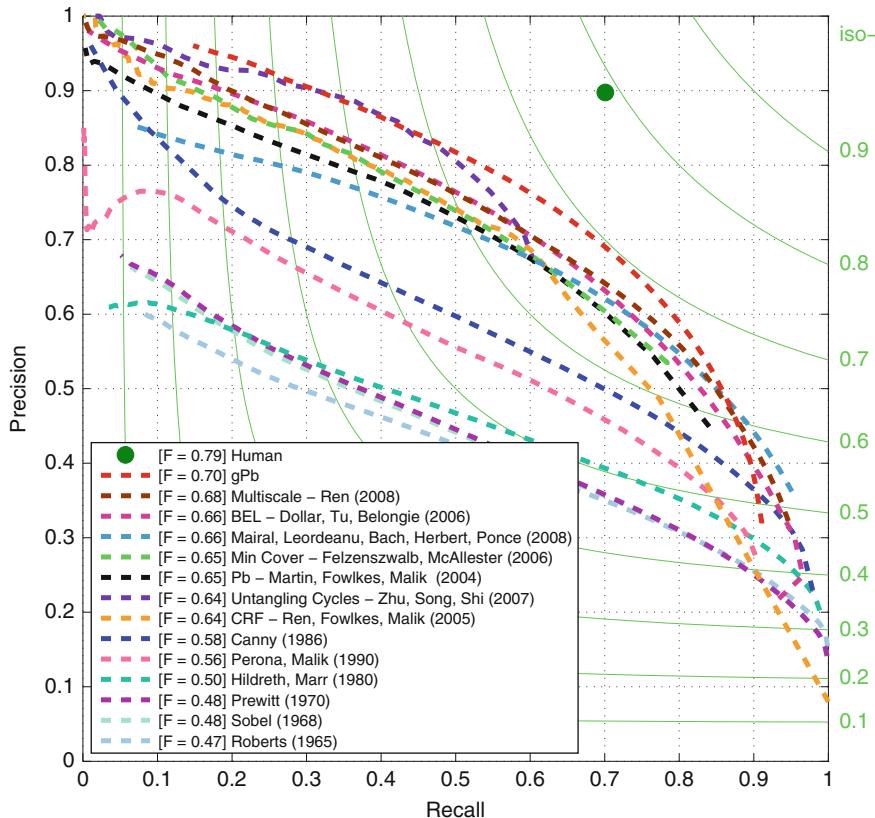

Top-performing boundary detectors integrate together local contrast measurements from multiple channels (row 1, brightness; 2 and 3, color; and 4, texture, through textons) and multiple orientations (column 2, vertical; and 3, horizontal). Red color means high probability being a boundary and blue otherwise. The combined boundary contrast (last row, last column) is much better than any individual channel

**Application**

Boundary detection is fundamentally connected to both image segmentation and object shape, and there should be no surprise that advances in boundary detection have led to many

interesting applications in segmentation and object recognition.

For image segmentation, the use of *intervening contour* [16] allows one to convert any boundary map to pairwise affinities for use in the Normalized Cuts framework, and many systems

Boundary Detection, Fig. 3 Precision-recall curves and F-measures of classical and modern boundary detection algorithms on the Berkeley benchmark. (Courtesy of [9], also see [1]). A variety of approaches have been proposed and evaluated on the benchmark. One can typi-

(e.g., [17]) have been using modern boundary detectors such as the *Pb* operator [8]. *Pb* is also used in [18], combined with the Watershed algorithm, to produce superpixels. Arbelaez et al. [9] proposed a hierarchical segmentation algorithm that, using the *gPb* boundary operator, produces compelling segmentation results and at the same time further improves the boundary detection accuracy.

For object recognition, boundary detectors such as *Pb* and *gPb* are often used to produce a boundary map, which is in turn used to compute shape descriptors. For instance, the work of Berg et al. [19] used *Pb* boundary maps with Geometric Blur for object and face recognition. The work of Ferrari et al. [20] used *Pb* to produce contour segments as a basis for shape matching.

cally observe qualitative improvements in the boundary detection accuracy as the F-measure increases. State-of-the-art boundary detectors perform much better than, for instance, the Canny detector

There are many segmentation-based approaches to recognition that also heavily rely on the quality of boundary detection (e.g., [21]).

State-of-the-art boundary detectors are sophisticated and require fairly intensive computation, which limits their applicability. There have been studies and efforts to speed up boundary detectors. In particular, the GPU-based detector of Catanzaro et al. [22] achieved a two-orders-of-magnitude improvement of speed over *gPb* without suffering any loss in boundary quality.

Definition

According to McGraw-Hill Encyclopedia of Science and Technology [1], calibration is the process of determining the performance parameters of an artifact, instrument, or system by comparing it with measurement standards. Adjustment may be a part of a calibration, but not necessarily. A calibration assures that a device or system will produce results which meet or exceed some defined criteria with a specified degree of confidence.

Background

In computer vision, there are multiple calibration problems. The most fundamental one is the camera calibration, which determines the intrinsic and extrinsic parameters of a camera. It is the first step toward 3D computer vision. Other problems include hand-eye calibration, color calibration, and photometric calibration.

As stated in [1], two important measurement concepts related to calibration are precision and accuracy. Precision refers to the minimum discernible change in the parameter being measured, while accuracy refers to the actual amount of error that exists in a calibration. All measurement processes used for calibration are subject to various sources of error. It is common practice to classify them as random or systematic errors. When a measurement is repeated many times, the results will exhibit random statistical fluctuations which may or may not be significant. Systematic errors are offsets from the true value of a parameter and, if they are known, corrections are generally applied, eliminating their effect on the calibration. If they are not known, they can have an adverse effect on the accuracy of the calibration. High-accuracy calibrations are usually accompanied by an analysis of the sources of error and a statement of the uncertainty of the calibration. Uncertainty indicates how much the accuracy of a calibration could be degraded as a result of the combined errors.

Definition

A non-single viewpoint system refers to a camera for which the light rays that enter the camera and contribute to the image produced by the camera do not pass through a single point. The analogous definition holds for *models* for non-single viewpoint systems. Hence, a non-single viewpoint camera or model does not possess a single center of projection. Nevertheless, a non-single viewpoint model (NSVM), like any other camera model such as the pinhole model, enables to project points and other geometric primitives into the image and to back-project image points or other image primitives, to 3D. Calibration of a non-single viewpoint model consists of a process that allows to compute the parameters of the model.

Background

There exist a large variety of camera technologies (“regular” cameras, catadioptric cameras, fish-eyes, etc.) and camera models designed for these technologies. Often, technologies are developed in order to accommodate a desired model, for example, to provide a uniform spatial resolution.

Most cameras used in computer vision and other areas can be well modeled by so-called single viewpoint, or central, camera models. These usually model the 3D-to-2D mapping carried out by a camera, *via* lines of sight (or camera rays) that all pass through a single point (the center of projection or optical center) and a mapping from these lines of sight to the image points where they hit the image plane.

Some camera types, especially some cameras having a wide field of view, but not only these, cannot be modeled very well using a single viewpoint model. This may be the case because a camera was designed to possess lines of sight that do not pass through a single point. This is, for example, the case for catadioptric cameras where the mirror surface is of conical shape: even if the camera looking at the mirror is positioned on the mirror’s axis, the lines of sight of the system do not converge to a single point; rather there exists a *viewpoint locus*. Another example is a single-lens stereo system consisting of a pinhole camera and two planar mirrors, such that the obtained images represent two perspective images acquired from two different effective viewpoints.

A camera may also be unintentionally of the non-single viewpoint type, for example, catadioptric cameras that were designed to have a single viewpoint but that due to a bad alignment of the camera and the mirror of the system lose the single viewpoint property. Another example are fish-eye cameras; fish-eye optics are complex, and in principle, one can probably consider them as non-single viewpoint systems. However, in this and the previous example, it is not clear without further investigation of the actual system under consideration, if a single viewpoint model or an NSVM is better suited. This indeed depends on “how much” the system deviates from having a single viewpoint, how close the scene is in a

typical application, how much image resolution is available, and so forth. This issue is further discussed in [1].

Finally, let us also note that it is possible to treat a set of multiple cameras that are rigidly attached to one another, as a single imaging system [2]. In case the cameras are sufficiently far from one another, the compound imaging system can be described as an NSVM. Particularly interesting is the case where there is no overlap in the fields of view of the individual cameras [3].

In the following, it is supposed that calibration is performed by acquiring one or several images of a calibration object, whose geometry is known and whose characteristic features (for simplicity, points shall be considered) can be extracted and identified in images.

Theory

There are different types of NSVMs. One usually distinguishes parametric from non-parametric such models. For example, for non-single viewpoint catadioptric systems, if the shape of the system's mirror is known or is known to belong to a parametric family of shapes, then the entire system can be described by few parameters: intrinsic parameters of the camera looking at the mirror, relative pose of mirror and camera, and, possibly, shape parameters for the mirror. If such a parametric model is considered, calibration is, conceptually speaking, analogous to that of pinhole cameras. The main difference to calibration of pinhole cameras usually concerns the initialization process that allows to compute initial estimates of the camera parameters. Other than that, one may in general formulate calibration by a bundle adjustment type optimization of camera parameters, by minimizing, for example, the reprojection error, i.e., a measure related to the distance between the predicted projections of points of the calibration object and those extracted in the images. Examples of parametric NSVMs are the so-called two-plane and GLC models [4–7], where lines of sight are parameterized by linear or higher-order transformations applied to

points in two basis planes, other similar models where lines of sight are parameterized by linear transformations [8–11], models for pushbroom and X-slit cameras [12–15], and others [16].

A different concept consists in using non-parametric models to calibrate cameras. An example is the raxel model introduced by Grossberg and Nayar [17]. It essentially associates, to each pixel, a ray in 3D supporting the line of sight and possibly properties such as its own radiometric response function. Importantly, one may use such a model without making any assumption about a parametric relationship between the position of pixels and the position and orientation of the associated lines of sight. Rather, one may store the coordinates of the lines of sight of all pixels, in a look-up table. Simplified versions of this model (without considering optical properties for individual pixels) have been used in several similar calibration approaches, for example [17–20].

The principle of these approaches is thus to compute, for every camera pixel, a line of sight in 3D. To do so, at least two images of a calibration object are required. The simplest scenario considers the case where the calibration object is displaced by some known motion, between the image acquisitions. For each image, one has to estimate correspondences between camera pixels and points on the calibration object. One way of achieving such dense correspondences is to use structured light principles, for instance, to use as calibration object a computer screen and to display a series of black-and-white patterns on it that encodes each pixel of the screen by a unique sequence of black-and-white intensities (e.g., Grey codes). Once correspondences of camera pixels and points of the calibration object (pixels of the computer screen in the above example) are known, the lines of sight can be computed by simply fitting straight 3D lines to the matched points on the calibration object. To do so, the latter must be expressed in the same 3D coordinate system, which is possible since it was assumed above that the motion of the calibration object between different acquisitions is known. This approach was proposed independently by different researchers [17–19].

The above approach requires a minimum of two images, for different positions of the calibration object, and knowledge of the object's displacements. An extension to the case of unknown displacements was proposed in [20]. That approach requires at least three images; from matches of camera pixels and points on the calibration object, it first recovers the displacements of the object using an analysis of this scenario's multi-view geometry and then computes lines of sights as above. Other approaches following this line are [21–23].

The above approaches compute, for each camera pixel, an individual line of sight. If one assumes that the relation between pixels and lines of sight is particular, for instance, radially symmetric about an optical axis, then alternative solutions become possible. Such a possibility is to use a non-parametric representation of the distortion or undistortion function of a camera, i.e., a function that maps viewing angles (angles between lines of sight and the optical axis) to distances in the image, between image points, and the principal point or a distortion center. This can be done for both single viewpoint and non-single viewpoint models. In the former case, it is assumed that all lines of sight pass through a single center of projection, whereas in the latter case, the model usually includes a mapping from viewing angles to the position of the intersection between lines of sight and the optical axis. Approaches of the latter type include [24, 25]. Besides making and using the assumption that the camera is radially symmetric, these calibration approaches resemble those explained above.

Different other approaches exist, for example, one based on the “surface model” [26], where the raxels of the model of Grossberg and Nayar are interpolated through the help of spline surfaces, or the method of [27] which estimates the refractive surface in front of a camera that makes the compound imaging system a non-central one. As for the case of multi-camera systems modeled as NSVMs, mentioned under “Background,” dedicated calibration approaches have been developed especially for the case of cameras with non-overlapping fields of view; see, for instance, [28].

Application

All approaches described above, be they parametric or non-parametric, allow to perform 3D-to-2D projection and/or 2D-to-3D back-projection, the latter meaning the mapping from an image point to the associated line of sight. By definition, the parametric models give analytical expression to perform these operations. As for non-parametric ones, projection and back-projection usually imply some interpolation and, possibly, a search. For instance, if a non-parametric model consists of a look-up table that gives, for each pixel, its line of sight, back-projection of an image point with non-integer coordinates requires interpolation, whereas projection of a 3D point requires the search of the closest line(s) of sight in the look-up table and again an interpolation stage.

Other than these particular aspects, NSVMs can be used for many structure-from-motion computations completely analogous to other camera models, in particular the pinhole model. Among the essential building blocks of structure-from-motion, there are pose estimation, motion estimation, and 3D point triangulation for calibrated cameras. As for pose and motion estimation (and other tasks), one usually requires two types of methods in an application: so-called minimal methods, which perform the estimation task from the minimum required number of point matches and which can be efficiently embedded in robust estimation schemes such as RANSAC, and non-linear optimization methods that refine initial estimates obtained from minimal methods. Minimal methods for pose [29–31] and motion estimation [32–34] are formulated analogously to those for the pinhole model, although their algebraic and algorithmic complexity is generally higher and the minimal configurations different (such as the required number of point matches or views).

Nevertheless, all that is essentially required by these methods from the NSVM is to compute lines of sight of interest points that are extracted and matched to another image (for motion estimation) or to a reference object (for pose estimation). As for the non-linear optimiza-

tion stage, the minimization of the reprojection errors requires 3D-to-2D projections to be carried out, which, as explained above, may require search and interpolation, in which case the computation of the cost function's derivatives may have to rely on numerical differentiation. Other than that, there is no major conceptual difference compared to pose/motion estimation with pinhole cameras.

Another essential structure-from-motion task is 3D point triangulation. Here again, suboptimal methods work with lines of sight computed by the camera model for interest points in the images, and optimal methods perform the non-linear optimization of reprojection errors, where the same considerations hold as above for pose and motion estimation.

Definition

Calibration of multi-camera setups is a process to estimate parameters of cameras which are fixed in a setup. It usually refers to the process to find relative poses of the cameras in a single coordinate system under the assumption of known intrinsic camera parameters.

Background

Many computer vision methods including 3D reconstruction from stereo cameras utilize the multiple cameras in a system, assuming that the relative poses of cameras in a single coordinate system is already known. While the camera calibration using a planar pattern [1] simplifies calibration process for intrinsic and extrinsic parameters of each camera, estimating camera poses in *a fixed global coordinate system* is still required.

The term “multi-camera setup” includes many different camera configurations such as a stereo, inward-looking cameras, outward-looking cameras, or camera sensor networks. Because each camera setup has different viewpoint and field of view (FOV) configuration, one single calibration method is not able to deal with all the multi-camera setups. Depending on the camera configuration, different calibration approach should be considered.

Theory

A projection matrix \mathbf{P}_i of a camera i in a multi-camera setup is given as

$$\mathbf{P}_i = \mathbf{K}_i [\mathbf{R}_i \; \mathbf{T}_i]. \quad (1)$$

The matrices \mathbf{R}_i and \mathbf{T}_i represent the pose of the camera i in a *predetermined* fixed coordinate system. More specifically, the matrices express a transformation between the fixed global coordinate system and the local camera coordinate system. The goal of the multi-camera calibration is to estimate the matrices \mathbf{R}_i and \mathbf{T}_i for all i in the system. The camera matrix \mathbf{K}_i represents

intrinsic parameters of the camera i , which can be assumed to be known by calibrating the intrinsic parameters of each camera independently in advance.

Multi-camera systems can be categorized into three configurations: inward-looking cameras, outward-looking cameras and large camera networks.

Inward-looking cameras The case that all the cameras in the system have a FOV shared. A stereo camera is considered *inward-looking* because the two cameras should see the same scene.

Outward-looking cameras The case that all the cameras in the system do not share their FOV. Because no FOVs are overlapped, it is usually called *non-overlapping cameras*.

Camera networks The case that some cameras share their FOVs but there are no common FOV for all cameras. Distributed cameras are usually in this category. Most likely, nearby cameras have a common FOV, farther cameras can not see it.

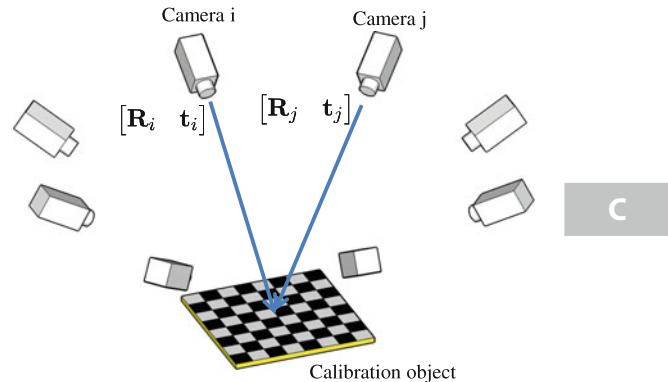

Each camera configuration has different constraints used in the multi-camera calibration, and the resulting calibration method becomes different to each other.

Inward-Looking Cameras

When all the cameras in the multi-camera setup have a common FOV, the multi-camera calibration is relatively simple. A calibration object is placed in the common FOV as shown in Fig. 1 so that each camera can see it, and the pose of the cameras with respect to the object coordinate system is estimated by using conventional pose estimation methods [2–4]. In this case, the common coordinate system of the multi-camera configuration is set to be the coordinate system of the calibration object.

For pose estimation of each camera, a planar pattern is preferable because it provides better visibility for all cameras. Note that, however, it is not limited to a planar pattern when the object visibility from every camera is ensured.

Sinha et al. [5] present an automatic calibration method using object silhouettes.

Calibration of Multi-camera Setups, Fig. 1
Calibration of inward-looking cameras

In this method, epipolar geometry between cameras is estimated from dynamic silhouettes and projective structure is recovered. Following self-calibration completes the Euclidean reconstruction. This aims especially for shape-from-silhouette or visual hull reconstruction.

Outward-Looking Cameras

When the FOVs of cameras in the system are not overlapped, it is impossible to place a calibration object which is observable from multiple cameras. The pose between cameras can be estimated by utilizing the fact that the transformation between cameras are fixed in motions called a rigidity constraint [6].

Assume that the coordinate systems of cameras i and j are transformed by a transformation \mathbf{R}_{ij} and \mathbf{t}_{ij} . When the camera i moves with a transformation $\Delta\mathbf{R}_i$ and $\Delta\mathbf{t}_i$, the motion of the camera j with a rotation $\Delta\mathbf{R}_j$ and a translation $\Delta\mathbf{t}_j$ is given as

$$\begin{bmatrix} \Delta\mathbf{R}_j & \Delta\mathbf{t}_j \\ \mathbf{0}^\top & 1 \end{bmatrix} = \begin{bmatrix} \mathbf{R}_{ij} & \mathbf{t}_{ij} \\ \mathbf{0}^\top & 1 \end{bmatrix} \begin{bmatrix} \Delta\mathbf{R}_i & \Delta\mathbf{t}_i \\ \mathbf{0}^\top & 1 \end{bmatrix} \begin{bmatrix} \mathbf{R}_{ij} & \mathbf{t}_{ij} \\ \mathbf{0}^\top & 1 \end{bmatrix}^{-1}, \quad (2)$$

and this equation can be rewritten in a $\mathbf{AX} = \mathbf{XB}$ form on the Euclidean group as

$$\begin{aligned} & \begin{bmatrix} \Delta\mathbf{R}_j & \Delta\mathbf{t}_j \\ \mathbf{0}^\top & 1 \end{bmatrix} \begin{bmatrix} \mathbf{R}_{ij} & \mathbf{t}_{ij} \\ \mathbf{0}^\top & 1 \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{R}_{ij} & \mathbf{t}_{ij} \\ \mathbf{0}^\top & 1 \end{bmatrix} \begin{bmatrix} \Delta\mathbf{R}_i & \Delta\mathbf{t}_i \\ \mathbf{0}^\top & 1 \end{bmatrix}. \end{aligned} \quad (3)$$

Solving the unknowns \mathbf{R}_{ij} and \mathbf{t}_{ij} on the Euclidean group is known as a *hand-eye calibration* in the robotics community [7–9]. Two or more motions of the camera rig provide enough number of constraints.

One practical problem is to estimate *motions* $\Delta\mathbf{R}$ and $\Delta\mathbf{t}$ of each camera. One stable way is to use calibration objects for each camera. First place a calibration object for each camera and take pictures while moving the camera rig. At each time frame, the poses of each camera can be estimated by using a conventional pose estimation method. The motions of cameras are computed by calculating the difference of the poses at different time frames. Note that the geometric relation between calibration objects is not required in calculating each camera motions. The only requirement is that the calibration objects are fixed in motions. Figure 2 shows the calibration objects for three non-overlapping cameras.

By solving the $\mathbf{AX} = \mathbf{XB}$ equation on the Euclidean group, the transformation between two cameras is obtained. If the multi-camera system

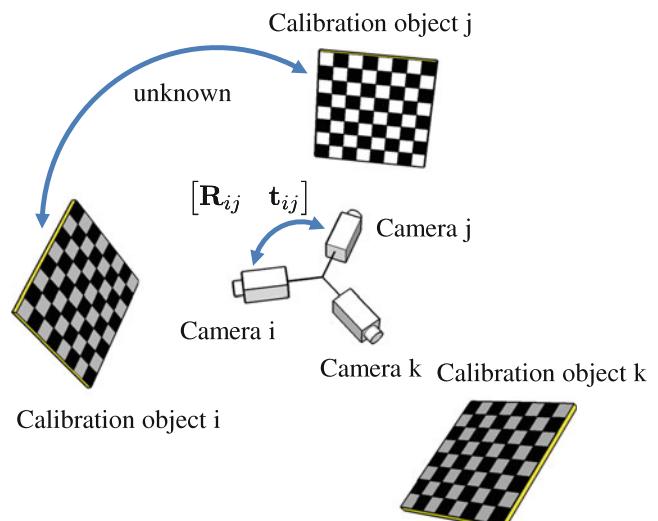

has more than two cameras, every camera can be registered in the fixed global coordinate system by chaining the transformations pairwisely. However, the pairwise chaining of transformation does not guarantee the globally consistent registration. In addition, the transformation between cameras may be inconsistent depending on the data provided to the $\mathbf{AX} = \mathbf{XB}$ solver. Dai et al. [10] represent a rotation averaging strategy to improve the consistency of the estimated transformation, and use a global bundle adjustment [11] for final polishing. Lebraly et al. [12] more focus on an sparse implementation of the global bundle adjustment to ensure the consistency in the fixed global coordinate system.

Kumar et al. [13] present completely different approach to use a mirror so that the cameras can observe the mirrored calibration pattern, and show successful calibration result for the ladybug camera.

Camera Networks

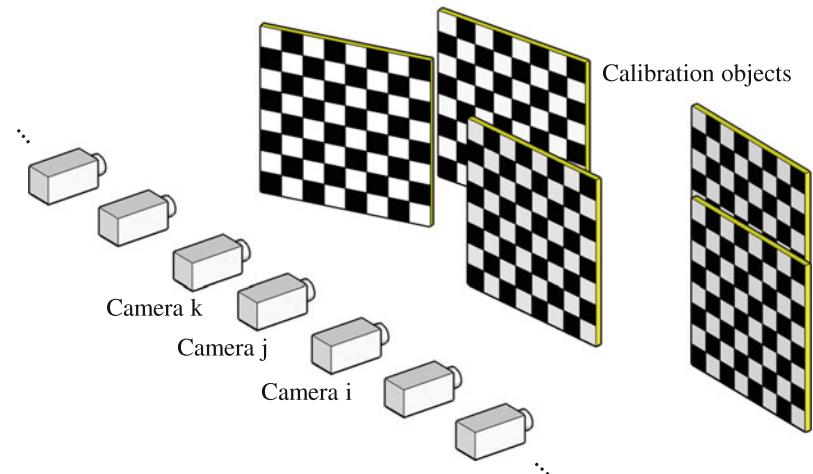

One general configuration is a camera network, which usually has many fixed cameras seeing in different directions. When every camera shares its FOV with any other camera in the network, relative transformations between the cameras can be estimated using calibration objects, and they are registered by chaining the transformation. In

Calibration of Multi-camera Setups,
Fig. 2 Calibration of outward-looking cameras

Calibration of Multi-camera Setups,

Fig. 3 Calibration of a camera network

fact, this calibration process is cast to a conventional structure from motion problem. Once all the relative transformations are obtained, globally consistent localization of the cameras in the fixed coordinate system is achieved by using bundle adjustment [11]. Figure 3 shows a possible placement of calibration objects in calibrating a camera network. Devarajan et al. [14] introduce a *vision graph* to describe the feature visibility between cameras, and try to optimize the graph network by belief propagation.

Baker and Aloimonos [15] present a method based on the multi-frame structure from motion algorithm, and use a rod with two LEDs at each end as a calibration object. The LEDs provides accurate and easily detectable correspondences for the precisely synchronized cameras by waving the rod.

Svoboda et al. [16] propose a convenient and complete self-calibration method using a laser pointer including intrinsic parameter estimation. The method is based on the stratification of the transformations; at first projective reconstruction is achieved by factorization and later upgraded to Euclidean space by imposing geometric constraints such as a square pixel assumption. Their source codes are available for public use.

If there is no camera sharing its FOV with others, it is challenging to establish the common global coordinate system. One idea is to use a mobile robot carrying a calibration object [17]. The location of the object is estimated by the

SLAM of the mobile robot. However, this is not stable enough for practical use yet.

Application

Multi-camera calibration is essential in constructing a system using multiple cameras depending on the applications and sensor configurations. The *inward-looking configuration* is generally used in many 3D reconstruction tasks such as stereo and visual hull reconstruction. The *outward-looking configuration* is useful to enlarge the effective FOV of the system, and especially for structure from motion applications. The most general *camera network* has diverse applications such as 3D reconstruction, surveillance, environmental monitoring and so on. Note that the camera network includes the inward-looking configuration of cameras.

Definition

Calibration of a projective camera is the process of determining an adjustment on the camera so that, after adjustment, it follows the pinhole or perspective projection model.

Background

A projective camera follows pinhole or perspective projection, which is also known as rectilinear projection because straight lines in a scene remain straight in an image. A real camera usually uses lenses with finite aperture, especially for low-end cameras (such as WebCams) or wide-angle cameras. Lens distortion also arises from imperfect lens design and manufacturing, as well as camera assembly. A line in a scene is not seen as a line in the image. A point in 3D space, its corresponding point in image, and the camera's optical center are not collinear. The linear projective equation is sometimes not sufficient, and lens distortion has to be considered or corrected beforehand.

Theory

According to [1], there are four steps in camera projection including lens distortion:

Step 1: *Rigid transformation* from world coordinate system (X_w, Y_w, Z_w) to camera one (X, Y, Z):

$$[X \ Y \ Z]^T = \mathbf{R} [X_w \ Y_w \ Z_w]^T + t$$

Step 2: *Perspective projection* from 3D camera coordinates (X, Y, Z) to *ideal* image coordinates (x, y) under pinhole camera model:

$$x = f \frac{X}{Z}, \quad y = f \frac{Y}{Z}$$

where f is the effective focal length.

Step 3: *Lens distortion*:

$$\check{x} = x + \delta_x, \quad \check{y} = y + \delta_y$$

where (\check{x}, \check{y}) are the *distorted* or *true* image coordinates and (δ_x, δ_y) are distortions applied to (x, y) . Note that the lens distortion described here is different from Tsai's treatment. Here, we go from ideal to real image coordinates, similar to [2].

Step 4: *Affine transformation* from real image coordinates (\check{x}, \check{y}) to *frame buffer* (pixel) image coordinates (\check{u}, \check{v}) :

$$\check{u} = d_x^{-1} \check{x} + u_0, \quad \check{v} = d_y^{-1} \check{y} + v_0,$$

where (u_0, v_0) are coordinates of the principal point and d_x and d_y are distances between adjacent pixels in the horizontal and vertical directions, respectively.

There are two types of distortions:

Radial distortion: It is symmetric; ideal image points are distorted along radial directions from the distortion center. This is caused by imperfect lens shape.

Decentering distortion: This is usually caused by improper lens assembly; ideal image points

are distorted in both radial and tangential directions.

The reader is referred to [3–6] for more details.

The distortion can be expressed as power series in radial distance $r = \sqrt{x^2 + y^2}$:

$$\begin{aligned} \delta_x &= x \left(k_1 r^2 + k_2 r^4 + k_3 r^6 + \dots \right) \\ &\quad + \left[p_1 (r^2 + 2x^2) + 2p_2 xy \right] \left(1 + p_3 r^2 + \dots \right), \\ \delta_y &= y \left(k_1 r^2 + k_2 r^4 + k_3 r^6 + \dots \right) \\ &\quad + \left[2p_1 xy + p_2 (r^2 + 2y^2) \right] \left(1 + p_3 r^2 + \dots \right), \end{aligned}$$

where k_i s are coefficients of radial distortion and p_j s are coefficients of decentering distortion.

Based on the reports in the literature [1, 2, 4], it is likely that the distortion function is totally dominated by the radial components and especially dominated by the first term. It has also been found that any more elaborated modeling not only would not help (negligible when compared with sensor quantization) but also would cause numerical instability [1, 2].

Denote the ideal pixel image coordinates by $u = x/d_x$ and $v = y/d_y$. By combining Steps 3 and 4 and if only using the first two radial distortion terms, we obtain the following relationship between (\check{u}, \check{v}) and (u, v) :

$$\check{u} = u + (u - u_0) \left[k_1 (x^2 + y^2) + k_2 (x^2 + y^2)^2 \right] \quad (1)$$

$$\check{v} = v + (v - v_0) \left[k_1 (x^2 + y^2) + k_2 (x^2 + y^2)^2 \right]. \quad (2)$$

Lens distortion parameters can be determined as an integrated part of geometric calibration [7]. This can be done by observing a known 3D target [1, 2, 6], by observing a 2D planar pattern [8], by observing a linear point pattern [9], or by moving the camera through a rigid scene [10]. The nonlinearity of the integrated projection

and lens distortion model does not allow for a direct calculation of all the parameters of the camera model. Camera calibration including lens distortion can be performed by minimizing the distances between the image points and their predicted positions, i.e.,

$$\min_{\mathbf{A}, \mathbf{R}, t, k_1, k_2} \sum_i \|m_i - \check{m}(\mathbf{A}, \mathbf{R}, t, k_1, k_2, \mathbf{M}_i)\|^2 \quad (3)$$

where $\check{m}(\mathbf{A}, \mathbf{R}, t, k_1, k_2, \mathbf{M}_i)$ is the projection of \mathbf{M}_i onto the image according to the pinhole model, followed by distortion according to Eq. (1) and Eq. (2). The minimization is performed through an iterative approach such as using the Levenberg-Marquardt method.

An alternative approach is to perform lens distortion correction as a separate process. Invariance properties under projective transformation are exploited. One is the “plumb line” constraint [4], which is based on the fact that a line in a scene remains a line in an image. Another is the cross-ratio constraint [2], which states that, for four collinear points with known distances between each other in 3D, their corresponding image points are collinear, and their cross-ratio remains the same. Due to lens distortion, projective invariants are not preserved, and we can use the variance to compute the distortion.

Definition

Calibration of radiometric falloff is the measurement of brightness attenuation away from the image center for a given camera, lens, and camera settings.

Background

Several mechanisms may be responsible for radiometric falloff. One is the optics of the camera, which may have a smaller effective lens opening for light incident at greater off-axis angles (i.e., irradiance toward the edges of an image). Radiometric falloff also occurs naturally due to foreshortening of the lens when viewed at increasing angles from the optical axis. A third cause is mechanical in nature, where light arriving at oblique angles is partially obstructed by camera components such as the field stop or lens rim. Digital sensors may also contribute to this falloff because of angle-dependent sensitivity to light. The profile of the radiometric falloff field varies with respect to camera, lens, and camera settings such as focal length and aperture.

Many computer vision algorithms assume that the image irradiance measured at the camera sensor is equal to the scene radiance that arrives at the camera. However, this assumption often does not hold because of radiometric falloff. It is therefore important to measure or estimate the radiometric falloff, and remove its effects from images.

Theory

Radiometric falloff, or vignetting, may be modeled as a function f that represents the proportion of image brightness I at an image position (x, y) relative to that at the image center (x_0, y_0) :

$$f(x, y) = \frac{I(x, y)}{I(x_0, y_0)}. \quad (1)$$

Because of approximate radial symmetry in the optical systems of most cameras, the radiometric falloff function may alternatively be expressed in terms of image distance r from the image center:

$$f(r) = \frac{I(r)}{I(0)}, \quad (2)$$

where $r = \sqrt{x^2 + y^2}$. The purpose of radiometric falloff calibration is to recover f , so that its inverse function f^{-1} can be applied to an image i , recorded by the same camera and camera settings, to obtain an image \tilde{i} without radiometric falloff:

$$\tilde{i}(x, y) = f^{-1}(i(x, y)). \quad (3)$$

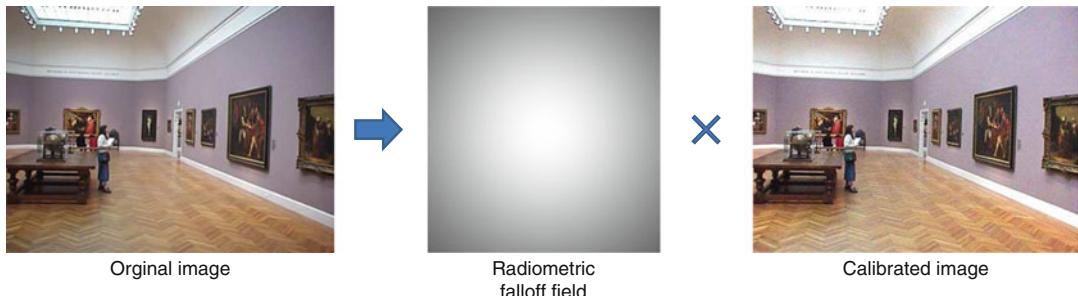

The effect of radiometric falloff calibration is illustrated in Fig. 1.

Methods

A basic method for calibration of radiometric falloff is to capture a reference image consisting of a uniform radiance field [1–4]. Since the scene itself contains no brightness variation, intensity differences in the image can be attributed solely to radiometric falloff. It must be noted that in these and other methods of falloff calibration, it is assumed that the camera response function is known.

Another approach examines image sequences with overlapping views of an arbitrary static scene [5–9]. In overlapping image regions, corresponding points are assumed to have the same scene radiance. Differences in their intensities are therefore a result of different radiometric falloff at their respective image positions. From the positions and relative intensities among each set of corresponding points, the radiometric falloff field can be recovered without knowledge of scene content. Most of these methods are designed to recover both the radiometric falloff field and the camera response function in a joint manner [6–9].

The radiometric falloff field may alternatively be estimated from a single arbitrary input image. To infer the falloff field in this case, the intensity variation caused by falloff needs to be distinguished from that due to scene content. This has been done using a segmentation-based approach that identifies image regions with reliable data for falloff estimation [10], and by examining the effect of falloff on radial gradient distributions in the image [11].

Calibration of Radiometric Falloff (Vignetting), Fig. 1 Image calibrated for radiometric falloff

Application

Calibration of radiometric falloff is of importance to algorithms such as shape-from-shading and photometric stereo that infer scene properties from image irradiance values. It is also essential in applications such as image mosaicing and segmentation that require photometric consistency of the same scene point appearing in different images, or different scene points within the same image.

A measured radiometric falloff field may be used to locate the optical center of the image, since radiometric falloff generally exhibits radial symmetry. The spatial variation of light transmission may also be exploited in sensing, such as to capture high dynamic range intensity values of scene points viewed from a moving camera [12].

- [Geometric Calibration](#)

Definition

Camera calibration is the process of determining certain parameters of a camera in order to fulfill desired tasks with specified performance measures. The reader is referred to entry Calibration for a general discussion on calibration.

Background

There are multiple camera calibration problems. The most common one, which almost becomes the synonym of camera calibration, is geometric calibration (see entry ► “[Geometric Calibration](#)”). It consists in determining the intrinsic and extrinsic parameters of a camera.

Other camera calibration problems include:

Stereo calibration. A stereo (or stereovision) system consists of multiple cameras. Stereo calibration determines the relative geometry (rotation and translation) between cameras. The intrinsic parameters of each camera can be determined separately as in camera calibration or jointly with the relative geometry.

Photometry concerns the measurement of quantities associated with light. Photometric calibration of a camera is a process of determining a function which converts the pixel values to photometric quantities such as SI (*Système International* in French) light units. A test chart of patches with known relative luminances is usually used for photometric calibration.

Color calibration. The pixel values of a color camera depend not only on the surface reflectance but also on the illuminating source. White balance is a common color calibration task, which uses a standard test target with known reflectance to remove the influence of lighting on the scene. Another common task is to calibrate multiple seemingly identical cameras which are not due to tolerance in fabrication.

Camera Extrinsic Parameters

- [Perspective Camera](#)

Definition

A *camera* is a device that records lights coming from the scene and saves them in images. These images may be still photographs or moving images (videos). The *camera model* describes the mathematical relationship between the 3D coordinates of a point in the scene from which the light comes from and the 2D coordinates of its projection onto the image plane. The ideal camera model is known as the pinhole camera model or perspective camera model, but other camera models exist such as thin and thick cameras.

Background

The term *camera* comes from the *camera obscura* (in Latin for “dark chamber”) [1]. A camera obscura is a dark room, consisting of a darkened chamber or box, into which light is admitted through a pinhole (later a convex lens), forming an image of external objects on a surface of wall, paper, or glass. A modern camera generally consists of an enclosed hollow with an opening (aperture) at one end for light to enter and a recording or viewing surface (such as a CCD or CMOS sensor) for capturing the light on the other end. A majority of cameras have a lens positioned in front of the camera’s opening to gather the incoming light and focus all or part of the image on the recording surface.

A camera may work with the light of the visible spectrum. If it records each of the red, blue, and green primary colors at each pixel, then the camera is called a color camera; if it only records the shades of black and white (the grey levels of the light intensity), the camera is called a black and white camera.

A camera may also work with the light outside of the visible spectrum, e.g., with the infrared (IR) light, and the camera is called the IR camera.

Pinhole Camera Model

A pinhole camera can be ideally modeled as the *perspective projection*. This is by far the most

popularly used model in the computer vision community. The reader is referred to the entry ▶ “[Perspective Camera](#)” for details.

Thin and Thick Lens Camera Models

Although pinhole cameras model quite well most of the cameras we use in the computer vision community, they cannot be used physically in a real imaging system. This is for two reasons:

- An ideal pinhole, having an infinitesimal aperture, does not allow to gather enough amount of light to produce measurable image brightness (called *image irradiance*).
- Because of the wave nature of light, diffraction occurs at the edge of the pinhole and the light spread over the image [2]. As the pinhole is made smaller and smaller, a larger and larger fraction of the incoming light is deflected far from the direction of the incoming ray.

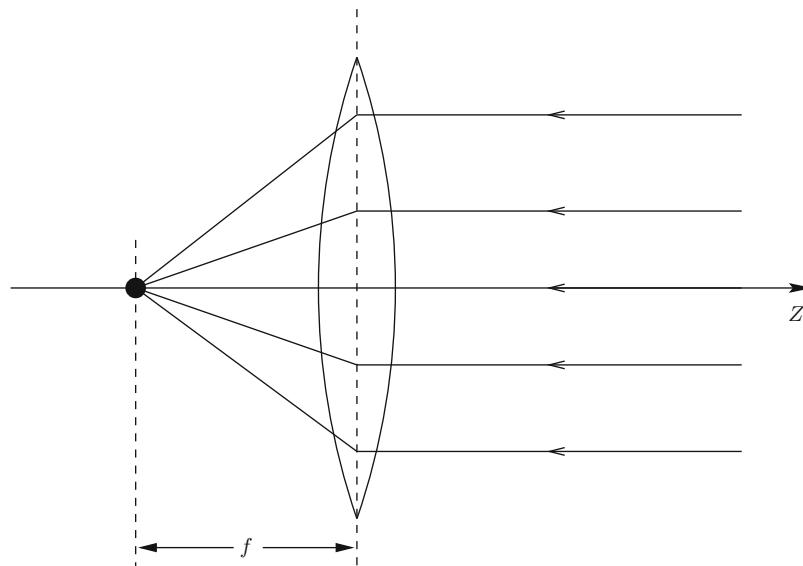

To avoid these problems, a real imaging system usually uses lenses with finite aperture. This appendix aims at having the reader know that there are other camera models available. One should choose an appropriate model for a particular imaging device [3, Sect. 2.A.1].

For an ideal lens, which is known as the *thin lens*, all optical rays parallel to the optical axis converge to a point on the optical axis on the other side of the lens at a distance equal to the so-called *focal length* f (see Fig. 1).

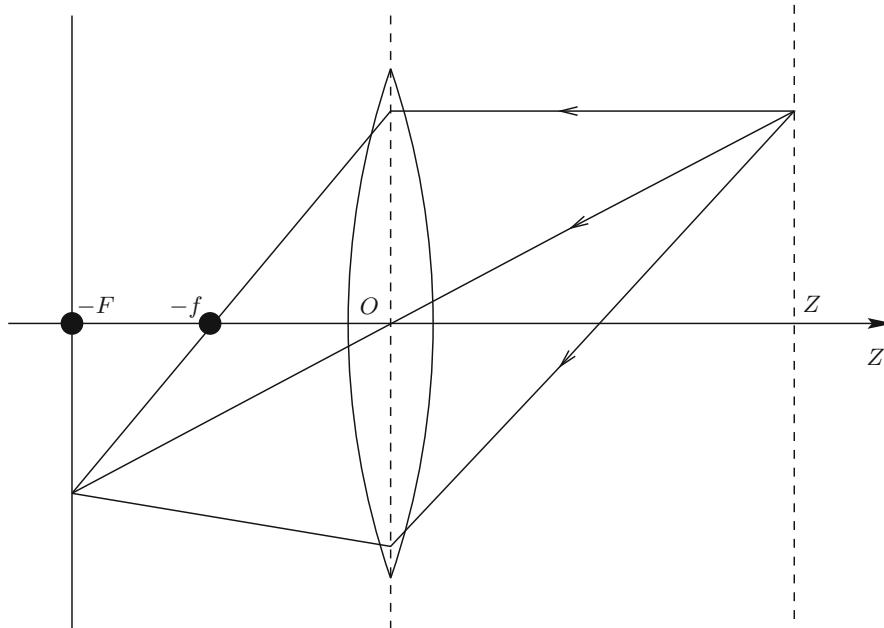

The light ray through the center of the lens is undeflected; thus a thin lens produces the same projection as the pinhole. However, it gathers also a finite amount of light reflected from (or emitted by) the object (see Fig. 2). By the familiar *thin lens law*, rays from points at a distance Z are focused by the lens at a distance $-F$, and Z and $-F$ satisfy

$$\frac{1}{Z} + \frac{1}{-F} = \frac{1}{-f}, \quad (1)$$

where f is the focal length.

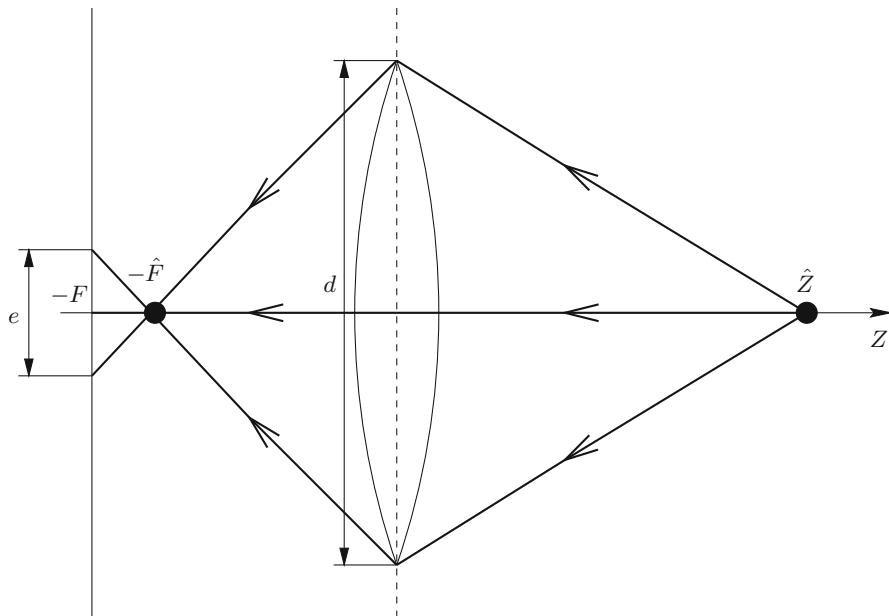

Camera Model, Fig. 1 Cross-sectional view of a thin lens sliced by a plane containing the optical axis. All light rays parallel to the optical axis converge to a point at a distance equal to the focal length

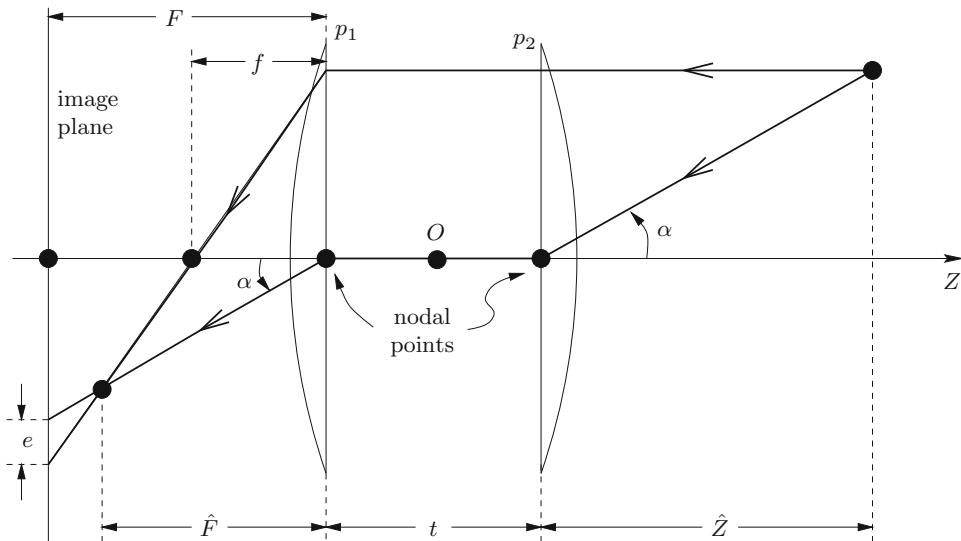

Camera Model, Fig. 2 A thin lens gathers light from a finite area and produces a well-focused image at a particular distance

If we put an image plane at the distance $-F$, then points at other distances than Z are imaged as small blur circles. This can be seen by considering the cone of light rays passing through the lens with apex at the point where

they are correctly focused [2]. The size of the blur circle can be determined as follows. A point at distance \hat{Z} is focused if it is imaged at a point $-\hat{F}$ from the lens (see Fig. 3), where

Camera Model, Fig. 3 Focus and blur circles

Camera Model, Fig. 4 Cross-sectional view of a thick lens sliced by a plane containing the optical axis

$$\frac{1}{\hat{Z}} + \frac{1}{-\hat{F}} = \frac{1}{-f}.$$

$$\frac{e}{d} = \frac{|F - \hat{F}|}{\hat{F}},$$

It gives rise to a blur circle on the image plane located at distance $-F$. The diameter of the blur circle, e , can be computed by triangle similarity

which gives

$$e = \frac{d}{\hat{F}} |F - \hat{F}| = \frac{fd}{\hat{Z}} \frac{|Z - \hat{Z}|}{|Z - f|},$$

where d is the diameter of the lens. If the diameter of blur circles, e , is less than the resolution of the image, then the object is well focused and its image is clean. The range of distances over which objects are focused “sufficiently well” is called the *depth of field*. It is clear that the larger the lens aperture d , the less the depth of field.

From (1), it is seen that for objects relatively distant from the lens (i.e., $Z \gg f$), we have $F = f$. If the image plane is located at distance f from the lens, then the camera can be modeled reasonably well by the pinhole.

It is difficult to manufacture a perfect lens. In practice, several simple lenses are carefully assembled to make a compound lens with better properties. In an imaging device with mechanism of focus and zoom, the lenses are allowed to move. It appears difficult to model such a device by a pinhole or thin lens. Another model, called the *thick lens*, is used by more and more researchers [4, 5].

An ideal thick lens is illustrated in Fig. 4. It is composed of two lenses, each having two opposite surfaces, one spherical and the other plane. These two planes p_1 and p_2 , called the *principal planes*, are perpendicular to the optical axis and are separated by a distance t , called the *thickness of the lens*. The principal planes intersect the optical axis at two points, called the *nodal points*. The thick lens produces the same perspective projection as the ideal thin lens, except for *an additional offset* equal to the lens thickness t along the optical axis. A light ray arriving at the first nodal point leaves the rear nodal point without changing direction. A thin lens can then be considered as a thick lens with $t = 0$.

It is thus clear that a thick lens can be considered as a thin lens if the object is relatively distant to the camera compared to the lens thickness (i.e., $\hat{Z} \gg t$). It can be further approximated by a pinhole only when the object is well focused (i.e., $F \approx \hat{F}$), and this is valid only locally.

Definition

Camera parameters are the parameters used in a camera model to describe the mathematical relationship between the 3D coordinates of a point in the scene from which the light comes from and the 2D coordinates of its projection onto the image plane. The *intrinsic parameters*, also known as *internal parameters*, are the parameters intrinsic to the camera itself, such as the focal length and lens distortion. The *extrinsic parameters*, also known as *external parameters* or *camera pose*, are the parameters used to describe the transformation between the camera and its external world.

Background

In computer vision, in order to understand the environment surrounding us with a camera, we have to know first the camera parameters. Depending on the accuracy we need to achieve and on the quality of the camera, some parameters can be neglected. For example, with a high-quality camera, the lens distortion can usually be ignored in most of the applications.

Theory

In the entry ► “[Perspective Camera](#)”, we describe the mathematical model of a perspective camera

with only a single parameter, the focal length f . The relationship between a 3D point and its image projection is described by

$$s\tilde{\mathbf{m}} = \mathbf{PM}, \quad (1)$$

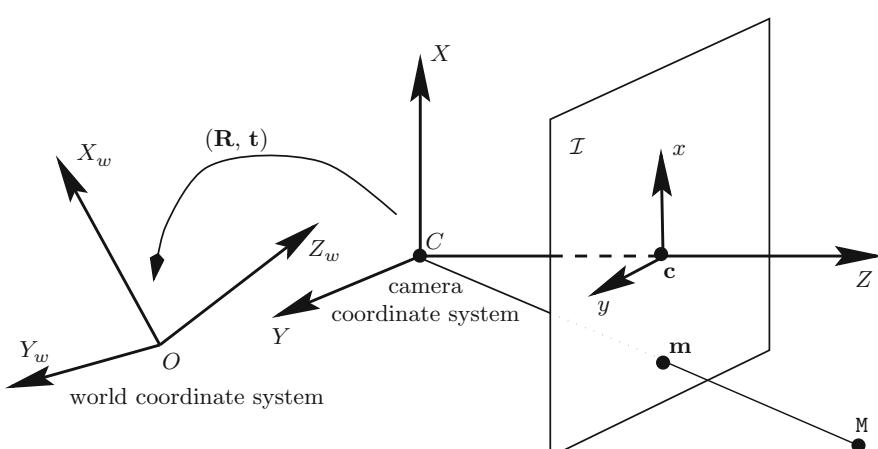

where $s = S$ is an arbitrary nonzero scalar and \mathbf{P} is a *projective projection matrix* given by

$$\mathbf{P} = \begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}.$$

Before proceeding, the reader needs to review the entry ► “[Perspective Camera](#)”.

Extrinsic Parameters

In the projective projection matrix described in the entry ► “[Perspective Camera](#)”, recapitulated above, we assumed that 3D points are expressed in the camera coordinate system. In practice, they can be expressed in any 3D coordinate system, which is sometimes referred as the *world coordinate system*. As shown in Fig. 1, we go from the old coordinate system centered at the optical center C (camera coordinate system) to the new coordinate system centered at point O (world coordinate system) by a rotation \mathbf{R} followed by a translation $\mathbf{t} = CO$. Then, for a single point, its coordinates expressed in the camera coordinate

Camera Parameters (Intrinsic, Extrinsic), Fig. 1 World coordinate system and camera extrinsic parameters

system, M_c , and those expressed in the world coordinate system, M_w , are related by

$$M_c = RM_w + t,$$

or more compactly

$$\tilde{M}_c = D\tilde{M}_w, \quad (2)$$

where D is a Euclidean transformation of the three-dimensional space

$$D = \begin{bmatrix} R & t \\ \mathbf{0}_3^T & 1 \end{bmatrix} \text{ with } \mathbf{0}_3 = [0, 0, 0]^T. \quad (3)$$

The matrix R and the vector t describe the orientation and position of the camera with respect to the new world coordinate system. They are called the *extrinsic parameters* of the camera.

From (1) and (2), we have

$$\tilde{m} = P\tilde{M}_c = PDM_w.$$

Therefore the new perspective projection matrix is given by

$$P_{\text{new}} = PD. \quad (4)$$

This tells us how the perspective projection matrix P changes when we change coordinate systems in the three-dimensional space: We sim-

ply multiply it on the right by the corresponding Euclidean transformation.

Intrinsic Parameters and Normalized Camera

This section considers the transformation in image coordinate systems. It is very important in practical applications because:

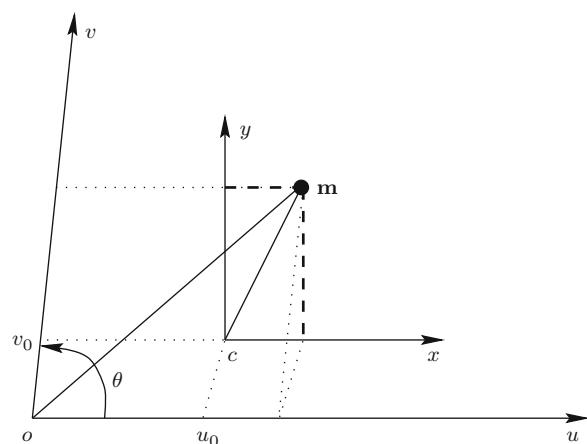

- We do not know the origin of the image plane in advance. It generally does not coincide with the intersection of the optical axis and the image plane.
- The units of the image coordinate axes are not necessarily equal, and they are determined by the sampling rates of the imaging devices.
- The two axes of a real image may not form a right angle.

To handle these effects, we introduce an affine transformation.

Consider Fig. 2. The original image coordinate system (c, x, y) is centered at the principal point c and has the same units on both x - and y -axes. The coordinate system (o, u, v) is the coordinate system in which we address the pixels in an image. It is usually centered at the upper left corner of the image, which is usually not the principal point c . Due to the electronics of acquisition, the pixels are usually not square. Without loss of generality, the u -axis is assumed to be parallel to the x -axis. The units along the u - and v -axes are assumed

Camera Parameters (Intrinsic, Extrinsic),

Fig. 2 Camera intrinsic parameters

to be k_u and k_v with respect to the unit used in (c, x, y) . The u - and v -axes may not be exactly orthogonal, and we denote their angle by θ . Let the coordinates of the principal point c in (o, u, v) be $[u_0, v_0]^T$. These five parameters do not depend on the position and orientation of the cameras and are thus called the camera *intrinsic parameters*.

For a given point, let $\mathbf{m}_{\text{old}} = [x, t]^T$ be the coordinates in the original coordinate system; let $\mathbf{m}_{\text{new}} = [u, v]^T$ be the pixel coordinates in the new coordinate system. It is easy to see that

$$\tilde{\mathbf{m}}_{\text{new}} = \mathbf{H}\tilde{\mathbf{m}}_{\text{old}},$$

where

$$\mathbf{H} = \begin{bmatrix} k_u & k_u \cot \theta & u_0 \\ 0 & k_v / \sin \theta & v_0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Since, according to (1), we have

$$s\tilde{\mathbf{m}}_{\text{old}} = \mathbf{P}_{\text{old}}\tilde{\mathbf{M}},$$

we conclude that

$$s\tilde{\mathbf{m}}_{\text{new}} = \mathbf{H}\mathbf{P}_{\text{old}}\tilde{\mathbf{M}},$$

and thus

$$\mathbf{P}_{\text{new}} = \mathbf{H}\mathbf{P}_{\text{old}} = \begin{bmatrix} f k_u & f k_u \cot \theta & u_0 & 0 \\ 0 & f k_v / \sin \theta & v_0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}. \quad (5)$$

Note that it depends on the products $f k_u$ and $f k_v$, which means that a change in the focal length and a change in the pixel units are indistinguishable. We thus introduce two parameters $\alpha_u = f k_u$ and $\alpha_v = f k_v$.

We will now define a special coordinate system that allows us to normalize the image coordinates [1]. This coordinate system is called the *normalized coordinate system* of the camera. In this “normalized” camera, the image plane is located at a unit distance from the optical center (i.e. $f = 1$). The perspective projection matrix of the normalized camera is given by

$$\mathbf{P}_N = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}. \quad (6)$$

For a world point $[X, Y, Z]^T$ expressed in the camera coordinate system, its normalized coordinates are

$$\begin{aligned} \hat{x} &= \frac{X}{Z} \\ \hat{y} &= \frac{Y}{Z}. \end{aligned} \quad (7)$$

A matrix \mathbf{P} defined by (5) can be decomposed into the product of two matrices:

$$\mathbf{P}_{\text{new}} = \mathbf{A}\mathbf{P}_N, \quad (8)$$

where

$$\mathbf{A} = \begin{bmatrix} \alpha_u & \alpha_u \cot \theta & u_0 \\ 0 & \alpha_v / \sin \theta & v_0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (9)$$

The matrix \mathbf{A} contains only the intrinsic parameters and is called *camera intrinsic matrix*. It is thus clear that the normalized image coordinates are given by

$$\begin{bmatrix} \hat{x} \\ \hat{y} \\ 1 \end{bmatrix} = \mathbf{A}^{-1} \begin{bmatrix} u \\ v \\ 1 \end{bmatrix}. \quad (10)$$

Through this transformation from the available pixel image coordinates, $[u, v]^T$, to the imaginary normalized image coordinates, $[\hat{x}, \hat{y}]^T$, the projection from the space onto the normalized image does not depend on the specific cameras. This frees us from thinking about characteristics of the specific cameras and allows us to think in terms of ideal systems in stereo, motion, and object recognitions.

The General Form of Perspective Projection Matrix

The camera can be considered as a system that depends upon the intrinsic and the extrinsic parameters. There are five intrinsic parameters: the scale factors α_u and α_v , the coordinates u_0 and

v_0 of the principal point, and the angle θ between the two image axes. There are six extrinsic parameters, three for the rotation and three for the translation, which define the transformation from the world coordinate system to the standard coordinate system of the camera.

Combining (4) and (8) yields the general form of the perspective projection matrix of the camera:

$$\mathbf{P} = \mathbf{A}\mathbf{P}_N\mathbf{D} = \mathbf{A}[\mathbf{R} \ \mathbf{t}]. \quad (11)$$

The projection of 3D world coordinates $\mathbf{M} = [X, Y, Z]^T$ to 2D pixel coordinates $\mathbf{m} = [u, v]^T$ is then described by

$$s\tilde{\mathbf{m}} = \mathbf{P}\tilde{\mathbf{M}}, \quad (12)$$

where s is an arbitrary scale factor. Matrix \mathbf{P} has $3 \times 4 = 12$ elements but has only 11 degrees of freedom because it is defined up to a scale factor.

Let p_{ij} be the (i, j) entry of matrix \mathbf{P} . Eliminating the scalar s in (12) yields two nonlinear equations:

$$u = \frac{p_{11}X + p_{12}Y + p_{13}Z + p_{14}}{p_{31}X + p_{32}Y + p_{33}Z + p_{34}} \quad (13)$$

$$v = \frac{p_{21}X + p_{22}Y + p_{23}Z + p_{24}}{p_{31}X + p_{32}Y + p_{33}Z + p_{34}}. \quad (14)$$

Camera *calibration* is the process of estimating the intrinsic and extrinsic parameters of a camera or the process of first estimating the matrix \mathbf{P} and then deducing the camera parameters from \mathbf{P} . A wealth of work has been carried out in this domain by researchers either in photogrammetry [2, 3] or in computer vision and robotics [4–9] (see [10] for a review). The usual method of calibration is to compute camera parameters from one or more images of an object of *known size and shape*, for example, a flat plate with a regular pattern marked on it. From (12) or (13) and (14), we have two nonlinear equations relating 2D to 3D coordinates. This implies that each pair of an identified image point and its corresponding point on the calibration object provides two constraints on the intrinsic

and extrinsic parameters of the camera. The number of unknowns is 11. It can be shown that, given N points ($N \geq 6$) in general position, the camera can be calibrated. The presentation of calibration techniques is beyond the scope of this book. The interested reader is referred to the above-mentioned references.

Once the perspective projection matrix \mathbf{P} is given, we can compute the coordinates of the optical center C of the camera in the world coordinate system. We first decompose the 3×4 matrix \mathbf{P} as the concatenation of a 3×3 submatrix \mathbf{B} and a 3-vector \mathbf{b} , that is, $\mathbf{P} = [\mathbf{B} \ \mathbf{b}]$. Assume that the rank of \mathbf{B} is 3. In the entry ▶ “Perspective Camera”, we explained that, under the pinhole model, the optical center projects to $[0, 0, 0]^T$ (i.e. $s = 0$). Therefore, the optical center can be obtained by solving

$$\mathbf{P}\tilde{C} = \mathbf{0}, \quad \text{that is, } [\mathbf{B} \ \mathbf{b}] \begin{bmatrix} C \\ 1 \end{bmatrix} = \mathbf{0}.$$

The solution is

$$C = -\mathbf{B}^{-1}\mathbf{b}. \quad (15)$$

Given matrix \mathbf{P} and an image point \mathbf{m} , we can obtain the equation of the 3-D semi-line defined by the optical center C and point \mathbf{m} . This line is called the *optical ray* defined by \mathbf{m} . Any point on it projects to the single point \mathbf{m} . We already know that C is on the optical ray. To define it, we need another point. Without loss of generality, we can choose the point D such that the scale factor $s = 1$, that is,

$$\tilde{\mathbf{m}} = [\mathbf{B} \ \mathbf{b}] \begin{bmatrix} D \\ 1 \end{bmatrix}.$$

This gives $D = \mathbf{B}^{-1}(-\mathbf{b} + \tilde{\mathbf{m}})$. A point on the optical ray is thus given by

$$\mathbf{M} = C + \lambda(D - C) = \mathbf{B}^{-1}(-b + \lambda\tilde{\mathbf{m}}),$$

where λ varies from 0 to ∞ .

Definition

Camera pose is referred to the position and orientation of a camera with respect to a reference coordinate system, which is usually known as the world coordinate system.

Background

Determining the camera pose is usually a first step toward perceiving the surrounding environment. In structure from motion where a camera is moving through the environment, one needs to determine the successive camera poses at different instants in order to reconstruct the surrounding environment in 3D. In a multi-camera (two or more) system, one needs to determine the relative camera pose, i.e., how one camera is related to other cameras.

Definition

A catadioptric system is a camera configuration where both lenses and mirrors are jointly used to achieve specialized optical properties. These configurations are referred to as *catadioptric*, where “cata” comes from mirrors (reflective) and “dioptric” comes from lenses (refractive).

Background

In 1637, René Descartes observed that the refractive and reflective “ovals” (conical lenses and mirrors) have the ability to focus light into one single point on illumination from a chosen point [1]. It was reported that the same results were derived by Feynman et al. [2] and Drucker and Locke [3]. In computer vision community, Baker and Nayar presented the complete class of single viewpoint catadioptric configurations with detailed solutions and degenerate cases [4]. Some of these results have been independently derived by Bruckstein and Richardson [5]. Survey of various catadioptric cameras, a review and details of their calibration, and 3D reconstruction algorithms can also be found in [6, 7].

Theory and Classification

The combination of mirrors and lenses provides a wide range of design possibilities leading to interesting applications in computer vision. Most catadioptric configurations have larger field of view compared to conventional pinhole cameras. Other important design goals are compactness of a sensor, a single effective viewpoint, image quality, focusing properties, or a desired projection function. The catadioptric cameras may be classified in many ways. In [6], Sturm et al. classify the catadioptric cameras in to five different types:

- Single-mirror central systems, having a single effective viewpoint
- Central systems using multiple mirrors
- Noncentral systems
- Single-lens stereo systems
- Programmable devices

In what follows, catadioptric cameras are classified into central and noncentral systems. Most of these catadioptric configurations were proposed by researchers along with specified calibration and 3D reconstruction algorithms.

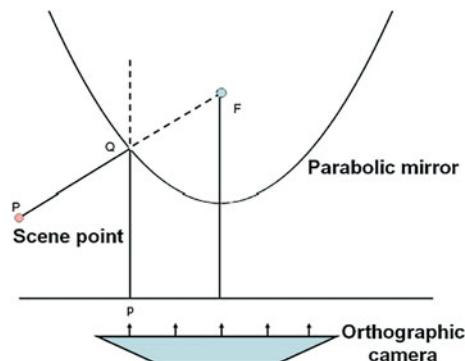

Central Catadioptric Configurations

It requires a very careful choice of the shape of the mirrors and their positioning to obtain a single effective viewpoint in catadioptric imaging. The single viewpoint design goal is important because it allows the generation of pure perspective images from the catadioptric images. Furthermore, it allows one to solve motion estimation and 3D reconstruction algorithms in the same way as perspective cameras:

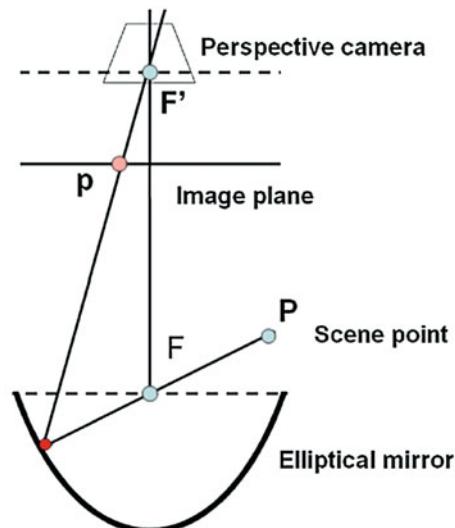

- *Planar mirror*: In [4, 8], it can be observed that by using planar mirrors along with a perspective camera, one can obtain a single viewpoint configuration. Since planar mirrors do not increase the field of view of the system, they are not very interesting for building omnidirectional cameras. Using four planar mirrors in a pyramidal configuration along with four perspective cameras, Nalwa [9] produced an

omnidirectional sensor of field of view of $360^\circ \times 50^\circ$. The optical centers of the four cameras and the angles made by the four planar faces are adjusted to obtain a single effective viewpoint for the system.

- *Conical mirrors*: By positioning the optical center of a perspective camera at the apex of a cone, one can obtain a single center configuration. Nevertheless, the only light rays reaching the camera after a reflection in the mirror are those grazing the cone. This case is thus not useful to enhance the field of view while conserving a single center of projection. However, in the work [10], it was proved that conical mirrors can be used to construct a non-degenerate single viewpoint omnidirectional cameras. The outer surface of the conical mirror forms a virtual image corresponding to the real scene behind the conical mirror. On placing the optical center of the pinhole camera at the vertex of the cone, the camera sees the world through the reflection on the outer surface of the mirror. In other words, the cone is not blocking the view. On the other hand, the cone is the view.
- *Spherical mirror*: If the optical center of a perspective camera is fixed at the center of a spherical mirror, one can obtain a single viewpoint configuration. Unfortunately, all that the perspective camera sees is its own reflection. As a result the spherical mirror produces a degenerate configuration without any advantage. Remember that by positioning the perspective camera outside the sphere, one can obtain a useful *noncentral* catadioptric camera.
- *Parabolic mirror*: Figure 1 shows a single viewpoint catadioptric system with a parabolic mirror and an orthographic camera. It is easier to study a catadioptric configuration by considering the back projection rather than the forward projection. Consider the back projection of an image point \mathbf{p} . The back-projected ray from the image pixel \mathbf{p} , starting from the optical center at infinity, is parallel to the axis of the parabolic mirror. This ray intersects and reflects from the surface of the mirror. The reflection is in accordance with the laws of

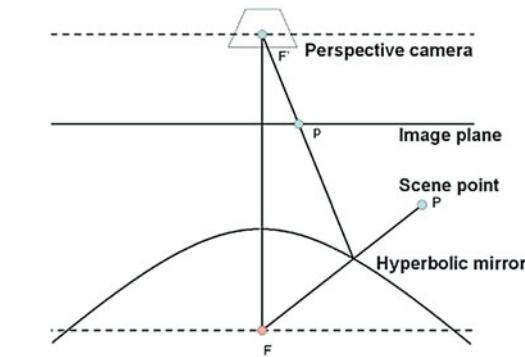

Catadioptric Camera, Fig. 1 Parabolic mirror + orthographic camera [8]. \mathbf{P} refers to the 3D scene point. \mathbf{F} , the focus of the parabolic mirror, is the effective viewpoint

Catadioptric Camera, Fig. 2 Elliptical mirror + perspective camera [4]. \mathbf{P} refers to the 3D scene point. \mathbf{F} and \mathbf{F}' refer to the two foci of the mirror and \mathbf{p} refers to the image point. \mathbf{F} is the effective viewpoint

reflection. This reflected light ray is nothing but the incoming light ray from a scene point \mathbf{P} in forward projection. The incoming ray passes through the focus \mathbf{F} if extended on the inside of the mirror. This point where all the incoming light rays intersect (virtually) is called the effective viewpoint.

- *Elliptical mirror*: Figure 2 shows a central catadioptric system with an elliptical mirror and a perspective camera. The optical center of the perspective camera is placed at the

Catadioptric Camera, Fig. 3 Hyperbolic mirror + perspective camera [4]. P refers to the 3D scene point. F and F' refer to the two foci of the mirror and p refers to the image point. F is the effective viewpoint

upper focus of the elliptical mirror. By back-projecting an image point p , one can observe the following. The back-projected ray, starting from the optical center at the upper focus of the elliptical mirror, intersects and reflects from the surface of the elliptical mirror. The reflected back-projected ray, or the incoming light ray, virtually passes through the lower focus of the mirror. Thus, the lower focus (F) is the effective viewpoint of the system.

- *Hyperbolic mirror:* In Fig. 3, a catadioptric system is shown with a hyperbolic mirror and a perspective camera. The optical center of the perspective camera is placed at the external focus of the mirror F' . The back-projected ray of the image point p starts from the optical center, which is the external focus F' of the mirror, of the perspective camera. Using the same argument as above, one can observe that the lower focus F is the effective viewpoint. The first known work to use a hyperbolic mirror along with a perspective camera at the external focus of the mirror to obtain a single effective viewpoint configuration is [11]. Later in 1995, a similar implementation was proposed in [12].

Noncentral Catadioptric Cameras

Single viewpoint configurations are extremely delicate to construct, handle, and maintain. By

relaxing this single viewpoint constraint, one can obtain greater flexibility in designing novel systems. In fact most real catadioptric cameras are geometrically noncentral, and even the few restricted central catadioptric configurations are usually noncentral in practice [13]. For example, in the case of para-catadioptric cameras, the telecentric lens is never truly orthographic and it is difficult to precisely align the mirror axis and the axis of the camera. In hyperbolic or elliptic configurations, precise positioning of the optical center of the perspective camera in one of the focal points of the hyperbolic or elliptic mirror is practically infeasible. In [14], Ramalingam et al. show that most of the practically used catadioptric configurations fall under an axial camera model where all the projection rays pass through a single line rather than a single point in space. A few noncentral catadioptric configurations are mentioned below. Analogous to the single viewpoint in central cameras, there is a *viewpoint locus* in non-central cameras. It can be defined as follows: a curve or other set of points such that all projection rays cut at least one of the points in the viewpoint locus. Usually, one tries to find the “simplest” such set of points:

- *Conical mirror:* On using a conical mirror in front of a perspective camera, one can obtain an omnidirectional sensor [15, 16]. Nevertheless this configuration does not obey the single viewpoint restriction (besides in the degenerate case of the perspective optical center being located at the cone’s vertex). If the optical center lies on the mirror axis, then the viewpoint locus is a circle in 3D, centered in the mirror axis (it can be pictured as a halo over the mirror). An alternative choice of viewpoint locus is the mirror axis. Otherwise, the viewpoint locus is more general.
- *Spherical mirror:* On using a spherical mirror along with a perspective camera, one can enhance the field of view of the imaging system [16–18]. Again this configuration does not obey the single viewpoint restriction (besides in the degenerate case of the perspective optical center being located at the sphere center).

- *Digital micro-mirror array*: Another interesting camera is the recently introduced programmable imaging device using a digital micro-mirror array [19]. A perspective camera is made to observe a scene through a programmable array of micro-mirrors. By controlling the orientations and positions of these mirrors, one can obtain an imaging system with complete control (both in terms of geometric and radiometric properties) over the incoming light ray for every pixel. However, there are several practical issues which make it difficult to realize the full potential of such an imaging system. First, current hardware constraints prohibit the usage of more than two possible orientations for each micro-mirror. Second, arbitrary orientations of the micro-mirrors would produce a discontinuous image which is unusable for many image processing operations.
- *Oblique cameras*: An ideal example for a noncentral camera is an oblique camera. No two rays intersect in an oblique camera [20]. In addition to developing multi-view geometry for oblique cameras, Pajdla also proposed a physically realizable system which obeys oblique geometry. The practical system consists of a rotating catadioptric camera that uses a conical mirror and a telecentric optics. The viewpoint locus is equivalent to a two-dimensional surface or a set of points, where each of the projection rays passes through at least one of the points. Different catadioptric configurations come with different calibration and 3D reconstruction algorithms. Recently, there has been a lot of interest in unifying different camera models and developing generic calibration and 3D reconstruction algorithms [21–24].

Application

Due to enhanced field of view, catadioptric cameras are mainly used in surveillance, car navigation, image-based localization, and augmented reality applications.

Definition

Center of projection is a single 3D point in space where all the light rays sampled by a conventional pinhole camera intersect.

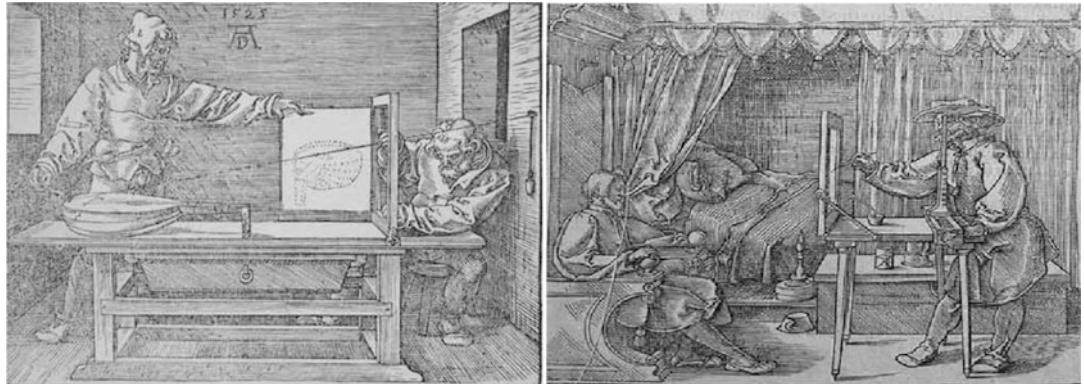

Background

Albrecht Dürer, a German artist, published a treatise on measurement using a series of illustrations of drawing frames and perspective machines. On the left side of Fig. 1, an apparatus for drawing a lute is shown. One end of a thread is attached to a pointer and the other end to a pulley on a wall. The thread also passes through a frame in between the lute and the pulley. When the pointer is fixed at different points on the lute, the vertical and horizontal coordinates of the thread, as it passes through the frame, are marked. By meticulously marking the coordinates for each point on the lute, the perspective image of the lute is created. It is obvious to see the intuition behind this setup, i.e., its similarity to a pinhole camera. The pulley is equivalent to the single viewpoint or the center of projection, the frame replaces the image plane, and finally, the thread is nothing but the light ray emerging from the scene. Though the principle is correct, the procedure is quite complicated. On the right side of Fig. 1, another perspective machine is shown. One can observe an artist squinting through a peep hole with one eye to keep a single viewpoint and tracing his sitter's features onto a glass panel. The idea is to trace the important features first and then transfer the drawing for further painting.

Theory

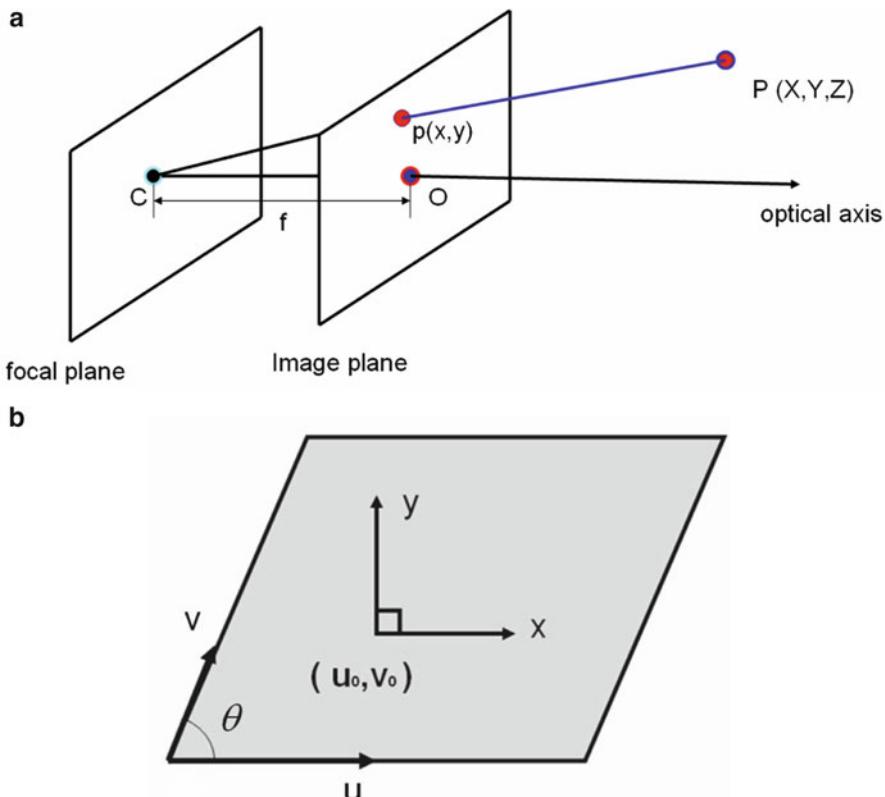

Pinhole Camera Model

Consider the perspective model that is shown in Fig. 2. Every 3D scene point $\mathbf{P}(X, Y, Z)$ gets projected onto the image plane to a point $\mathbf{p}(x, y)$ through the optical center \mathbf{C} . The optical axis is the perpendicular line to the image plane passing through the optical center. The center of radial symmetry in the image or principal point, i.e., the point of intersection of the optical axis and the image plane, is given by \mathbf{O} . The distance between \mathbf{C} (optical center) and the image plane is the focal length f . The optical center of the camera is the origin of the coordinate system. The image plane is parallel to the XY plane, held at a distance of f from the origin. Using the basic laws of trigonometry, one can observe the following:

Center of Projection, Fig. 1 *Left:* One of Albrecht Dürer's perspective machines, which was used to draw a lute in the year 1525 [1]. *Right:* An artist uses the

perspective principle to accurately draw a man sitting on a chair, by looking at him through a peep hole with one eye, and tracing his features on a glass plate

Center of Projection, Fig. 2 (a) Perspective camera model. (b) The relationship between (u, v) and (x, y) is shown

$$x = \frac{fX}{Z}, y = \frac{fY}{Z}$$

Once expressed in homogeneous coordinates, the above relations transform to the following:

$$\begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \sim \begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix}$$

where the relationship \sim stands for “equal up to a scale.”

Practically available CCD cameras deviate from the perspective model. First, the principal point (u_0, v_0) does not necessarily lie on the geometrical center of the image. Second, the horizontal and vertical axes (u and v) of the image are not always perfect perpendicular. Let the angle between the two axes be θ . Finally, each pixel is not a perfect square and consequently, f_u and f_v are the two focal lengths that are measured in terms of the unit lengths along u and v directions. By incorporating these deviations in the camera model, one can obtain the following scene (X, Y, Z) to image (u, v) transformation:

$$\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} \sim \begin{bmatrix} f_x & f_v \cot \theta & u_0 & 0 \\ 0 & \frac{f_v}{\sin \theta} & v_0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix}$$

In practice, the 3D point is available in some world coordinate system that is different from the camera coordinate system. The motion between these coordinate systems is given by (R, t) :

$$\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} \sim \begin{bmatrix} f_x & f_v \cot \theta & u_0 \\ 0 & \frac{f_v}{\sin \theta} & v_0 \\ 0 & 0 & 1 \end{bmatrix} [R - Rt] \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix} \quad (1)$$

$$M = \begin{bmatrix} f_x & f_v \cot \theta & u_0 \\ 0 & \frac{f_v}{\sin \theta} & v_0 \\ 0 & 0 & 1 \end{bmatrix} [R - Rt]$$

$$K = \begin{bmatrix} f_x & f_v \cot \theta & u_0 \\ 0 & \frac{f_v}{\sin \theta} & v_0 \\ 0 & 0 & 1 \end{bmatrix}$$

The 3×4 matrix M that projects a 3D scene point P to the corresponding image point p is called the projection matrix. The 3×3 matrix K that contains the internal parameters $(u_0, v_0, \theta, f_x,$

$f_y)$ is generally referred to as the *intrinsic* matrix of a camera.

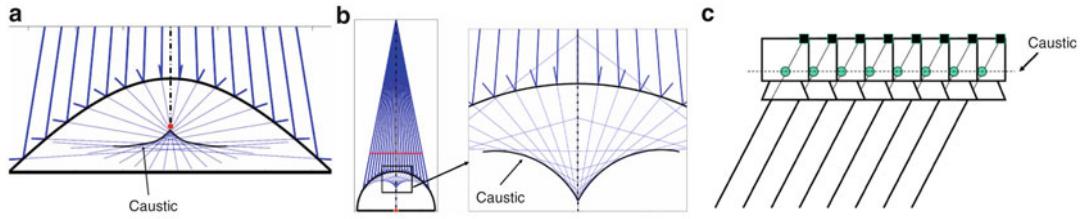

In back projection, given an image point p , the goal is to find the set of 3D points that project to it. The back projection of an image point is a ray in space. One can compute this ray by identifying two points on this ray. The first point can be the optical center C , since it lies on this ray. Since $MC = 0$, C is nothing but the right nullspace of M . Second, the point $M^+ p$, where M^+ is the pseudoinverse of M , lies on the back-projected ray because it projects to point p on the image. Thus, the back projection of p can be computed as follows:

$$P(\lambda) = M^+ p + \lambda C$$

The parameter λ allows to get different points on the back-projected ray.

Caustics

In a single viewpoint imaging system, the geometry of the projection rays is given by the effective viewpoint and the direction of the projection rays. In a noncentral imaging system, *caustic*, a well-known terminology in the optics community, can be utilized for representing the geometry of projection rays [2]. A caustic refers to the loci of viewpoints in 3D space to represent a noncentral imaging system. Concretely, the envelope of all incoming light rays that are eventually imaged is defined as the caustic. A caustic is referred to as diacaustic for dioptric (lens-based systems) and catacaustic (mirror-based systems) for catadioptric systems. A complete study of conic catadioptric systems has been done [3]. Once the caustic is determined, each point on the caustic represents a light ray by providing its position and the direction. Position is given by the point on the caustic, and orientation is related to the concept of tangent. Figure 3 shows the caustic for several noncentral imaging systems. For a single viewpoint imaging system, the caustic is a degenerate one being a single point. Simple methods exist for the computation of the caustic from the incoming light rays such as local conic approximations [4] and the so-called Jacobian

Center of Projection, Fig. 3 Caustics for several imaging systems **(a)** Hyperbolic catadioptric system **(b)** Spherical catadioptric system **(c)** Pushbroom camera

method [5]. A few examples for caustics are shown in Fig. 3.

Generalized and Multi-perspective Imaging Models

Many novel camera models have multiple centers of projection and they cannot be explained by a simple parametric pinhole model. In computer vision, there has been significant interest in generalizing the camera models to reuse the existing calibration and 3D reconstruction algorithms for novel cameras. In order to do this, first renounce on parametric models and adopt the following very general model: a camera acquires images consisting of pixels; each pixel captures light that travels along a ray in 3D. The camera is fully described by:

- The coordinates of these rays (given in some local coordinate system).
- The mapping between pixels and rays; this is basically a simple indexing.

The generic imaging model is shown in Fig. 4. This allows to describe all above models and virtually any camera that captures light rays traveling along straight lines. The above imaging model has already been used, in more or less explicit form, in various works [3, 6–16], and is best described in [6]. There are conceptual links to other works: acquiring an image with a camera of the general model may be seen as sampling the plenoptic function [17], and a light field [18] or lumigraph [19] may be interpreted as a single image, acquired by a camera of an appropriate design. More details of generic imaging

model, their calibration, and 3D reconstruction algorithms can also be found in [20].

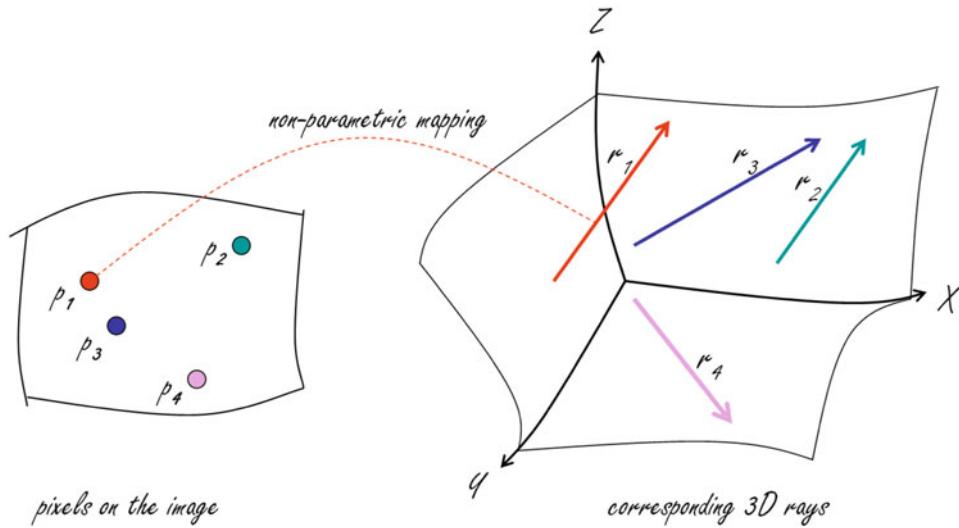

Taxonomy of Generic Imaging Models

Central Model: All the projection rays go through a single point, the optical center. Examples are mentioned below:

- The conventional perspective camera forms the classical example for a central camera.
- Perspective+radial or decentering distortion.
- Central catadioptric configurations using parabolic, hyperbolic, or elliptical mirrors.
- Fish-eye cameras can be considered as approximate central cameras.

Axial Model [21]: All the projection rays go through a single line in space, the *camera axis*. Examples of cameras falling into this class are:

- Stereo systems consisting of 2, 3, or more central cameras with collinear optical centers.
- Noncentral catadioptric cameras of the following type: the mirror is any surface of revolution and the optical center of the central camera looking at it (can be any central camera, not only perspective) lies on its axis of revolution. It is easy to verify that in this case, all the projection rays cut the mirror's axis of revolution, i.e., the camera is an axial camera, with the mirror's axis of revolution as camera axis. Note that catadioptric cameras with a spherical mirror and a central camera looking at it are always axial ones.
- X-slit cameras [22] (also called two-slit or crossed-slit cameras), and their special case of linear push-broom cameras [23].

Center of Projection, Fig. 4 The main idea behind the generic imaging model: The relation between the image pixels (p_1, p_2, p_3, p_n) and their corresponding projection rays (r_1, r_2, r_3, r_n) is *non-parametric*

Noncentral Cameras: A noncentral camera may have completely arbitrary projection rays. Common examples are given below:

- Multi-camera system consisting of 3 or more cameras, all of whose optical centers are not collinear.
- Oblique camera: This is an ideal example for a noncentral camera. No two rays intersect in an oblique camera [8].
- Imaging system using a micro-mirror array [24]. A perspective camera is made to observe a scene through a programmable array of micro-mirrors. By controlling the orientations and positions of these mirrors, one can obtain an imaging system with complete control (both in terms of geometric and radiometric properties) over the incoming light ray for every pixel.
- Noncentral mosaic: An image sequence is captured by moving the optical center of a perspective camera in a circular fashion [3]. The center columns of the captured images are concatenated to create a noncentral mosaic image.
- Center strip mosaic: The optical center of the camera is moved [3]. The center columns of the captured images are concatenated to form

a center strip mosaic. The resulting mosaic corresponds to a noncentral camera.

These three classes of camera models may also be defined as existence of a linear space of d dimensions that has an intersection with all the projection rays: $d = 0$ defines central, $d = 1$ axial, and $d = 2$ general noncentral cameras.

A detailed survey of various camera models, calibration, and 3D reconstruction algorithms is given in [25].

Change Detection

Joseph Mundy

Vision Systems Inc., Providence, RI, USA

Synonyms

Normalcy modeling

Definition

A determination that there are significant differences between visual scenes

Background

Change detection is a key task for computer vision algorithms. The goal is to compare two or more visual scenes and report any significant differences between scenes. As with many vision tasks, the meaning of *significant* is application-dependent. The change detection task can be rendered less ambiguous by considering the types of changes that are not typically of interest. Examples of changes that are usually irrelevant are:

- different camera viewpoint
- varying illumination
- wind-based motion, e.g., vegetation and flags
- weather, e.g., snow and rain

The implementation of algorithms that can detect interesting changes while ignoring trivial changes such as these is a very difficult problem, and only quite limited change detection capabilities have achieved to date. It is also the case that the change detection task, when viewed

broadly, overlaps the scope of many other vision tasks such as visual inspection and moving object detection.

Early attempts at change detection were based on simple strategies such as thresholding the magnitude of intensity differences between a reference image and an image that manifests change. This simple approach is only practical if the scene and imaging conditions are closely controlled so that the only scene changes are due to events of interest. Such highly controlled conditions can be found in industrial applications where the lighting and camera pose are accurately maintained. For example, missing components in a circuit board can be detected by comparing the image intensity of a high-quality *master* board with images of boards with potentially missing components or other flaws. In this application, images are accurately registered to the master image, so that intensity differences correspond to physical differences in the boards. The detected changes correspond to missing components or additional material such as excess solder.

A more advanced change detection principle is to classify elements of a scene into categories of interest. Then two scenes can be compared as to the presence or absence of various category instances. Change detection based on this principle can be successful if the classification process is insensitive to the types of irrelevant scene variations mentioned above. This classification approach has been applied extensively to the detection of changes in multi-spectral aerial and satellite imagery [1]. Multi-spectral images typically have four or more color bands, so that each pixel is a feature vector that can be subjected to standard classifiers. Image regions are classified into types such as roads, vegetation, forest, and water. Images can then be compared to determine the change in area of each category. This approach requires pixel-level image-to-image registration, which in turn is only effective if the viewpoint change between the images is small and the spatial resolution of the images is low. More recently, the segmentation of images into semantic categories has been achieved by neural networks. Changes are then detected in

terms of differences in categories produced by the network. Examples of this approach are [2–4].

Given the complexity of scene appearance and contextual variations, the great majority of change detection algorithms have adopted a learning approach based on the observation of a number of images. In this learning paradigm, it is assumed that changes are rare so that a statistical model for *normal* image appearance can be formed without removing regions of the image that represent change. A good example of this principle is learning the normal appearance of a road surface in a set of images that depict moving vehicles on the road. In any given image, some of the road surface is visible and contributes correct image appearance information to the model. In other images, different parts of the surface may be visible. The assumption is that over a large set of training images, the frequency of vehicle appearance at any given road surface point will be small compared to the frequency of the road appearance. This approach can also be denoted as *background modeling* because a model is being constructed for the scene background rather than the moving or changing objects, i.e., foreground. This approach can also be considered as developing a model for *normalcy* where changes are infrequent, i.e., abnormal.

This statistical modeling principle has received widespread acceptance with the advent of cheap computing power and the significance of video data, which provides large training samples. A classical reference is the work of Stauffer and Grimson, who implemented a moving object detection system in online video streams [2]. An important aspect of change detection in video is that illumination and atmospheric properties vary relatively slowly compared to the video frame rate. Under this condition, statistical appearance models can gradually adapt to such variations and not manifest them as change.

The effects of viewpoint and illumination can be overcome through the use of active 3-d range sensors such as LIDAR (Light Detection and Ranging) or laser triangulation. Scene illumination is provided by the sensor itself and therefore

has known direction and spatial extent. The result is a 3-d point cloud of samples from scene surfaces and associated surface reflectance values. In this approach, change is detected by measuring the distance between two 3-d scene point sets after they have been accurately registered together. Missing points or points that are significantly far from the reference point set are considered to be change. Such change points can be grouped into a connected region to further characterize the change. An example of this strategy is the work of Girardeau Montaut et al. [6].

Theory

The applications of change detection are so broad that a complete theoretical background is beyond the scope of an encyclopedia entry. Moreover, the success of change detection is critically dependent on accurate registration of the reference and current scenes so that change is due solely to the actual scene differences. However, the registration of scene images or 3-d data is a topic in its own right and will not be considered here. Instead, two important statistical methods will be described that have achieved considerable success in image-based change detection: the joint probability method by Carlotto [7] and the background modeling method by Stauffer and Grimson [5].

Joint Probability Method

This approach can accommodate scenes with significant differences in illumination and even between images taken with different sensor modalities such as visible and IR wave lengths. The method typically is applied to two images, $x_1(i, j)$ and $x_2(i, j)$, where the pixel intensity values, x , are considered to be random variables. It is assumed that the images are registered and the joint histogram, $p(x_1, x_2)$, of the intensity values at each pixel is accumulated. The expected intensity of a pixel in image 2, given the image value in image 1, is defined by

$$\tilde{x}_2(x_1) = \int x_2 p(x_2|x_1) dx_2$$

where

$$p(x_2|x_1) = \frac{p(x_1, x_2)}{p(x_1)}.$$

Change is then defined as values of

$$c_{21}(i, j) = \|x_2(i, j) - \tilde{x}_2(x_1(i, j))\|$$

that exceed a decision threshold. The same analysis can be applied in reverse to compute

$$c_{12}(i, j) = \|x_1(i, j) - \tilde{x}_1(x_2(i, j))\|$$

Gaussian Mixture Method

A second approach to modeling normal scene appearance is to associate a probability distribution with each image pixel location as shown in Fig. 1. This distribution accounts for normal variations in image intensity for each pixel across a set of images. It is assumed that the images are spatially registered so that a pixel in each image corresponds to the same surface element in the scene. An example of such registration is provided by a fixed video camera viewing a dynamic scene with moving objects and a stationary background.

The intensity of a given pixel will sometimes be due to background and sometimes foreground moving objects. Thus an appropriate distribution for the overall appearance variation is a Gaussian mixture distribution defined by,

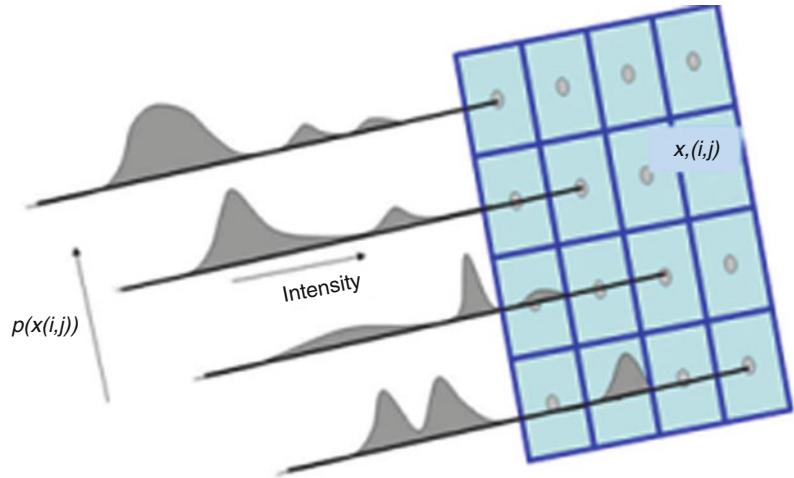

$$p(x) = \sum_k \frac{\omega_k}{\sqrt{2\pi}\sigma_k} e^{-\frac{1}{2}\frac{(x-\mu_k)^2}{\sigma_k^2}}$$

The distribution parameters, ω_k , μ_k , and σ_k , are learned using a continuous online update algorithm where a new intensity sample, $x^{n+1}(i, j)$, is associated with an existing mixture component if it is within a few standard deviations of the component mean or a new mixture is initiated. The update procedure for a scalar pixel intensity sample after n observations is defined by the following equations.

$$\omega_k^{n+1} = \frac{n\omega_k^n + 1}{n+1}$$

Change Detection, Fig. 1

The appearance of each pixel is modeled by a Gaussian mixture distribution

C

$$\mu_k^{n+1} = \frac{n \mu_k^n + x^{n+1}}{n + 1}$$

$$(\sigma_k^{n+1})^2 = \frac{n (\sigma_k^n)^2 + (x^{n+1} - \mu_k^n)^2}{n + 1}$$

The update is applied if the sample x^{n+1} is with a specified number of standard deviations from one of the mixture component means. If a new sample is not within the capture range of one of the mixture components, then a new mixture component is added with user-specified default weight and standard deviation. When the limit on the number of mixture components is reached, the component with the smallest value of ω_k^n / σ_k^n is discarded. This component is the least informative (greatest entropy) of the mixture.

The update can be applied continuously over a video sequence, and the mixture parameters will adapt to the normal appearance of the scene. Change is detected as pixel intensities having low probability density according to the mixture distribution. It is the case that such change objects will introduce new modes into the mixture. However, these modes will typically have low weight compared to appearance mixture components corresponding to the stable scene background.

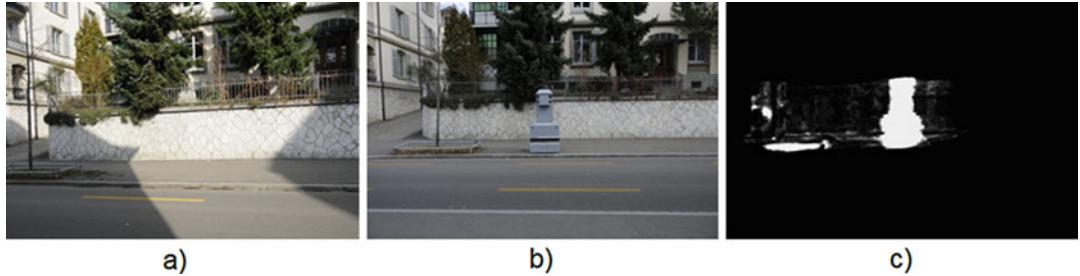

The probability of change can be computed as a Bayesian posterior based on the scene background mixture. That is,

$$p(\text{change} | x) = \frac{P_{\text{change}}}{P_{\text{change}} + (1 - P_{\text{change}}) p(x | \text{background})}$$

Here x is the observed intensity and $p(x | \text{background})$ is the Gaussian mixture learned from the sequence of images. The probability P_{change} is the prior belief that the pixel exhibits change and $p(\text{change} | x)$ is the posterior belief after observing the current image intensity value. This result is based on the assumption that image intensities are normalized to the range [0, 1] and the probability density for foreground (change) intensities is uniform, i.e., $p(x | \text{change}) = 1$. Change is detected for pixels having $p(\text{change} | x)$ greater than a threshold.

Open Problems

In spite of considerable research on change detection, the current state-of-the-art algorithms only perform well in scenes where appearance is highly consistent and viewpoint variations can be eliminated by using a fixed camera or by direct comparison of 3-d data. One possible way forward is the work of A. Osman Ulusoy [8] where a 4-d representation is maintained in a volumetric grid. As new images are observed, the prior 3-d model appearances in the form of Gaussian mixtures are replaced by the current

Change Detection, Fig. 2 An example of 4-d modeling **(a)** A rendering of the 4-d model at time t . **(b)** A rendering of the model at t' where an object (light blue) has been added. **(c)** The 3-d change between t and t' [9]

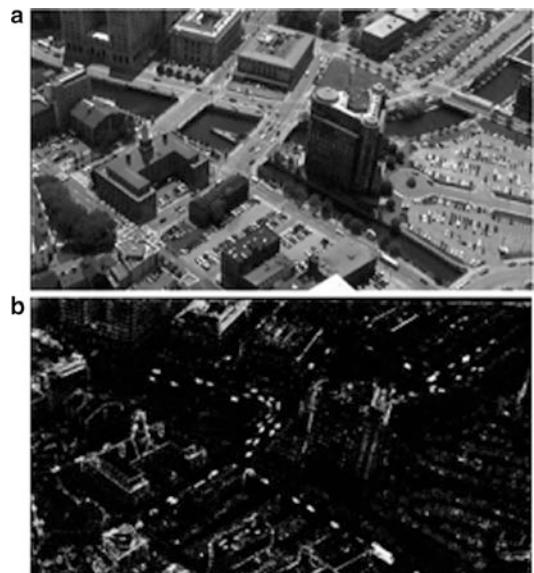

Change Detection, Fig. 3 Change detection based on joint probability. **(a)** Satellite image from May 2006. **(b)** Image from November 2006. **(c)** Significant changes shown in white [10]. (Images copyright Digital Globe)

illumination conditions. The probability of image appearance is then predicted using the prior geometry and new appearance models. Changes in scene structure become evident as low probability regions in each image manifesting the change. The change in 3-d structure can be recovered from the multiple image observations, and a new 4-d model instance is created. An example is shown in Fig. 2. Note the significant difference in illumination between time t and t' .

Experimental Results

An example of detected changes using the joint probability method is shown in Fig. 3. Note that significantly different appearance of the orchard on the right and different overall image contrast does not result in change since the differences are accumulated into the joint probability distribution. The method does not completely account for specular reflections of some of the building roofs (e.g., center and lower left) since these occur relatively infrequently. However, changes in the location of cars in the roadway at the center are detected with reasonable accuracy.

Change Detection, Fig. 4 An example of change probability computed using a Gaussian background mixture model **(a)** A typical video frame **(b)** The value of $p(\text{change} | x)$ displayed with white = 1

An example of change detection using the Gaussian mixture model is shown in Fig. 4.

In this example, a sequence of aerial video frames are registered to a common ground plane

and provide updates to the Gaussian mixture model at each pixel. Some false change probability can be seen at occluding boundaries and for metal building roofs that cause large variation in image intensity as the viewpoint changes. The actual changes in the scene are the moving vehicles on the roadways, which exhibit highly salient change probability values.

Chromaticity

Michael H. Brill

Datacolor, Lawrenceville, NJ, USA

C

Related Concepts

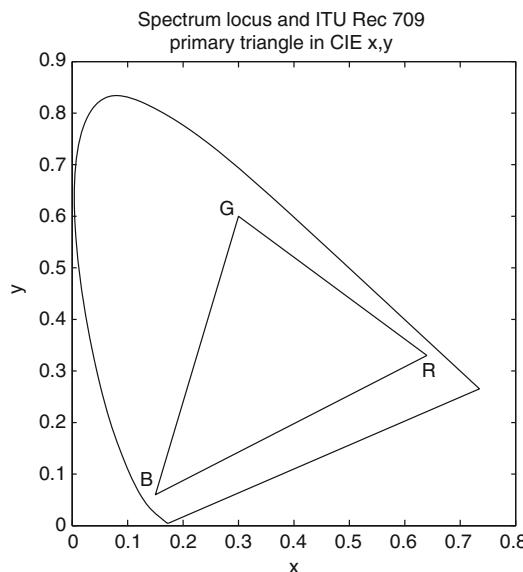

- Trichromatic Theory

Definition

Chromaticity is a representation of the tristimulus values of a light (see entry on ► “Trichromatic Theory”) by only two numbers, computed so as to suppress via ratios the absolute intensity of the light. The two numbers (called chromaticity coordinates) define a space (called chromaticity space) in which any additive mixture of two lights lies on a straight line between those two lights.

Theory

Most often, chromaticity is derived from a standardized tristimulus coordinate system representing human vision (e.g., a CIE XYZ system [1, 2]). If a light has tristimulus values X, Y, and Z, its chromaticity coordinates are conventionally defined as the ratios $x = X/(X + Y + Z)$ and $y = Y/(X + Y + Z)$. More generally, the chromaticity coordinates could be defined as the ratios $q_1 = (aX + bY + cZ)/(pX + qY + rZ)$ and $q_2 = (dX + eY + fZ)/(pX + qY + rZ)$, where a, b, c, d, e, f, p, q, r are constants that do not depend on the light. The above mapping from (X, Y, Z) to (q₁, q₂) is called a homogeneous central projection. It has the property of showing straight lines in (X, Y, Z) as straight lines in (q₁, q₂). Hence it is obvious from looking at the chromaticity coordinates of three lights whether one of the lights could have been additively mixed from the other two. This property is useful for visualizing the color gamut (set of producible colors) of a self-luminous trichromatic display

Chromaticity, Fig. 1 CIE (x, y) chromaticity diagram with spectrum locus and RGB display primaries

such as a cathode-ray tube (CRT) or a liquid-crystal display (LCD). The primaries (say, red, green, and blue) for such displays define three points in chromaticity space, and the triangle they generate spans the chromaticities producible by the display.

To illustrate the geometry of chromaticity, the figure below shows the 1931 CIE (x, y) diagram (Fig. 1). The horseshoe-shaped curve (from 380 nm at the left-hand end to 720 nm on the right-hand end) is the set of all monochromatic lights within the space, and is called the spectrum locus. The straight line connecting the ends of the curve is the line of purples. (There are no monochromatic purples.) Finally, the vertices of the triangle inside the spectrum locus represent the R, G, and B display primaries prescribed by ITU Recommendation 709. This set of primaries is only one example of many prescribed by standards bodies [3], and of even more sets manifested in real displays.

Various useful constructions are possible in chromaticity space. For example, the dominant wavelength of a light is defined by the point on the spectrum locus intercepted by a ray from

the agreed-upon white chromaticity through the chromaticity of the light in question. Another example is the set of lights defined by the black-body radiators (parameterized by their temperature). These lights collectively define the black-body locus, which of course lies within the spectrum locus. The set of conventional daylights also forms a curve that is close to the blackbody locus. As another example, it is possible to transform from one tristimulus primary set to another such set using only information in the chromaticity domain [4].

Because a digital camera is a trichromatic device, one can also think of a camera's response to light as having a chromaticity. Such chromaticities are useful because they suppress spatial variations of light intensity in an image (e.g., at shadow boundaries) and thereby facilitate image segmentation by object color (see entry on Band Ratios). Of course, band-ratio pairs are more general than chromaticities because the ratios can be separately defined without the mixture-on-a-straight-line constraint required for a chromaticity.

It should be noted that camera chromaticity is not at all the same as the human-vision chromaticity and must not be confused with it. In fact, two lights that have the same human-vision chromaticity can have different camera chromaticities, and vice versa. This effect is related to metamerism as noted in the entry on Trichromatic Theory. It should also be noted that, for the same reason, camera-derived values I, H, S used by computer-vision and image-processing applications are also not transformable to human perceptual attributes (e.g., intensity, hue, and saturation).

For both cameras and humans, chromaticity generalizes to a non-trichromatic system (i.e., one that has a number of different sensor types that is different from three). A sensor system with N sensor types delivers N-stimulus values for each light, the chromaticity space has N-1 dimensions (so as to suppress the light intensity), and the chromaticity coordinates comprise a homogeneous central projection out of the space of N-stimulus values.

Definition

A cognitive system is an autonomous system that can perceive its environment, learn from experience, anticipate the outcome of events, act to pursue goals, and adapt to changing circumstances.

Background

There are several scientific perspectives on the nature of cognition and on how it should be modeled. All fall under the general umbrella of cognitive science which embraces the disciplines of neuroscience, artificial intelligence, cognitive psychology, linguistics,

and epistemology. Among these differing perspectives, however, there are two broad classes: the *cognitivist* approach based on symbolic information processing representational systems, and the *emergent systems* approach, encompassing connectionist systems, dynamical systems, and enactive systems, all based to a lesser or greater extent on principles of self-organization [1–4]. A third class – *hybrid systems* – attempts to combine something from each of the cognitivist and emergent paradigms. All three approaches have their origins in cybernetics [5] which in the decade from 1943 to 1953 made the first efforts to formalize what had up to that point been purely psychological and philosophical treatments of cognition. The intention of the early cyberneticians was to create a science of mind, based on logic. Examples of the application of cybernetics to cognition include the seminal paper by McCulloch and Pitts “A logical calculus immanent in nervous activity” [6] and Ashby’s “Design for a Brain” [7].

Theory

The initial attempt in cybernetics to create a science of cognition was followed by the development of an approach referred to as *cognitivism*. The birth of the cognitivist paradigm, and its sister discipline of Artificial Intelligence, dates from a conference held at Dartmouth College, New Hampshire, in July and August 1956 and attended by people such as John McCarthy, Marvin Minsky, Allen Newell, Herbert Simon, and Claude Shannon. Cognitivism holds that cognition is achieved by computation performed on internal symbolic knowledge representations in a process whereby information about the world is abstracted by perception, and represented using some appropriate symbolic data-structure, reasoned about, and then used to plan and act in the world. The approach has also been labeled by many as the information processing or symbol manipulation approach to cognition [1, 8–10]. In most cognitivist approaches concerned with the creation of artificial cognitive systems, the

symbolic representations are the descriptive product of a human designer. This is significant because it means that they can be directly accessed and interpreted by humans and that semantic knowledge can be embedded directly into and extracted directly from the system. In cognitivism, the goal of cognition is to reason symbolically about these representations in order to effect the required adaptive, anticipatory, goal-directed behavior. Typically, this approach to cognition will deploy machine learning and probabilistic modeling in an attempt to deal with the inherently uncertain, time-varying, and incomplete nature of the sensory data that is used to drive this representational framework. Significantly, in the cognitivist paradigm, the instantiation of the computational model of cognition is inconsequential: any physical platform that supports the performance of the required symbolic computations will suffice [8]. This principled separation of operation from instantiation is referred to as functionalism.

In the emergent paradigm, cognition is the process whereby an autonomous system becomes viable and effective in its environment. It does so through a process of self-organization by which the system continually maintains its operational identity through the moderation of mutual system-environment interaction. In other words, the ultimate goal of an emergent cognitive system is to maintain its own autonomy. In achieving this, the cognitive process determines what is real and meaningful for the system: the system constructs its reality – its world and the meaning of its perceptions and actions – as a result of its operation in that world. Consequently, the system’s understanding of its world is inherently specific to the form of the system’s embodiment and is dependent on the system’s history of interactions, i.e., its experiences. This mutual-specification of the system’s reality by the system and its environment is referred to as co-determination [11] and is related to the concept of radical constructivism [12]. This process of making sense of its environmental interactions is one of the foundations of the enactive approach to cognition [13]. Cognition is also the means by which the system compensates for the immediate

nature of perception, allowing it to anticipate environmental interaction that occurs over longer time scales, i.e., cognition is intrinsically linked with the ability of an agent to act prospectively: to deal with what might be, not just with what is. Many emergent approaches adhere to the principle that the primary model for cognitive learning is anticipative skill construction rather than knowledge acquisition. Thus, processes which guide action and improve the capacity to guide action form the root capacity of all intelligent systems [14].

As noted already, the emergent paradigm embraces connectionist systems, dynamical systems, and enactive systems. Connectionist systems rely on parallel processing of non-symbolic distributed activation patterns using statistical properties, rather than logical rules, to process information and achieve effective behavior [15]. In this sense, the neural network instantiations of the connectionist model are dynamical systems that capture the statistical regularities in training data [16]. Dynamical systems theory has been used to complement classical approaches in artificial intelligence [17] and it has also been deployed to model natural and artificial cognitive systems [10, 18, 19]. Although dynamical systems theory approaches often differ from connectionist systems on several fronts, it is better perhaps to consider them complementary ways of describing cognitive systems, dynamical systems addressing macroscopic behavior at an emergent level, and connectionist systems addressing microscopic behavior at a mechanistic level [20]. Enactive systems take the emergent paradigm even further. Enaction [13, 21–23] asserts that cognition is a process whereby the issues that are important for the continued existence of a cognitive entity are brought out or enacted: co-determined by the entity and the environment in which it is embedded. Thus, enaction entails that a cognitive system operates autonomously, that it generates its own models of how the world works, and that the purpose of these models is to preserve the system's autonomy.

Considerable effort has gone into developing hybrid approaches which combine aspects

of cognitivist and emergent systems. Typically, hybrid systems exploit symbolic knowledge to represent the agent's world and logical rule-based systems to reason about this knowledge in order to achieve goals and select actions, while at the same time using emergent models of perception and action to explore the world and construct this knowledge. Thus, hybrid systems still use cognitivist representations and representational invariances but they are constructed by the system itself as it interacts with and explores the world rather than through a priori specification or programming. Consequently, as with emergent systems, the agent's ability to understand the external world is dependent on its ability to interact flexibly with it, and interaction is the organizing mechanism that establishes the association between perception and action.

Cognitivism and artificial intelligence research are strongly related. In particular, Newell and Simon's "Physical Symbol System" approach to artificial intelligence [8] has been extremely influential in shaping how we think about intelligence, natural as well as computational. In their 1976 paper, two hypotheses are presented: the *Physical Symbol System Hypothesis* and the *Heuristic Search Hypothesis*. The first hypothesis is that a physical symbol system has the necessary and sufficient means for general intelligent action. This implies that any system that exhibits general intelligence is a physical symbol system *and* any physical symbol system of sufficient size can be configured to exhibit general intelligence. The second hypothesis states that the solutions to problems are represented as symbol structures and that a physical-symbol system exercises its intelligence in problem-solving by search, i.e., by generating and progressively modifying symbol structures in an effective and efficient manner until it produces a solution structure. This amounts to an assertion that symbol systems solve problems by heuristic search, i.e., the successive generation of potential solution structures. The task of intelligence, then, is to avert the ever-present threat of the exponential explosion of search. Subsequently, Newell defined intelligence as the degree to which a system approximates the ideal

of a knowledge-level system [24]. A knowledge-level system is one which can bring to bear *all* its knowledge onto *every* problem it attempts to solve (or, equivalently, every goal it attempts to achieve). Perfect intelligence implies complete utilization of knowledge. It brings this knowledge to bear according to the *principle of maximum rationality* which was proposed by Newell in 1982 [25] as follows: “If an agent has knowledge that one of its actions will lead to one of its goals, then the agent will select that action.” Anderson [26] later offered a slightly different principle, the *principle of rationality*, sometimes referred to as rational analysis, stated as follows: “the cognitive system optimizes the adaptation of the behavior of the organism.” Note that Anderson’s principle considers optimality to be necessary for rationality, something that Newell’s principle does not.

Cognitivist and emergent approaches are normally contrasted on the basis of the symbolic or non-symbolic nature of their computational operation and representational framework. Cognitivist systems typically use production systems to effect rule-based manipulation of symbol tokens whereas emergent systems exploit dynamical processes of self-organization in which representations are encoded in global system states. However, the distinction between cognitivist and emergent is not restricted to the issue of symbolic representation and they can be contrasted on the basis of several other characteristics such as semantic grounding, temporal constraints, inter-agent epistemology, embodiment, perception, action, anticipation, adaptation, motivation, autonomy, among others [27].

The differences between the cognitivist and the emergent paradigm can be traced to their underlying distinct philosophies [28]. Broadly speaking, cognitivism is dualist, functionalist, and positivist. It is dualist in the sense that there is a fundamental distinction between the mind (the computational processes) and the body (the computational infrastructure and, if required, the physical structure that instantiates any physical interaction). It is functionalist in the sense that the actual instantiation and

computational infrastructure is inconsequential: any instantiation that supports the symbolic processing is sufficient. It is positivist in the sense that they assert a unique and absolute empirically-accessible external reality that is apprehended by the senses and reasoned about by the cognitive processes. In contrast, emergent systems are neither dualist nor functionalist, since the system’s embodiment is an intrinsic component of the cognitive process, nor positivist, since the form and meaning of the system’s world is dependent in part on the system itself. The emergent paradigm, and especially the enactive approach, can trace its roots to the philosophy of phenomenology [28, 29].

A criticism often leveled at cognitivist systems is that they are relatively poor at functioning effectively outside well-defined problem domains because they tend to depend on in-built assumptions and embedded knowledge arising from design decisions. Emergent systems should in theory be much less brittle because they develop through mutual specification and co-determination with the environment. However, the ability to build artificial cognitive systems based on emergent principles is very limited at present, and cognitivist and hybrid systems currently have more advanced capabilities within a narrower application domain.

Any cognitive system is inevitably going to be complex. Nonetheless, it is also the case that it will exhibit some degree of structure. This structure is often encapsulated in what is known as a cognitive architecture [30]. Although used freely by proponents of the cognitivist, emergent, and hybrid approaches to cognitive systems, the term “cognitive architecture” originated with the seminal cognitivist work of Newell et al. [25]. Consequently, the term has a very specific meaning in this paradigm where cognitive architectures represent attempts to create unified theories of cognition [24, 31], i.e., theories that cover a broad range of cognitive issues, such as attention, memory, problem-solving, decision-making, learning, from several aspects including psychology, neuroscience, and computer science. In the cognitivist paradigm, the focus of a cognitive architecture is on the aspects of cognition

that are constant over time and that are independent of the task. Since cognitive architectures represent the fixed part of cognition, they cannot accomplish anything in their own right and need to be provided with or acquire knowledge to perform any given task. For emergent approaches to cognition, which focus on development from a primitive state to a fully cognitive state over the lifetime of the system, the architecture of the system is equivalent to its phylogenetic configuration: the initial state from which it subsequently develops through ontogenesis.

Open Problems

The study of cognitive systems is a maturing discipline with contrasting approaches. Consequently, there are several open problems. These include the role of physical embodiment, the need for development, the system's cognitive architecture, the degree of autonomy required, the issue of symbol grounding, the problem of goal specification, the ability to explain the rationale for selection actions, the problem of generating generalized concepts and transferring knowledge from one context to another, and the interdependence of perception and action. The nature of any resolution of these problems is inextricably linked to the choice of paradigm: cognitivist, emergent, or hybrid.

The role of physical embodiment in a cognitive system [32–34] depends strongly on the chosen paradigm. Due to their functionalist characteristics, cognitivist systems do not depend on physical embodiment to operate successfully but there is nothing to prevent them from being embodied if that is what the task in hand requires. Emergent systems, by definition, require embodiment since the body plays a key role in the way a cognitive system comes to understand – make sense of – its environment. If a body is required, the form of embodiment must still be specified [35]. This is significant because, in the emergent paradigm at least, the ability of two cognitive agents to communicate effectively requires them to have similar embodiments so that they have

a shared history of interaction and a common epistemology.

The extent to which a cognitive system requires a capacity for development and, if so, the mechanisms by which development can take place are both open problems. In natural systems, growth is normally associated with development. However, growth in artificial systems remains a distant goal, although one whose achievement would open up many avenues of fruitful enquiry in cognitive systems. For current state-of-the-art cognitive systems, one can define development as the process by which a system discovers for itself the models that characterize its interactions with its environment. This contrasts with learning as the process whereby the parameters of an existing model are estimated or improved. Development, then, requires a capacity for self-modification [36] and in embodied emergent systems leads to an increased repertoire of effective actions and a greater ability to anticipate the need for and outcome of future actions [27].

The capacity to develop introduces another open issue: the minimal phylogenetic configuration – the perceptual, cognitive, and motoric capabilities with which a system is endowed at “birth” – that is required to facilitate subsequent ontogenesis – development and learning through exploration and social interaction [27]. This issue is related to the specification of the system's cognitive architecture and the necessary and sufficient conditions that must be satisfied for cognitive behavior to occur in a system. In addressing these issues, there is a trade-off between the initial phylogeny and the potential for subsequent development. This trade-off is reflected by the existence of two types of species in nature: precocial and altricial. Precocial species are those that are born with well-developed behaviors, skills, and abilities which are the direct result of their genetic make-up (i.e., their phylogenetic configuration). As a result, precocial species tend to be quite independent at birth. Altricial species, on the other hand, are born with poor or undeveloped behaviors and skills, and are highly dependent for support. However, in contrast to precocial species, they proceed to learn complex cognitive skills over their lifetime (i.e., through

ontogenetic development). The precocial and the altricial effectively define a spectrum of possible configurations of phylogenetic configuration and ontogenetic potential [37]. The problem is to identify a feasible point in this spectrum that will yield a cognitive system capable of developing the skills we require of it.

Autonomy is a crucial issue for cognitive systems [38] but the degree of autonomy required is unclear. To an extent, it depends on how autonomy is defined and which paradigm of cognition is being considered. Definitions range from self-regulation and homeostasis to the ability of a system to contribute to its own persistence [39]. In the former case, self-regulation is often cast as a form of self-control so that the systems can operate without interference from some outside agent, such as a human user. In the latter case, autonomy is the self-maintaining organizational feature of living creatures that enables them to use their own capacities to manage their interactions with the world in order to remain viable [14]. Cognitivist systems tend to adopt the former definition, emergent systems, the latter.

Broadly speaking, cognitivist systems exploit symbolic representations while emergent systems exploit sub-symbolic state-based representations, with hybrid systems using both. The manner in which cognitivist and hybrids systems ground their symbolic representations in experience is still an open issue [40], with some arguing for a bottom-up approach [41] and others for a process of learned association, where meaning is attached rather than grounded [37].

The opening definition of a cognitive system states that it can act to achieve goals. The specification of these goals poses a significant challenge due to the autonomous nature of cognitive systems. It is more easily resolved for cognitivist systems since the goals can be hard-wired into the cognitive architecture. It is less clear how goals can be specified in an emergent system since the over-arching goal here is the maintenance of the system's autonomy. The goals of such a system reflect its intrinsic motivations and its associated value system [42]. The problem is to understand how to engineer this value system to ensure that the system is motivated to act in a

way that satisfies goals which are external to the system and to decide how these goals can be communicated to the system.

Ideally, in addition to the characteristics of a cognitive system listed in the opening definition – autonomy, perception, learning, anticipation, goal-directed action, and adaptation – a cognitive computer system should also be able to say what it is doing and why it is doing it, i.e., it should be able to explain the reasons for an action [43]. This would enable the system to identify potential problems which might appear when carrying out a task and it would know when it needed new information in order to complete that task. Consequently, a cognitive system would be able to view a problem in several different ways and to look at different alternative ways of tackling it. In a sense, this is something similar to the issue discussed above about cognition involving an ability to anticipate the need for actions and their outcome. The difference in this case is that the cognitive system is considering not just one but many possible sets of needs and outcomes. In a sense, it is adapting *before* things do not go according to plan. From this point of view, cognition also involves a sense of self-reflection.

Cognitive systems also learn from experience and adapt to changing circumstances. To do this, the system must have some capacity for generalization so that concepts can be formed from specific instances and so that knowledge and know-how can be transferred from one context to another. This capacity would allow the system to adapt to new application scenarios and to explore the hypothetical situations that arise from the self-reflection mentioned above. It is unclear at present how such generalized conceptual knowledge and know-how should be generated, represented, and incorporated into the system dynamics.

Perception and action have been demonstrated to be co-dependent in biological systems. Perceptual development depends on what actions an infant is capable of and what use objects and events afford in the light of these capabilities. This idea of the action-dependent perceptual interpretation of an object is referred to as its affordance [44]. In neuroscience, the

tight relationship between action and perception is exemplified by the presence of mirror neurons, neurons that become active when an action is performed and when the action or a similar action is observed being performed by another agent. It is significant that these neurons are specific to the goal of the action and not the mechanics of carrying it out. The related Ideomotor Theory [45] asserts the existence of such a common or co-joint representational framework for perception and action. Such a framework would facilitate the inference of intention and the anticipation of an outcome of an event due to the goal-oriented nature of the action. The realization of an effective co-joint perception-action framework remains an important challenge for cognitivist and emergent approaches alike.

Although clearly there are some fundamental differences between the cognitivist and the emergent paradigms, the gap between the two shows some signs of narrowing. This is mainly due to (1) a recent movement on the part of proponents of the cognitivist paradigm to assert the fundamentally important role played by action and perception in the realization of a cognitive system [32]; (2) the move away from the view that internal symbolic representations are the only valid form of representation [2]; and (3) the weakening of the dependence on embedded a priori knowledge and the attendant-increased reliance on machine learning and statistical frameworks both for tuning system parameters and the acquisition of new knowledge. This suggests that hybrid approaches may be the way forward, especially if a principled synthesis of cognitivist and emergent approaches is possible, such as “dynamic computationalism” [2] or “computational mechanics” [46]. Hybrid approaches appear to many to offer the best of both worlds – the adaptability of emergent systems and the advanced starting point of cognitivist systems – since the representational invariances and representational frameworks need not be learned but can be designed in and since the system populates these representational frameworks through learning and experience. However, it is uncertain that one can successfully combine what are ultimately highly incompatible

underlying philosophies. Opinion is divided, with arguments both for (e.g., [2, 40, 46]) and against (e.g., [47]).

Definition

Cognitive vision refers to computer vision systems that can pursue goals, adapt to unexpected

changes of the visual environment, and anticipate the occurrence of objects or events.

Background

The field of cognitive vision grew from the broader area of computer vision in response to a need for vision systems that are more widely applicable, that are able adapt to novel scenes and tasks, that are robust to unexpected variations in operating conditions, and that are fast enough to deal with the timing requirements of these tasks [1]. Adaptability entails the ability to acquire knowledge about the application domain, thereby removing the need to embed all the required knowledge in the system when it is designed. Robustness allows the system to be tolerant to changes in environmental conditions so that system performance is not negatively impacted by them when carrying out a given task. Speed and the ability to pay attention to critical events are essential when providing feedback to users and devices in situations which change unexpectedly [2, 3].

While computer vision systems routinely address signal processing of sensory data and reconstruction of 3D scene geometry, cognitive vision goes beyond this by providing a capability for conceptual characterization of the scene structure and dynamics using qualitative representations. Having knowledge about the scene available in conceptual form allows the incorporation of consistency checks through the use of, e.g., logic inference engines. These checks can be applied both to the knowledge that is embedded in the system at the outset and the knowledge that the system learns for itself. Consistency checking applies across several scales of space and time, requiring cognitive vision to have an ability to operate with past, present, *and* future events. These consistency checks are one way in which the robustness associated with cognitive vision can be achieved [4]. Furthermore, the conceptual knowledge generated by cognitive vision can, if required, be communicated to a human user in natural language [5]. This linguistic communication is one manifestation of an autonomous system

demonstrating its understanding of the visual events in its environment [4].

Theory

Cognitive vision entails abilities to anticipate future events and to interpret a visual scene in the absence of complete information. To achieve this, a cognitive system must have the capacity to acquire new knowledge and to use it to fill in gaps that are present in what is being made immediately available by the visual sensors: to extrapolate in time and space to achieve a more robust and effective understanding of the underlying behavior of the sensed world. In the process, the system learns, anticipates, and adapts. These three characteristics of learning, anticipation, and adaptivity are the hallmarks of cognition, in general, and cognitive vision, in particular [6, 7].

A key property of cognitive vision is its capacity to exhibit a robust performance even in scenarios that were not anticipated when it was designed. The degree to which a system can deal with unexpected circumstances will vary. Systems that can adapt autonomously to arbitrary situations are unrealistic at present but it is plausible that they should be able to deal with new variants of visual form, function, and behavior, and also incremental changes in context. Ideally, a cognitive vision system should be able to recognize and adapt to novel variations in the current visual environment, generalize to new contexts and application domains, interpret and predict the behavior of agents detected in the system's environment, and communicate an understanding of the environment to other systems, including humans.

A cognitive vision system is a visually enabled cognitive system, defined in this encyclopedia as “an autonomous system that can perceive its environment, learn from experience, anticipate the outcome of events, act to pursue goals, and adapt to changing circumstances.” Since cognitive vision is principally a mode of perception, physical action – with the possible exception of the camera movements associated with active vision – usually falls outside its scope. However, speech acts may be involved when

communicating an interpretation of the scene in conceptual terms through language [8]. Since cognitive vision is a particular type of cognitive system, all the issues identified in the cognitive system entry in this encyclopedia apply equally to cognitive vision. They will not be revisited here apart from noting that there are several scientific perspectives on the nature of cognition and on how it should be modeled. Among these differing perspectives, there are two broad classes: the *cognitivist* approach based on symbolic information processing representational systems, and the *emergent systems* approach, encompassing connectionist systems, dynamical systems, and enactive systems, all based to a lesser or greater extent on principles of self-organization. A third class – *hybrid systems* – attempts to combine something from each of the cognitivist and emergent paradigms. The vast majority of cognitive vision systems adopt either a cognitivist or a hybrid approach, with matching cognitive architectures [9].

The term *visual cognition* is strikingly similar to the term *cognitive vision*. However, they are not equivalent. Visual cognition is a branch of cognitive psychology concerned with research on visual perception and cognition in humans [10–12]. It addresses several distinct areas such as object recognition, face recognition, scene understanding, visual attention (including visual search, change blindness, repetition blindness, and the control of eye movements), short-term and long-term visual memory, and visual imagery. It is also concerned with the representation and recognition of visual information currently being perceived by the senses and with reasoning about memorized visual imagery. Thus, visual cognition addresses many visual mechanisms that are relevant to cognitive vision but without necessarily treating the entire cognitive system or the realization of these mechanisms in artificial systems.

Application

Several applications of cognitive vision may be found in [13–15]. Examples include natural

language description of traffic behavior [8], autonomous control of cars [16], and observation and interpretation of human activity [17, 18].

Open Problems

All of the open problems associated with cognitive systems apply equally to cognitive vision. Three which are particularly relevant are highlighted here.

The first concerns embodiment [19]. There is no universal agreement on whether or not a cognitive vision system must be embodied. Even if it is, several forms of embodiment are possible. One form is a physical robot capable of moving in space, manipulating the environment, and experiencing the physical forces associated with that manipulation. Other forms of embodiment do not involve physical contact and simply require the system to be able to change the state of its visual environment, for example, a surveillance system which can control ambient lighting. These alternative forms of embodiment are consistent with the cognitivist and hybrid paradigms of cognition but do not satisfy the requirements of the emergent approach.

Learning in cognitive vision presents several significant challenges. Since cognitive vision systems do not have all the knowledge required to carry out their tasks, they need to learn. More specifically, they need to be able to learn in an incremental, continuous, open-ended, and robust manner, with learning and recognition being interleaved, and with both improving over time. Since the learning process will normally be effected autonomously without supervision, the learning technique needs to be able to distinguish between good and bad data, otherwise bad data may corrupt the representation and cause errors to become embedded and to propagate. Furthermore, the use of learning in several domains is required, including perceptual (spatiotemporal) and conceptual (symbolic) domains, as well as in mapping between them. The mapping from perceptual to conceptual facilitates communication, categorization, and reasoning, whereas the mapping from conceptual

to perceptual facilitates contextualization and embodied action. Learning may be interpreted in a restricted sense as the estimation of the parameter values that govern the behavior of models that have been designed into the system, or in a more general sense as the autonomous generation of mappings that represent completely new models.

The identification and achievement of goals in cognitive vision presents a further challenge. With cognitivist approaches, goals are specified explicitly by designers or users in terms of the required outcome of cognitive behavior. With emergent approaches, goals are more difficult to specify since cognitive behavior is an emergent consequence of the system dynamics. Consequently, they have to be specified in terms of constraints or boundary conditions on the system configuration, either through phylogenetic configuration or ontogenetic development, or both. It is a significant challenge to understand how implicit goals can be specified and incorporated, and how externally communicated goals can be introduced to the system from its environment or from those interacting with it, e.g., through some form of conditioning, training, or communication.

Definition

Color constancy is the ability to perceive colors as approximately constant even though the light entering the eye varies with the illuminant. Color constancy also names the field of research investigating the extent of this ability, i.e., the conditions under which a color is actually perceived as constant and which factors influence color constancy. Computer scientists working in the field of color constancy try to mimic this ability in order to produce images which are independent of the illuminant, i.e., color constant. Simple color constancy algorithms, also known under the name automatic white balance, are used in digital cameras to compute a color- corrected output image. The input of a color constancy

algorithm is often one image taken under an arbitrary illuminant, and the output of a color constancy algorithm is frequently the image as it would appear had it been taken with a canonical illuminant such as CIE Standard Illuminant D65 or a spectrally uniform illuminant.

Background

An introduction to computational color constancy is given by [1]. Color is a product of the brain [2]. When an observer perceives an object, processing starts with the retinal sensors. The sensors in the retina measure the light entering the eye. However, the light entering the eye is dependent on both the spectral characteristics of the illuminant and the reflectance properties of the object. Therefore, without any additional processing, the measured light varies with the illuminant.

In the eye, two different types of retinal sensors exist: rods and cones. The rods are used for viewing when little light is available. The cones are mostly used in bright light conditions for color vision. Three types of cones can be distinguished which absorb light primarily in the red, green, and blue parts of the spectrum. Similarly, a digital sensor often measures the incident light in three different parts of the spectrum and uses red, green, and blue sub-sensors. However, cameras with four sub-sensors, e.g., red, green, blue, and cyan, also exist.

Suppose that an observer views a diffusely reflecting surface which uniformly reflects the incident light. Now assume that the surface is illuminated by a candle. A candle emits more light toward the red part of the spectrum. The candle light will reach the surface where part of the light will be absorbed and the remainder will be reflected. Part of the reflected light enters the eye where it is measured. The sensitivity function of the sensors in combination with the amount of light entering the eye will determine how strongly the sensors respond. Now consider another illuminant with a higher color temperature, e.g., daylight or an electronic flash. Such an illuminant will emit more light toward the blue spectrum compared to the candle. If the same surface is

viewed with an illuminant that has a high color temperature, then the sensors shift their response toward the blue part of the spectrum. Assuming a normalized response of all three sensors, then the reflected light will have a red color cast when the surface is illuminated by a candle. The measured light will appear white during daylight, and it will have a blueish color cast for an illuminant with a high color temperature. The observer however will be able to call out the correct color of the surface independent of the illuminant. Color constancy algorithms try to mimic this ability by computing an image which is independent of the illuminant.

Theory

Let $I(\lambda, x, y)$ be the irradiance captured by either a digital sensor or by the eye at position (x, y) for wavelength λ . Let $S_i(\lambda)$ be the response function of sensor i . Then the response of the sensor $c_i(x, y)$ at position (x, y) is given by

$$c_i(x, y) = \int S_i(\lambda) I(\lambda, x, y) d\lambda.$$

The integration is done over all wavelengths to which the sensor responds. Assuming three receptors with sensitivity in the red, green, and blue parts of the spectrum, then $i \in \{r, g, b\}$. In this case, the measurement of the sensor is a three-component vector $\mathbf{c} = [c_r, c_g, c_b]$.

The irradiance I falling onto the sensor is a result of the light reflected from an object patch. Let $L(\lambda, x, y)$ be the irradiance falling onto a diffusely reflecting object patch which is imaged at position (x, y) of the sensor arrangement. Let $R(\lambda, x, y)$ be the reflectance of the imaged object patch. Thus,

$$I(\lambda, x, y) = G(x, y) R(\lambda, x, y) L(\lambda, x, y)$$

where $G(x, y)$ is a geometry factor which takes the orientation between the surface and the light source into account. For a diffusely reflecting surface, $G(x, y) = \cos \alpha$ where α is the angle between the unit vector which points from the

surface into the direction of the light source and the normal vector at the corresponding surface position. Thus, the sensor response can be written as

$$c_i(x, y) = G(x, y) \int S_i(\lambda) R(\lambda, x, y) L(\lambda, x, y) d\lambda.$$

C

From this equation, it is apparent that the sensor response depends on the orientation of the patch relative to the light source (because of $G(x, y)$); it depends on the sensitivity S_i of the sensor i , on the reflectance of the object patch $R(\lambda, x, y)$, and on the illuminant $L(\lambda, x, y)$.

Color constancy algorithms frequently assume that the sensitivity of the sensors is very narrow-band. Assuming that they have the shape of a delta function, $S_i = \delta(\lambda - \lambda_i)$, it holds that

$$c_i(x, y) = G(x, y) \int \delta(\lambda - \lambda_i) R(\lambda, x, y) L(\lambda, x, y) d\lambda,$$

$$c_i(x, y) = G(x, y) R(\lambda_i, x, y) L(\lambda_i, x, y).$$

This equation is often written in the form

$$c_i(x, y) = G(x, y) R_i(x, y) L_i(x, y)$$

where the only difference to the previous equation is that the index i is used instead of the parameter λ_i . In this treatment, sensor response, reflectance, and the illuminant is considered only for three distinct wavelengths, i.e., color bands, with $i \in \{r, g, b\}$.

A color constancy algorithm tries to discount the illuminant by computing a color constant descriptor $d(\mathbf{c})$ which is independent of the illuminant $\mathbf{L}(x, y) = [L_r(x, y), L_g(x, y), L_b(x, y)]$. Geusebroek et al. [3] have derived several different descriptors which can be computed from \mathbf{c} and are invariant to some imaging conditions such as viewing direction, surface orientation, highlights, illumination direction, illumination intensity, or illumination color. Apart from computing a color constant descriptor, a color constancy algorithm usually tries to output an image of the scene which would

either correspond to the perception of a human photographer observing the scene or it would correspond to the image that would have resulted if a spectrally uniform illuminant or illuminant D65 had been used.

An ideal solution to the problem of color constancy would be to compute $\mathbf{R}(x, y) = [R_r(x, y), R_g(x, y), R_b(x, y)]$ from the sensor responses. It is of course clear that this problem cannot be solved without making additional assumptions, because for each position on the sensor array, one only has three measurements, but there are seven unknowns (shading, reflectance, and illumination components). Note that the above model for image generation is already a simple model assuming narrowband sensor responses.

A frequently made assumption is that the illuminant varies slowly over the image, while reflectance is able to change abruptly between sensor responses. Since color constancy algorithms are based on certain assumptions, they will not work correctly if the assumptions are violated. In many cases, it is possible to find images where the color constancy algorithm does not perform as intended. The goal is to develop algorithms which perform well on most everyday scenes.

Simple Algorithms

If a single illuminant illuminates the scene uniformly, i.e., $L_i(x, y) = L_i$, then it suffices to estimate a three-component vector $\tilde{\mathbf{L}}$ from all the measured sensor responses with $\tilde{\mathbf{L}} \approx \mathbf{L}$. Given an estimate $\tilde{\mathbf{L}}(x, y)$, a color constant descriptor can be computed by dividing the sensor response by the estimate of the illuminant.

$$\begin{aligned} \frac{c_i(x, y)}{\tilde{L}_i(x, y)} &= \frac{G(x, y)R_i(x, y)L_i(x, y)}{\tilde{L}_i(x, y)} \\ &\approx \frac{G(x, y)R_i(x, y)L_i(x, y)}{L_i(x, y)} \\ &= G(x, y)R_i(x, y) \end{aligned}$$

Such an output image will be a shaded reflectance image. In other words, a diagonal color transform suffices if the sensor response is very narrow-band. Some color constancy algorithms, however,

also use a general 3×3 matrix transform or work with higher polynomial base functions to compute a color-corrected output image [4].

It is also possible to transform a given image taken under one illuminant \mathbf{L} to another image taken under a different illuminant \mathbf{L}' . This can be done by multiplying each sensor response vector by a diagonal matrix whose elements are set to $k_i = \frac{L'_i}{L_i}$. The coefficients k_i are called von Kries coefficients. Necessary and sufficient conditions on whether von Kries chromatic adaptation gives color constancy have been derived by [5].

A simple algorithm to estimate the color of the illuminant is the white patch Retinex algorithm. It is a simplified version of the parallel Retinex algorithm [6]. In order to understand how this algorithm works, suppose that a white patch, i.e., a uniformly reflecting patch, is contained in the imaged scene which is uniformly illuminated. Assuming a normalized sensor response, then the response of the sensors on the white patch will be an estimate of the illuminant. For the white patch, it holds that $R_i = 1$ which leads to $c_i(\text{white patch}) = GL_i$. The white patch algorithm treats each color band separately and searches for the maximum response which is assumed to be an estimate of the illuminant.

$$\tilde{L}_i = \max_{x, y} c_i(x, y)$$

Instead of locating the maximum response, one can also compute a histogram of the sensor responses and then set the estimate of the illuminant at some percentage from above. This will lead to a more robust estimate of the illuminant. Figure 1b shows the output of the white patch Retinex algorithm for a sample image shown in Fig. 1a. The illuminant was estimated at 5% from above using a histogram approach for each color band.

Another simple algorithm is based on the gray-world assumption which is due to [7]. According to Buchsbaum, the world is gray on average. Let a_i be the global average of all sensor responses for color channel i where n is the number of sensors.

Color Constancy, Fig. 1 (a) sample input image (b) results for the white patch Retinex algorithm using a histogram (c) results for the gray-world assumption

$$a_i = \frac{1}{n} \sum_{x,y} c_i(x, y) = \frac{1}{n} \sum_{x,y} G(x, y) R_i(x, y) L_i(x, y)$$

$$a_i = \frac{k}{2} L_i.$$

Assuming a uniform illuminant $L_i(x, y) = L_i$ and an independence between shading and reflectance, then

$$\begin{aligned} a_i &= L_i \frac{1}{n} \sum_{x,y} G(x, y) R_i(x, y) \\ &= L_i E[G(x, y) R_i(x, y)] \\ &= L_i E[G(x, y)] [R_i(x, y)] \end{aligned}$$

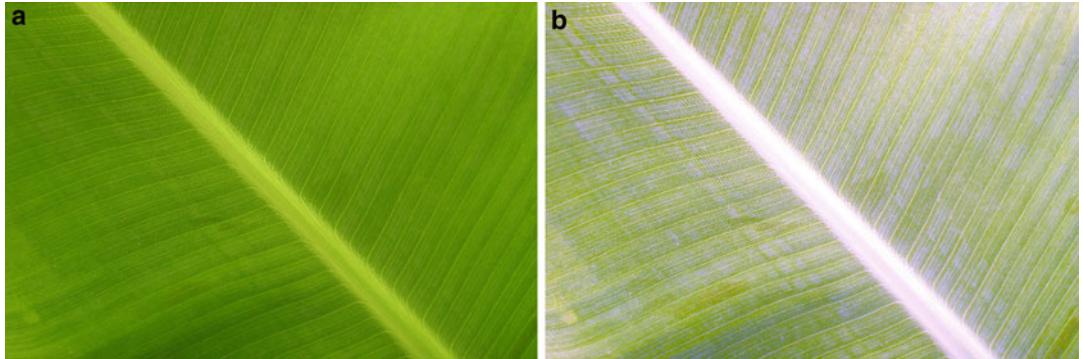

where $E[x]$ denotes the expected value of x . Suppose that a large number of differently colored objects are contained in the scene. Thus, a uniform distribution of colors is assumed. This results in $E[R_i(x, y)] = \frac{1}{n} \sum_{x,y} R_i(x, y) = \frac{1}{2}$ assuming a range of $[0, 1]$ for reflectances and $E[G(x, y)] = k$ where k is a constant. The result is

Hence, the illuminant is proportional to global space average color $L_i \propto a_i$, and an estimate of the illuminant can be obtained by setting

$$\tilde{L}_i = 2a_i.$$

Using $k = 1$ assumes that all patches are frontally oriented or alternatively that the geometry factor is subsumed into a combined reflectance and geometry factor. Figure 1c shows the results for the gray-world assumption on a sample image. Figure 2 shows the results for another image where the assumption that a large number of different-colored objects are contained in the scene is not fulfilled. In this case, the gray-world assumption will not work correctly.

Most color constancy algorithms estimate the illuminant as a three-component descriptor $\tilde{\mathbf{L}}$. If the actual illuminant \mathbf{L} is known for an image, then it is possible to compute the angular error e

Color Constancy, Fig. 2 (a) image of a leaf from a banana plant (b) results for the gray-world assumption

between the estimated illuminant and the actual illuminant for a given image.

$$e = \cos^{-1} \frac{\tilde{\mathbf{L}} \cdot \mathbf{L}}{|\tilde{\mathbf{L}}| |\mathbf{L}|}$$

Van de Weijer et al. [8] have introduced the gray-edge hypothesis. While the gray-world assumption suggests that the world is gray on average, the gray-edge hypothesis suggests that image derivatives are gray on average. Van de Weijer et al. also showed that several seemingly different color constancy algorithms can be treated using a uniform paradigm. Only three parameters suffice to describe many color constancy algorithms. Let $G_\sigma(x, y)$ be a Gaussian filter with scale parameter σ . Let p be the Minkowski norm and let n be the order of the derivative, then the illuminant $\tilde{\mathbf{L}}(n, p, \sigma)$ can be estimated using these three parameters

$$\tilde{\mathbf{L}}(n, p, \sigma)$$

$$= \frac{1}{k} \left(\iint |\nabla^n \mathbf{c}(x, y) \otimes G_\sigma(x, y)|^p dx dy \right)^{\frac{1}{p}}$$

where k is a scaling factor and \otimes denotes convolution. Figure 3 shows which color constancy algorithms correspond to which parameters. The shades of gray algorithm uses the Minkowski norm p . The higher the Minkowski norm p , the higher the emphasis on larger measurements.

Brainard and Freeman [9] have addressed the problem of color constancy using Bayesian

decision theory. Color constancy can also be learned. Bianco et al. [10] have trained a convolutional neural network to predict scene illumination. Their approach estimates the illuminant locally. If the local illuminant estimates are sufficiently similar, then a uniform illuminant illuminating the entire scene is assumed, and pooling is used to arrive at a single illuminant. Cheng et al. [11] trained regression trees to estimate the illuminant based on simple image features. Barron and Tsai [12] treat illuminant estimation as a spatial localization task in the context of a convolutional neural network. In turn, a complete posterior distribution over illuminants is created instead of computing a single illuminant estimate. Because most natural scene illumination is not arbitrary but biased (e.g., sunlight with varying color temperatures or artificial lighting), a color constancy algorithm based on learning techniques can make use of this bias and achieve state-of-the-art performance.

Uniform vs Nonuniform Illumination

Many color constancy algorithms assume that the scene is uniformly illuminated by a single illuminant. If multiple light sources are distributed over the scene, then it is assumed that these light sources can be combined into a single average illuminant. This is possible provided that the light sources are sufficiently distant from the scene. If the illumination is uniform, then only a three-component descriptor has to be estimated from the input image. However, in practice, many scenes are illuminated nonuniformly.

Color Constancy, Fig. 3

Classification of color constancy algorithms based on derivative number n , Minkowski norm p and gaussian smoothing σ

| Algorithm | n | p | σ |
|---|-----|----------|----------|
| Gray World Assumption | 0 | 1 | 0 |
| White Patch Retinex | | ∞ | 0 |
| Shades of Gray | | p | 0 |
| Gray Edge | | 1 | σ |
| Local Space Average Color (with Gaussian Smoothing) | 0 | 1 | σ |

Very often, one has several different illuminants. For instance, daylight may be falling through a window, while artificial lights have already been turned on inside a building. Nonuniform illumination may also be present outside during a sunny day. Consider a family sitting in the garden under a red umbrella and a photographer taking a photograph of the family members. The family would be illuminated by light reflected from the red umbrella, while the surrounding would be illuminated by direct sunlight. A digital camera usually corrects for a single illuminant. Thus, either the family members would have a red color cast to them or the background colors would not look right in the resulting image.

Algorithms have also been developed which can cope with a spatially varying illuminant. Land and McCann's Retinex algorithm [6] is a parallel algorithm for color constancy which allows for a nonuniform illumination. They only considered one-dimensional paths over the sensor array. Horn [13] extended Land's Retinex algorithm to two dimensions. Barnard et al. [14] extended the 2D gamut constraint algorithm to scenes with varying illumination. Bianco et al. [10] estimate illumination locally using a convolutional neural network.

Ebner [1] developed a computational model for color perception. Most computational color constancy algorithms cannot be mapped readily to the processing done by the human brain. Apart from providing excellent color constancy performance, a correct model also needs to be in line with data from experimental psychology. For instance, color perception seems to improve if an observed object moves [15]. Of course all algorithms based on neural networks can be mapped to the human brain. Neurons responding strongly whenever a patch with a certain color is presented to an observer irrespective of the illumination

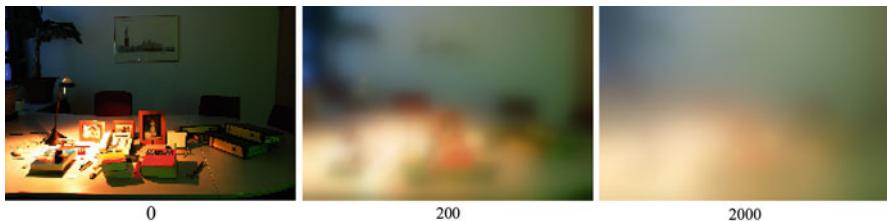

have been found in visual area V4 [2]. It appears that the final stages of color constancy processing are performed by the brain in V4. A review of cortical mechanisms of color vision is given by [16].

Laterally connected neurons are able to estimate the color of the illuminant locally using the gray-world assumption [1]. Each neuron or processing element receives the raw measurement c_i from the sensor. Using the lateral connections, it is possible to compute local space average color. Let $a_i(x, y)$ be the current estimate of local space average color for a processing element located at position (x, y) . Each processing element receives the estimate of local space average color from neighboring elements and averages the neighboring estimates to update its own estimate. A small component from the sensor measurement is then added to this estimate. Let p be a small percentage and let $N(x, y)$ be the neighborhood of the processing element at position (x, y) , then the computation of a processing element consists of the following two updates:

$$a'_i(x, y) = \frac{1}{|N(x, y)|} \sum_{(x', y') \in N(x, y)} a_i(x', y')$$

$$a_i(x, y) = (1 - p)a'_i(x, y) + pc_i(x, y)$$

The two updates are carried out iteratively. This process converges to local space average color which is an estimate of the illuminant, $\tilde{L}_i(x, y) = 2a_i(x, y)$. Figure 4 shows local space average color after 0, 200 and 2000 iterations using $p = 0.0001$ given the input image shown in Fig. 5b. The extent of the averaging is determined by the parameter p , i.e., the strength of the lateral connections. Figure 5c, d shows the output when local space average color is used to estimate the illuminant locally. Local average color was computed for a down-scaled image (25% in each

Color Constancy, Fig. 4 Local space average color after 0, 200 and 2000 iterations

Color Constancy, Fig. 5 (a and b) input images (c and d) results using local space average color

direction) the original image had 768×512 pixels.

However, other approaches may also be used by the human visual system. Gao et al. [17] suggest that a maximum operation on the output of the double-opponent cells might be used.

Advanced Reflectance Models

The theoretical model of color image formation, which has been given above, assumed that objects diffusely reflect the incident light. This is not the case for all surfaces, e.g., brushed metal or plastics. Especially for plastic objects or objects

covered with gloss varnish a more elaborate reflectance model is more appropriate. The dichromatic reflection model [18] assumes that reflectance is composed of interface reflectance, which occurs at the boundary between the object's surface and air, and body reflectance which is due to the scattering of light below the object's surface. In other words, the reflection of light from the object's surface is assumed to be partially specular and partially diffuse. Color constancy algorithms have also been developed using the dichromatic reflection model. Some algorithms also work with multispectral images

and try to recover the full spectrum of the illuminant (see [19]).

Application

Color constancy algorithms are ideal for color correction in digital photography. In digital photography, the goal is to obtain a color-corrected image that corresponds nicely to human perception. A printed photograph or a photograph viewed on a computer display should appear in exactly the same way that the human observer (the photographer) perceived the scene. Besides digital photography, color constancy algorithms can be applied in the context of most computer vision tasks. For many tasks, one should try to estimate object reflectances. For instance, image segmentation would not be as difficult, if object reflectance could be correctly determined. Similarly, color-based object recognition is easier if performed on reflectance information. Thus, color constancy algorithms should often be applied as a pre-processing step. This holds especially for autonomous mobile robots equipped with a vision system because autonomous mobile robots need to operate in different environments under different illuminants.

Experimental Results and Datasets

A comparison of computational color constancy algorithms is given by [20] for synthetic as well as real image data. Extensive comparisons are also given by [10–12]. Data for computer vision and computational color science can be found at the Simon Fraser University, Canada (www2.cs.sfu.ca/~colour/data/). A repository has also been created by the color group at the University of East Anglia, UK (colour.cmp.uea.ac.uk/datasets/). A multi illuminant data set is available from the Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany (www5.cs.fau.de/research/data/multi-illuminant-dataset/).

Definition

A color model is a mathematical model describing the way colors are specified by

three-dimensional coordinates in such terms as three numerical values, three perceptual attributes, or three primary colors.

Background

The human retina contains three types of cones L, M, and S as photoreceptors, which respond best to light of long, medium, and short wavelengths, respectively, in the visible range. Since the perception of color depends on the response of these cones, it follows in principle that visible color can be mapped into a three-dimensional space in terms of three numbers.

Trichromatic color vision theory is closely related to such three types of color sensors. The trichromatic theory by Young and Helmholtz suggests that any colors and spectra in the visible range can be visually matched using mixtures of three primary colors. These primary colors are usually red, green, and blue. Most image output devices such as television screens, computer and video displays, and image projectors create visible colors by using additive mixtures of the three primary colors.

Digital cameras also capture color by using the same principle of trichromatic color vision. They usually use three different types of sensors which primarily respond to the red, green, and blue parts of the visible spectrum. Therefore, a color model mathematically describing the color coordinate system is crucial for analysis, evaluation, and the rendering of color images.

Theory

Color Model for RGB Color Signals

Most color models used in computer vision and image processing are based on the RGB primaries. This is because color images captured by digital cameras are all represented by the RGB primaries, and image output devices such as displays and projectors are based on an additive mixture of the RGB primaries. Therefore, the simplest color model (called RGB color space) uses a Cartesian coordinate system defined by

(R, G, B) triples. This system, however, is not available for colorimetry, because the spectral-sensitivity curves of cameras are generally not coincident with the color-matching functions.

The RGB space is not a perceptually uniform color space. In computer graphics and image processing applications, approximately uniform spaces derived from RGB are defined in terms of the three attributes: hue (H), saturation (S), and value (V) (representing lightness). For example, the HSV model by Smith [9] was defined as a nonlinear transform of RGB given in 8 bits:

$$\begin{aligned} H &= \tan^{-1} \left\{ \frac{\sqrt{3}(g-b)}{(r-g)+(r-b)} \right\} \\ S &= 1 - \text{Min}/V \end{aligned} \quad (1)$$

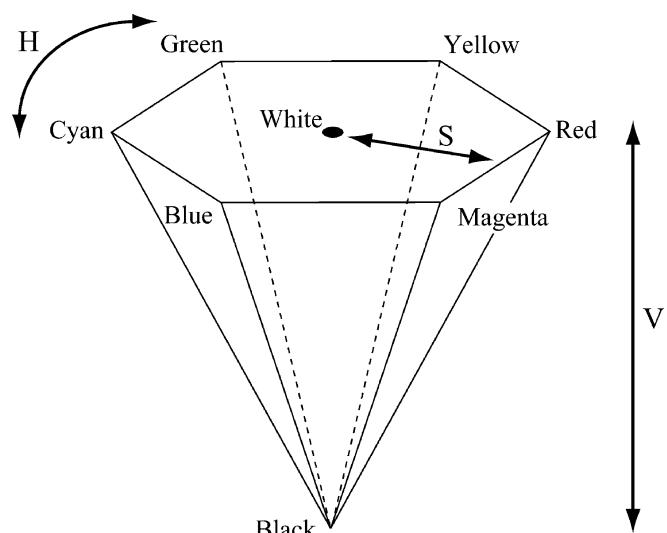

$$V = \text{Max}$$

where

$$\begin{aligned} r &= R/255, \quad g = G/255, \quad b = B/255, \\ \text{Max} &= \max(r, g, b), \quad \text{Min} = \min(r, g, b). \end{aligned}$$

This model represents a hexagonal color space as seen in Fig. 1, where the saturation decreases monotonically as the value decreases. Figure 2 represents the improved HSV model to a double hexagonal space, which is defined as:

Color Model, Fig. 1
Single hexagonal color space

$$\begin{aligned} H &= \tan^{-1} \left\{ \frac{\sqrt{3}(g-b)}{(r-g)+(r-b)} \right\} \\ S &= \text{Max} - \text{Min} \end{aligned} \quad (2)$$

$$V = (R+g+b)/3$$

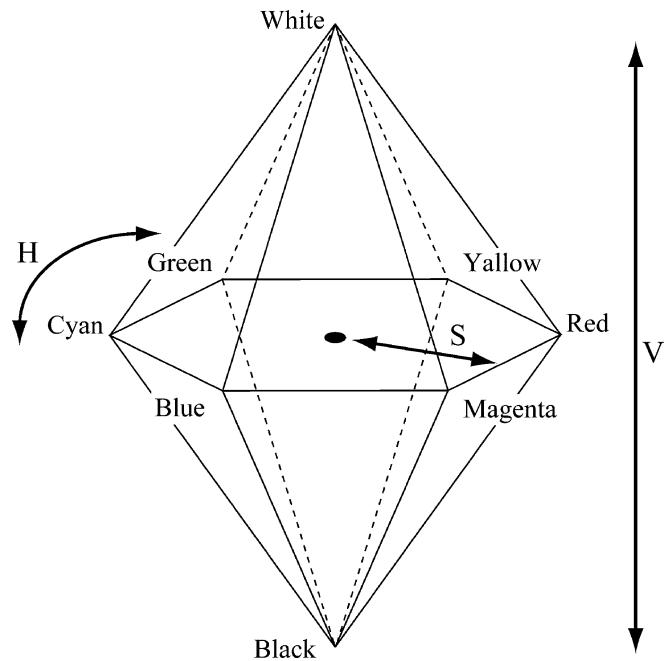

Color Model for Colorimetry

The CIE-XYZ color system for colorimetry was created by the International Commission on Illumination (CIE). This color system was derived from a series of visual experiments of color matching [1]. The tristimulus values of a color were used for representing the amounts of three primary colors needed to match the test color. The tristimulus values depend on the observer's field of view. Therefore, the CIE defined the standard observer and a set of three color-matching functions, called $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$. The chromatic response of the standard observer is characterized by the three color-matching functions. Figure 3 shows the CIE 1931 2° standard observer color-matching functions.

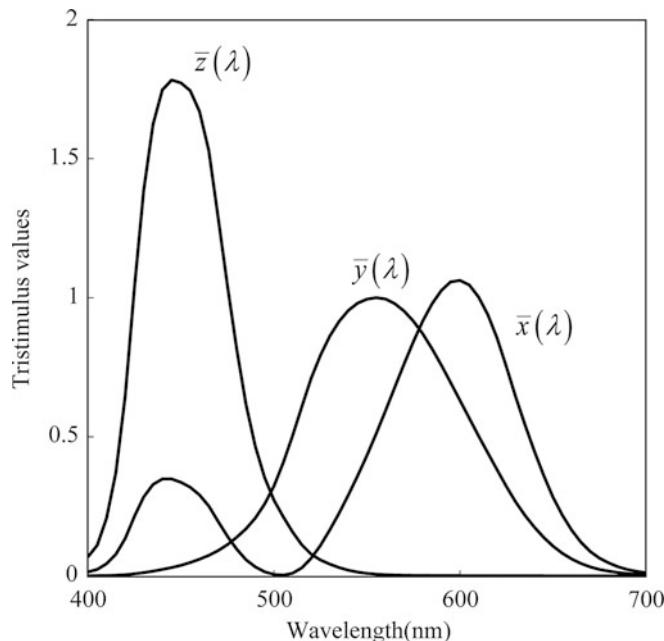

The tristimulus values for a color signal with a spectral-power distribution $L(\lambda)$ are then given by:

$$\begin{aligned} X &= k \int_{\lambda} L(\lambda) \bar{x}(\lambda) d\lambda \\ Y &= k \int_{\lambda} L(\lambda) \bar{y}(\lambda) d\lambda \\ Z &= k \int_{\lambda} L(\lambda) \bar{z}(\lambda) d\lambda \end{aligned} \quad (3)$$

Color Model, Fig. 2
Double hexagonal color space

Color Model, Fig. 3 CIE 1931 2° standard observer color-matching functions

where the integration on the wavelength λ is normally calculated over the range of visible spectrum 400–700 nm, and the coefficient k is a normalizing constant. In application to photometry, the Y tristimulus value becomes the luminance of the color signal. In application to object color, the tristimulus values become:

$$\begin{aligned} X &= k \int_{\lambda} E(\lambda) S(\lambda) \bar{x}(\lambda) d\lambda \\ Y &= k \int_{\lambda} E(\lambda) S(\lambda) \bar{y}(\lambda) d\lambda \\ Z &= k \int_{\lambda} E(\lambda) S(\lambda) \bar{z}(\lambda) d\lambda \end{aligned} \quad (4)$$

where $S(\lambda)$ is the surface-spectral reflectance of the illuminated object, and $E(\lambda)$ is the spectral-power distribution of the light source illuminating the object. In this case, the Y tristimulus value becomes the luminance factor of the object-color stimulus. The constant factor is usually chosen as:

$$k = 100 \left/ \int_{\lambda} S(\lambda) \bar{x}(\lambda) d\lambda \right.. \quad (5)$$

The chromaticity coordinates (x, y) of a given color are defined as:

$$x = \frac{X}{X + Y + Z}, \quad y = \frac{Y}{X + Y + Z}. \quad (6)$$

Figure 4 depicts the chromaticity diagram, where all visible chromaticities are located within the horseshoe-shaped region. The outer curved boundary is the spectral locus, corresponding to monochrome light with the most saturated color. Less saturated colors are located in the inside of the region with white at the center. The triangle of sRGB represents the gamut of a standard RGB color space proposed by HP and Microsoft in 1996 [10]. Recently, usual monitors, printers, and the Internet are based on this standard space. The triangle of Adobe RGB represents the gamut of an RGB color space developed by Adobe Systems in 1998 [11]. This color space, improving the gamut of sRGB primarily in cyan-green, is used for desktop publishing.

It should be noted that the CIE XYZ tristimulus values were not defined for color differences. Two colors with a constant difference in the tristimulus values may look very different, depending on where the two colors are located in the (x, y) chromaticity diagram.

Color Model for Uniform Color Space

Many people believe that a uniform color space is most useful for applications where perceptual errors are evaluated. The CIE 1976 $L^*a^*b^*$ color system (also called CIE LAB color system) was designed to approximate a perceptually uniform color space in terms of the tristimulus values

XYZ. It is defined as follows:

$$\begin{aligned} L^* &= 116(Y/Y_n)^{1/3} - 16 \\ a^* &= 500[(X/X_n)^{1/3} - (Y/Y_n)^{1/3}] \\ b^* &= 200[(Y/Y_n)^{1/3} - (Z/Z_n)^{1/3}] \end{aligned} \quad (7)$$

C

where (X_n, Y_n, Z_n) are the tristimulus values of the reference white point. This system provides an opponent-color space with dimension L^* for lightness and a^* and b^* for opponent-color dimensions. $L^*=0$ and $L^*=100$ indicate black and white, respectively. The axes of a^* and b^* take the position between red and green and the position between yellow and blue, respectively.

The two-dimensional chromaticity diagram is expressed in the orthogonal coordinate system of (a^*, b^*) . The chromaticity components can also be expressed in a cylindrical system of chroma and hue, where the chroma and hue angle are defined respectively by:

$$\begin{aligned} C_{ab}^* &= (a^{*2} + b^{*2})^{1/2} \\ h_{ab} &= \arctan^{-1}(b^*/a^*) \end{aligned} \quad (8)$$

The color difference between two color stimuli 1 and 2 is defined as follows:

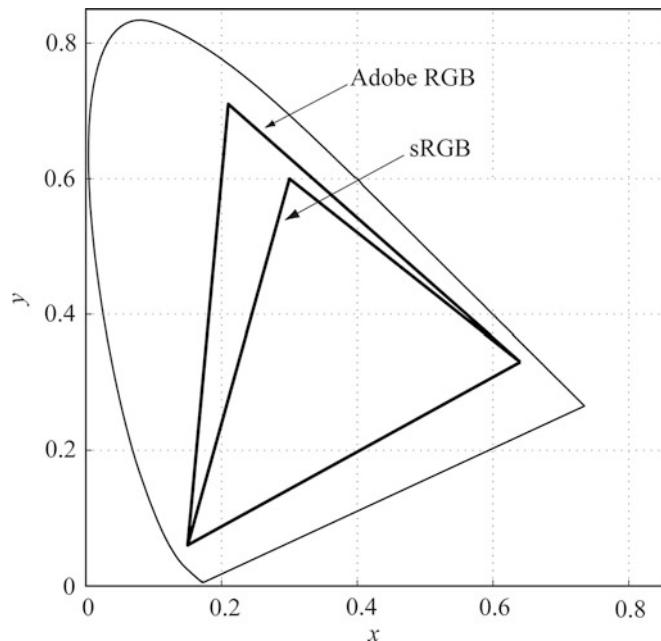

$$\Delta E_{ab}^* = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}, \quad (9)$$

where $\Delta L^* = L_1^* - L_2^*$, $\Delta a^* = a_1^* - a_2^*$, and $\Delta b^* = b_1^* - b_2^*$. Figure 5 depicts the Munsell color system with value 5 on the (a^*, b^*) chromaticity coordinates under the reference condition of illuminant D_{65} . The color system approximates roughly the Munsell uniform color space.

Color Model for Color Order System

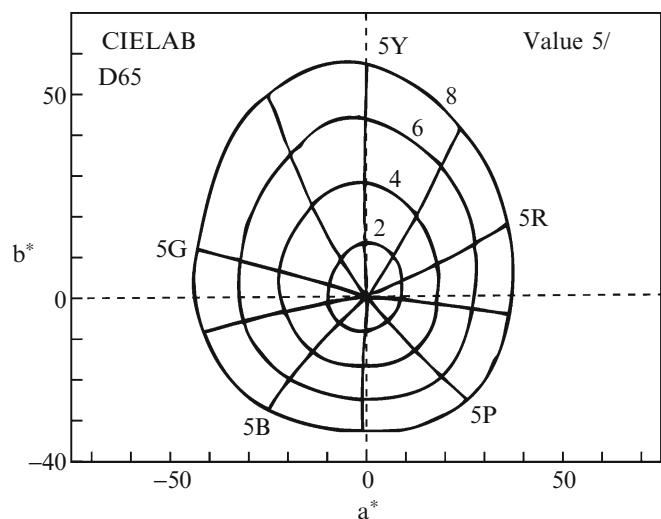

Color order systems were created to order colors in terms of intuitive perceptual attributes. Most colored samples, used as a reference in many design and engineering applications, are made in equal steps of perceptual attributes.

Color Model, Fig. 4 CIE 1931 chromaticity diagram

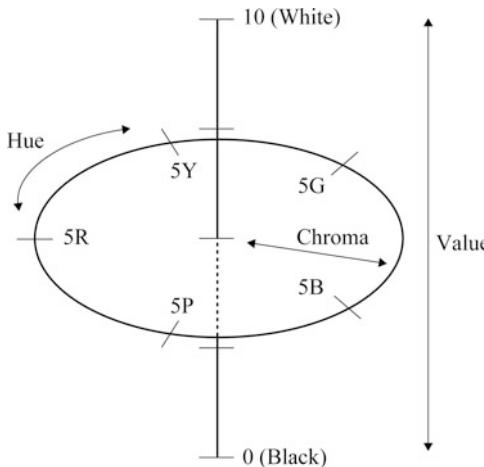

Color Model, Fig. 5

Munsell color system with Value 5 on the (a^* , b^*) chromaticity coordinates

The Munsell color order system is one of the most widely used systems in the world. This system is based on the three perceptual attributes, hue, value (representing lightness), and chroma (representing saturation), and is organized in a cylindrical coordinate system as shown in Fig. 6. Hue is arranged as a circle, value as the axis perpendicular to the hue circle and chroma as the distance from the center.

The Munsell color samples are arranged in equal steps of each attribute, where each sample is described using a three-part syntax of hue chroma/value. For example, 5YR 8/4 indicates a color sample with the hue of 5YR (yellow-red), the chroma of level 4, and the value of level 8. A conversion table to reproduce the Munsell color samples in terms of the CIE tristimulus values was given by Newhall et al. [12]. The table

Color Model, Fig. 6 Organization of the Munsell color system

contains the luminance factor Y and chromaticity coordinates (x, y) equivalent to the Munsell notation system (H, V, C), under the condition of the CIE standard illuminant C. It should be noted that there is no formula for a color notation conversion between the Munsell and CIE system, except for the table. Therefore, the conversion was carried out by interpolating the table data.

Obviously, this method is not efficient from the point of view of mass data processing by computers. Tominaga [13] developed a method for color notation conversion, between the Munsell and CIE systems by means of neural networks. In the neural network method, it is not necessary to use the special database of color samples. This is because the knowledge of conversion between the two color spaces is stored in a small set of the weighting parameters in a multilayer feedforward network.

Definition

Color similarity is a measure that reflects the strength of relationship between two colors.

Background

A measure of similarity between colors is needed when one color region is matched to another region among color images, for example, a purple region is more similar to a blue region than a green region. Therefore, the similarity between two colors is an important metric in not only color science but also imaging science and technology (including computer vision). If color similarity is measured, it allows people to determine the strength of relationship in terms of numerical values; otherwise, it will be determined in non-numerical ways.

Thus, the benefit of color similarity is its application to various techniques of image analysis, such as noise removal filters, edge detectors, object classification, and image retrieval.

Theory

Color similarity is usually represented in the range of either interval $[-1, 1]$ or interval $[0, 1]$. Let $\mathbf{x}_i = [x_{i1}, x_{i2}, x_{i3}]$ be a three-dimensional vector specifying a color feature at location i in a color image. The similarity measure $s(\mathbf{x}_i, \mathbf{x}_j)$ between two color features is a symmetric function whose value is larger when color features \mathbf{x}_i and \mathbf{x}_j are closer. The color feature is specified by three coordinates in color space (or color model). Color space is defined in many different ways in color and image science, where color spaces such as RGB, L*a*b*, L*u*v*, YIQ, and HSI are often used.

On the other hand, color dissimilarity is also used for measuring the discrepancy between two colors. This quantity is usually represented in a positive range of $[0, 1]$ because the dissimilarity is measured by a “normalized distance” between two colors. A dissimilarity measure $d(\mathbf{x}_i, \mathbf{x}_j)$ is a symmetric function whose value is larger

when color features \mathbf{x}_i and \mathbf{x}_j are more dissimilar. Therefore, a relationship between two measures of color similarity and color dissimilarity is given by:

$$s(\mathbf{x}_i, \mathbf{x}_j) = 1 - d(\mathbf{x}_i, \mathbf{x}_j), \quad (1)$$

where the color similarity $s(\mathbf{x}_i, \mathbf{x}_j)$ is bounded by $[0, 1]$. Note that when the color similarity is one (i.e., exactly same), the color dissimilarity is zero, and when color similarity is zero (i.e., quite different), the color dissimilarity is one. If the color similarity is defined in the range $[-1, 1]$, then:

$$s(\mathbf{x}_i, \mathbf{x}_j) = 1 - 2d(\mathbf{x}_i, \mathbf{x}_j). \quad (2)$$

Note in this case that the color dissimilarity of 1 (i.e., quite different) corresponds to the color similarity of -1 , and when the color dissimilarity of 0 (i.e., exactly same) corresponds to the color similarity of 1. In many cases, measuring dissimilarity is easier than measuring similarity. Once dissimilarity is measured, it can easily be normalized and converted to the similarity measure. Therefore, color dissimilarity measures are first described in the following.

Color Dissimilarity Measures

The most commonly used dissimilarity measure to quantify the distance between two color vectors

\mathbf{x}_i and \mathbf{x}_j is the weighted Minkowski metric:

$$d(\mathbf{x}_i, \mathbf{x}_j) = c \left(\sum_{k=1}^3 \xi_k |x_{ik} - x_{jk}|^L \right)^{1/L}, \quad (3)$$

where c is the nonnegative scaling parameter for $d(\mathbf{x}_i, \mathbf{x}_j) \in [0, 1]$ and the exponent L defines the nature of the distance metric. The parameter ξ_k , for $\sum_k \xi_k = 1$, measures the weight assigned to the color channel k . Usually it is determined $\xi_k = 1/3, \forall k$ (e.g., [1,2]). In the case $L = 1$ in (3), the measure is known as Manhattan distance, which is also called city-block distance, absolute value distance, and taxicab distance [3].

$$d(\mathbf{x}_i, \mathbf{x}_j) = c \sum_{k=1}^3 |x_{ik} - x_{jk}|. \quad (4)$$

The dissimilarity measure represents distance between points in a city road grid. It examines the absolute differences between a pair of colors. In the case $L = 2$ in (3), the measure is known as Euclidean distance which is the most common use of distance.

$$d(\mathbf{x}_i, \mathbf{x}_j) = c \left(\sum_{k=1}^3 (x_{ik} - x_{jk})^2 \right)^{1/2}. \quad (5)$$

In the case $L \rightarrow \infty$ in (3), the measure is known as Chebyshev distance which is also called Kolmogorov-Smirnov Statistic [4], chessboard distance, and maximum value distance. It examines the absolute magnitude of the differences between coordinates of a pair of objects.

$$d(\mathbf{x}_i, \mathbf{x}_j) = c \max_k |x_{ik} - x_{jk}|. \quad (6)$$

As a well-known dissimilarity metric based on the Minkowski metric, [6] color difference ΔE_{ab}^* is useful [5, 7]. ΔE_{ab}^* is the Euclidean distance between two colors in CIEL*a*b* color space as follows:

$$\Delta E_{ab}^*(\mathbf{x}_i, \mathbf{x}_j) = \left((L_i^* - L_j^*)^2 + (a_i^* - a_j^*)^2 + (b_i^* - b_j^*)^2 \right)^{1/2}, \quad (7)$$

where $\mathbf{x}_i = [L_i^*, a_i^*, b_i^*]$ and $\mathbf{x}_j = [L_j^*, a_j^*, b_j^*]$. Please note that ΔE_{ab}^* is used as a “distance” with $c = 1$ in (5). When $\Delta E_{ab}^* \approx 2.3$, it corresponds to a just noticeable difference (JND) of surface colors [8, 9]. Perceptual nonuniformities in the underlying CIEL*a*b* color space, however, have led to the CIE refining their 1976 definition over the years. The refined color difference ΔE_{94}^* is defined in the L*C*h color space [10]. Given a reference color $\mathbf{x}_i = [L_i^*, C_i^*, h_i^*]$ and another color $\mathbf{x}_j = [L_j^*, C_j^*, h_j^*]$, the difference is:

$$\Delta E_{94}^*(\mathbf{x}_i, \mathbf{x}_j) = \left(\left(\frac{L_i^* - L_j^*}{K_L} \right)^2 + \left(\frac{C_i^* - C_j^*}{1 + K_1 C^*} \right)^2 + \left(\frac{h_i^* - h_j^*}{1 + K_2 C^*} \right)^2 \right)^{1/2} \quad (8)$$

where C^* represents the geometrical average of chroma, and K_L , K_1 , and K_2 represent the weighting factors which depend on the application (in original definition, $K_L = 1$, $K_1 = 0.045$, and $K_2 = 0.015$ for graphic arts). Since the 1994 definition did not adequately resolve the perceptual uniformity issue, the CIE refined their definition, adding five corrections:

1. A hue rotation term (RT), to deal with the problematic blue region
2. Compensation for neutral colors
3. Compensation for lightness
4. Compensation for chroma
5. Compensation for hue

The definition of the CIEDE2000 color difference is explained in Ref. [11].

Color Similarity Measure

The simplest color similarity measure is an angular separation similarity. It represents a cosine angle between two color vectors, which is often called as coefficient of correlation. In this measure, similarity in orientation is expressed through the normalized inner product as:

$$s(\mathbf{x}_i, \mathbf{x}_j) = \mathbf{x}_i \cdot \mathbf{x}_j / |\mathbf{x}_i| |\mathbf{x}_j| \quad (9)$$

which corresponds to the cosine of the angle between the two color vectors \mathbf{x}_i and \mathbf{x}_j . Since similar colors have almost parallel orientations, (*while significantly different colors point in different directions in a 3-D color space*) the normalized inner product can be used to quantify orientation similarity between the two color vectors.

The correlation coefficient is a standardized angular separation by centering the coordinates to their mean value. Let $\bar{x}_i = \frac{1}{p} \sum_{k=1}^p x_{ik}$ and $\bar{x}_j = \frac{1}{p} \sum_{k=1}^p x_{jk}$; the correlation coefficient

between these two vectors \mathbf{x}_i and \mathbf{x}_j is given as follows:

$$s(\mathbf{x}_i, \mathbf{x}_j) = \frac{\sum_{k=1}^p |x_{ik} - \bar{x}_i| |x_{jk} - \bar{x}_j|}{\left(\sum_{k=1}^p (x_{ik} - \bar{x}_i)^2\right)^{1/2} \left(\sum_{k=1}^p (x_{jk} - \bar{x}_j)^2\right)^{1/2}}. \quad (10)$$

In (10) the color similarity between two points is shown as $p = 3$ shows. Then the correlation coefficient can be applied to color region similarity, such as textured regions by setting $p = 3 \times n$ (where n is the number of pixels).

There are many other methods to measure the similarity between two color vectors. So depending on the nature and the objective of the problem at hand, it is possible that one method is more appropriate than the other.

Application

The formulation of similarity between two color vectors is of paramount importance for the development of the vector processing techniques. These include noise removal filters, edge detectors, image zoomers, and image retrievals.

► Color Model

Definition

A color space describes the range of colors – the *gamut* – that an imaging device or software has to work with. Consequently, the design of these color spaces allows a user to modify images in a predefined manner based on the specific needs of the application.

Theory

Color spaces may be generally separated into those that are defined for analysis of color by color scientists (*colorimetric color spaces*) and those that are used for image/color editing.

Color Spaces for Colorimetric Analysis

Color spaces for colorimetric analysis are typically based on the human observer. Central to such color spaces is the CIEXYZ *color matching functions*, which are based on CIERGB color matching functions – based in turn on the LMS cone fundamentals. CIE is an abbreviation for the International Commission on Illumination (Commission International de L'Eclairage) that is the body that is responsible for standardization of data in this field. However, the ability to directly measure the cone functions of an observer is only a recent development. Researchers had originally inferred the cone functions based on psychophysical experiments measuring the RGB color matching functions. Consequently, the CIE had standardized the color matching functions long before the cone functions could be directly measured. Details of how the color matching functions were developed are well documented in the book by Wyszecki and Stiles that is arguably a cornerstone of colorimetry [27].

The RGB color matching functions, denoted $\{\bar{r}(\lambda), \bar{g}(\lambda), \bar{b}(\lambda)\}$, are shown in Fig. 1a.

Note that these color matching functions have negative excursions, due to the fact that there are some colors that reside outside the triangle formed by these three primaries – a negative excursion in the primaries' weights is the only way to represent a color outside this triangle. In order to address this problem, the CIE also published a set of color matching functions with nonnegative values, denoted $\bar{x}(\lambda), \bar{y}(\lambda), \bar{z}(\lambda)$ and shown in Fig. 1b. These are known generally as the CIEXYZ color matching functions. Note that these are now fictitious, nonphysical primaries. The equations for computing these special “tristimulus” values, in XYZ color space, are:

$$\begin{aligned} X &= k \int_{\lambda} \bar{x}(\lambda) i_r(\lambda) d\lambda \\ Y &= k \int_{\lambda} \bar{y}(\lambda) i_r(\lambda) d\lambda \\ Z &= k \int_{\lambda} \bar{z}(\lambda) i_r(\lambda) d\lambda. \end{aligned} \quad (1)$$

where $i_r(\lambda)$ denotes the spectral power distribution of the light energy incident on the retina, and

k denotes a normalization factor that is set to 683 lumens/Watt in the case of absolute colorimetry and to $100 / \int_{\lambda} \bar{y}(\lambda) i_r(\lambda) d\lambda$ for relative colorimetry. In the case of relative colorimetry, this means a value of $Y = 100$ denotes the brightest color – the illuminant reflecting from a perfect reflecting diffuser.

The first set of color matching functions published by the CIE were originally empirically determined for a 2° field – the bipartite field used for matching a subtended 2° angle on the observers' retina. Following the 1931 publication, W. S. Stiles and J. M. Burch conducted experiments [25] to measure color matching functions for larger fields of view. This was combined with the findings of Speranskaya [24] into the publication by the CIE of a 10° observer in 1964 [5]. The difference between these two standard observers is significant enough to warrant a clear specification of which observer color matching functions are used in experimental work. More specifically, the 10° observer has noticeable shifts of the color matching functions in the blue direction due to the fact that the subtense of the stimulus encompasses a larger portion of the retina and hence more S cones and also increased macular pigment absorption.

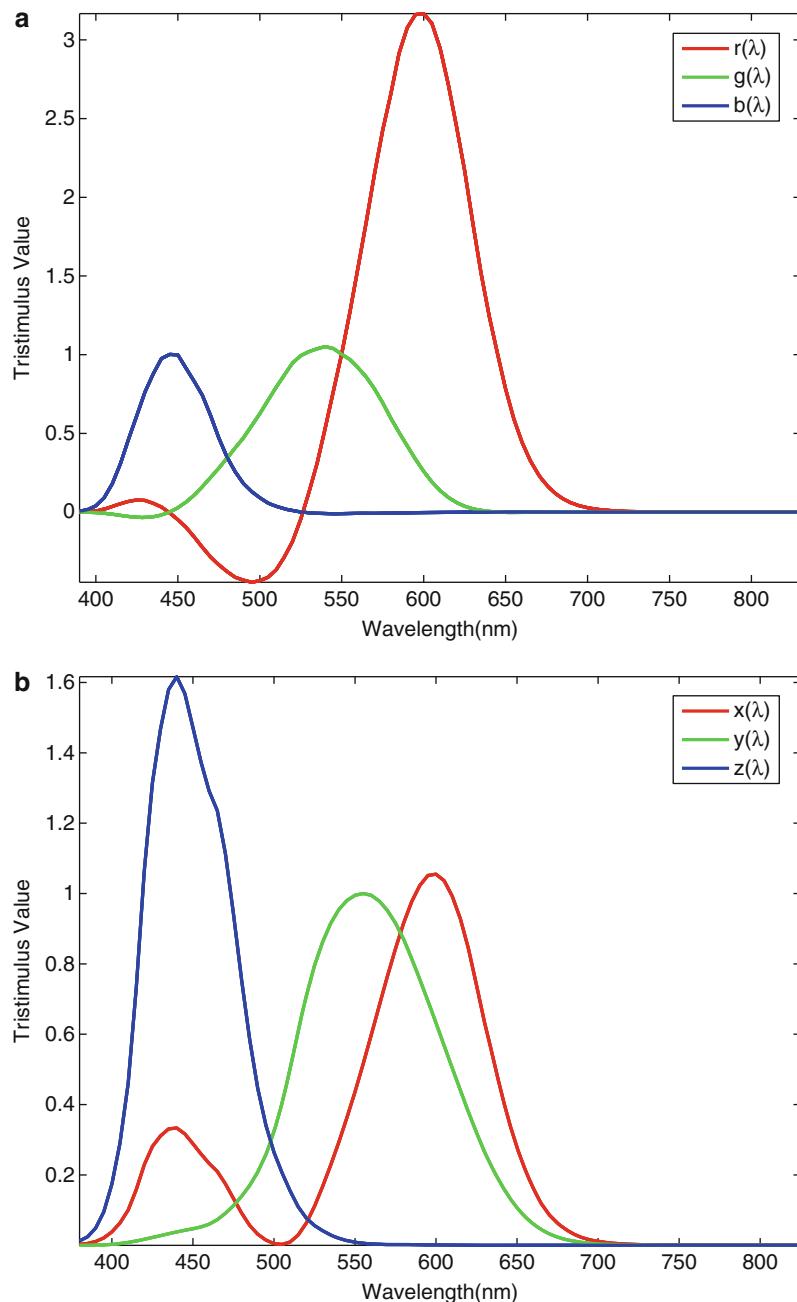

In the CIE colorimetric system, an XYZ tristimulus value uniquely specifies a color. However, a convenient 2D representation of the tristimulus values led to the projection of the tristimulus values by normalizing by the sum of the three values. These “chromaticity” values are given by:

$$\begin{aligned} x &= \frac{X}{X + Y + Z} \\ y &= \frac{Y}{X + Y + Z}. \end{aligned} \quad (2)$$

A color may be specified uniquely by its (x, y) chromaticity coordinates and its luminance Y , and is often used to describe a color since the tristimulus values are straightforward to derive from the (x, y, Y) values. The biggest advantage of the (x, y) chromaticity coordinates is that they specify a magnitude-independent hue

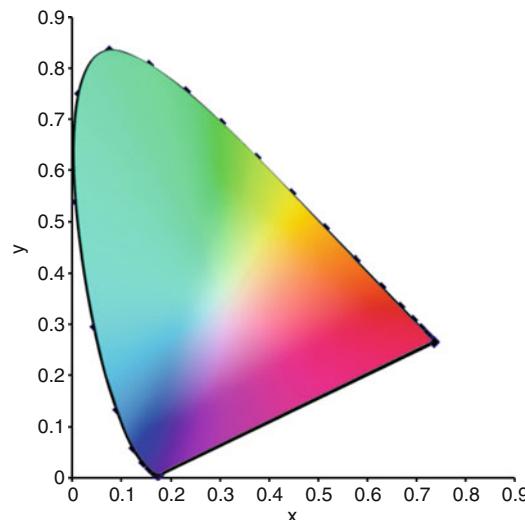

Color Spaces, Fig. 1 (a)

RGB color matching functions (b) XYZ color matching functions including Judd-Vos modifications

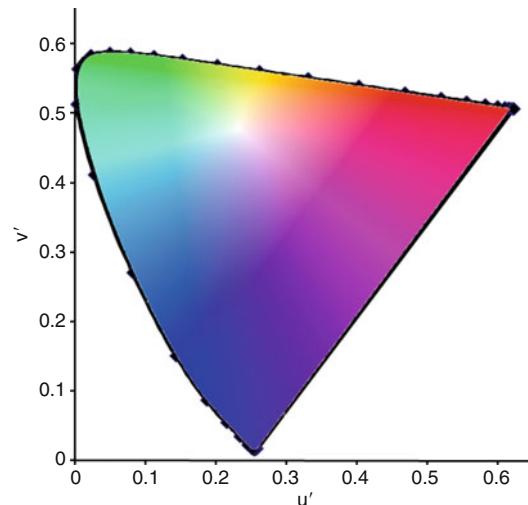

and purity of a color. A chromaticity diagram (see Fig. 2) is typically used to specify a color using its chromaticity coordinates. In Fig. 2, the horseshoe-shaped locus denotes the locus of monochromatic stimuli visible to the standard 2° observer (the gamut of visible colors). Shorter wavelength stimuli (starting at 380 nm, eliciting

a relatively strong blue response) reside in the lower left of this horseshoe shape while the longer wavelengths (ending at 830 nm, eliciting a relatively strong red response) reside on the lower right, with the top of the horseshoe curve around 520 nm (eliciting a strong green response). The line connecting the blue and red corners is

Color Spaces, Fig. 2 CIE xy chromaticity diagram for a 2° observer

Color Spaces, Fig. 3 CIE UCS $u'v'$ chromaticity diagram for a 2° observer

referred to as the *line of purples*. Colors on this line, although on the border of the gamut, have no counterpart in monochromatic sources of light and hence have no wavelengths associated with them.

The (x, y) chromaticity diagram is perceptually nonuniform: Unit vectors in the chromaticity space do not correspond to a unit change in perception even if the luminance is kept constant. In an attempt to improve the uniformity of the chromaticity diagram, in 1976, the CIE published a uniform chromaticity scale (UCS) diagram that scaled and normalized the XYZ tristimulus values [6]. This chromaticity diagram is denoted by u' , v' axes, which are related to the XYZ tristimulus values by the following equations:

$$\begin{aligned} u' &= \frac{4X}{X + 15Y + 3Z} \\ v' &= \frac{9Y}{X + 15Y + 3Z}. \end{aligned} \quad (3)$$

Figure 3 shows the UCS. Just as in the case of Fig. 2, in this figure, the horseshoe-shaped locus represents the gamut of visible colors.

The CIEXYZ color space does not have perceptual correlates that would make it useful for common use. In an attempt to add perceptual

behavior to color spaces, based on earlier works of many researchers, the CIE proposed a lightness scale along with two chromatic scales. The CIELAB color space is one such space, where the axes are denoted by L^* (Lightness), a^* (redness–greenness), and b^* (yellowness–blueness). For a stimulus given by a tristimulus value X , Y , and Z , the CIELAB coordinates are given by:

$$\begin{aligned} L^* &= 116 f(Y/Y_n) - 16 \\ a^* &= 500 [f(X/X_n) - f(Y/Y_n)] \\ b^* &= 200 [f(Y/Y_n) - f(Z/Z_n)], \text{ where} \\ f(t) &= t^{1/3}, \text{ for } t > 0.008856 \\ f(t) &= 7.787 t + 16/116 \text{ otherwise.} \end{aligned} \quad (4)$$

In the above equations, the subscript n denotes the tristimulus values corresponding to the reference white chosen, which makes the CIELAB color space a relative color space. Given the CIELAB coordinates in a three-dimensional space, correlates of chroma and hue may be derived as follows:

$$C^*_{ab} = (a^{*2} + b^{*2})^{1/2} \quad (5)$$

$$h^*_{ab} = \tan^{-1}(b^*/a^*). \quad (6)$$

Under highly controlled viewing conditions, a CIELAB ΔE difference of 1 correlates with a single just noticeable difference in color. It is to be noted though that the CIELAB color difference measure was designed for color differences between uniform color patches in isolation.

In a similar construct, the CIE also recommended a CIELUV color space, based on the uniform chromaticity scale (UCS). This uses a subtractive shift from the reference white instead of the normalization based on division that is used in the CIELAB space. The equations to transform a tristimulus value from u^*, v^* coordinates to CIELUV are given by:

$$\begin{aligned} L^* &= 116 f(Y/Y_n) - 16 \\ u^* &= 13 L^*(u' - u'_n) \\ v^* &= 13 L^*(v' - v'_n), \quad \text{where} \\ f(t) &= t^{1/3}, \quad \text{for } t > 0.008856 \\ f(t) &= 7.787 t + 16/116 \quad \text{otherwise.} \end{aligned} \quad (7)$$

The u', v' coordinates for a tristimulus value are computed using (3). As in the CIELAB definitions, the subscript n denotes the u', v' coordinates of the reference white being used. The descriptions of the u^* and v^* axes are similar to those in CIELAB: approximating redness–greenness and yellowness–blueness directions.

Based on these correlates, the CIE recommends that color difference measures in the two uniform-perception spaces CIELAB and CIELUV be given by the Euclidean difference between the coordinates of two color samples:

$$\begin{aligned} \Delta E^*_{ab} &= \left[(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2 \right]^{1/2} \\ \Delta E^*_{uv} &= \left[(\Delta L^*)^2 + (\Delta u^*)^2 + (\Delta v^*)^2 \right]^{1/2} \end{aligned} \quad (8)$$

where the differences are given between the corresponding color coordinates in the CIELAB and CIELUV spaces between the standard and test samples.

Many improvements to this basic color difference measure have been proposed and adopted over the years involving scaling the lightness,

chroma, and hue differences appropriately based on the application and the dataset of samples to which the color difference measure has been adapted or improved [7]. Typically, color difference thresholds are dependent on application and thresholds for *perceptibility* judgments are significantly lower than thresholds for *acceptability* judgments. These color spaces were designed for threshold color differences and their application to supra-threshold (larger than about 5 units of ΔE) color differences is to be handled with care [17]. Many other color difference measures have been proposed and more recently, the CIE DE2000 has been adopted as a measure of color difference, again for uniform color patches under highly controlled viewing conditions, and is slowly gaining acceptance [7, 15].

These color spaces provide a powerful tool to model and quantify color stimuli and are used both in color difference modeling for color patches and, as well, have more recently been used to describe color appearance (see [19]). Models based on describing colors based on lightness, chroma, and hue are powerful in their abilities to enable communication of color stimuli, as well.

Color spaces for colorimetric analysis have the advantage that the need for communicating these colors to others can be done without much ambiguity, if the viewing conditions (reference white) are specified and well controlled. Arguably, the biggest disadvantage is that it is not straightforward to understand what a certain color coordinate in a certain color space would mean to an observer without having to use mathematical equations.

Color Spaces for Editing

Color spaces for editing are specifically designed with the following key requirements:

- Colors have perceptual correlates that are easily understood, such as hue, saturation, brightness, purity, etc.
- Colors described in these spaces are reproducible – within reason – across different media: monitors, printers, etc.

- Colors in these spaces are defined based on primaries – the axes:
 - On the display side of the world of color applications, these spaces are additive, defined by red, green, and blue primaries: Equal amounts of red and green will give yellow.
 - On the printing side, primaries are defined roughly by cyan, magenta, yellow, and black, and these spaces are subtractive: Knowing the print surface, equal densities of cyan and yellow will give green.

A Brief Note on “Gamma”

If a color system is linear, then for additive combinations of colors, a unit input of a color corresponds to a globally constant unit of the output signal; whereas for nonlinear combinations, a transfer function would determine the input–output relationship. This nonlinearity is often used in digital systems with limited available bits and in signal compression systems to take advantage of the available output signal bit depth by stretching small input codes over a larger range of output codes and compressing the larger input codes into a smaller output dynamic range. This is referred to as *gamma encoding*.

From an encoding perspective, in its simplest form, the input–output relationship is typically given by a gain-offset-gamma model, given by:

$$y = \text{round} \left[\left(2^N - 1 \right) (\alpha x + \beta)^{\gamma} \right] \quad (9)$$

where α denotes a scalar gain, N denotes the number of bits in a system, β is a scalar offset, γ denotes a power law with values larger than 1 (typically around 2.2), and x and y denote the normalized input and output signals respectively [1]. In encoding systems, the three channels typically have the same parameters α , β , γ , N . Display systems based on cathode ray tubes (CRTs) have an inherent response that follows the inverse relationship – large steps in input signal at the low end of the input signal cause a small change in output whereas at the upper end of the signal range, small steps caused large output

changes. It so happens that gamma encoding (using a power law of γ on the linear luminance input) the input prior to transmitting the data to a CRT display causes the display luminance to follow similar steps resulting in a net unity transfer function. This is also a useful means of encoding data to maximize bit-depth usage while reducing visibly apparent contouring on the output data and display [10, 18]. In the case of a quantized color space, for reasons of perceptual uniformity, it is preferable to establish a nonlinear relationship between color values and intensity or luminance.

RGB Color Model

The specification of a color in the RGB color space implies a linear (after gamma is removed) or nonlinear (gamma applied) combination of the red, green, and blue primaries in varying strengths. In RGB color spaces, the manner in which colors are reproduced varies from device to device. For example, a color specified as an RGB triplet is more than likely going to look different from one display device to another when the exact same RGB triplet is provided as input, due to differences in the “color” of the primaries and also differences in gamma curves. This makes the RGB space a device-dependent color space. Specifying colors in device-dependent color spaces, although not preferred from a color-reproduction perspective, is often resorted to due to its ease in comprehension. An RGB color model can represent any color within an RGB color cube, as shown in Fig. 4. This color model is most commonly used in display applications where data is additive in nature.

For example, a full-strength yellow color is specified by (1.0, 1.0, 0.0), denoting the use of the red and green primaries at full strength and the blue primary completely turned off. In an 8-bit system, this will correspond to a code value of (255,255,0). A three-primary display with three independent color primaries (typically denoted by their CIE x,y chromaticity values along with that of white) is specified by:

$$\begin{bmatrix} x_R & x_G & x_B & x_W \\ y_R & y_G & y_B & y_W \end{bmatrix}. \quad (10)$$

An introduction to how specifications such as those in (10) may be used to generate a transformation matrix from RGB to XYZ for linear RGB is given in the book [18].

Different RGB color spaces differ in their gamma values and the chromaticity coordinates in (10). A useful compilation of various RGB color spaces may be found in a Web site hosted by Bruce Lindbloom [11].

A color mixing matrix for additive colors mixing is shown in Table 1, stating, for example, that a cyan color would be created using maximum intensity of green and blue primaries and none of the red primary.

CMY/CMYK Color Model

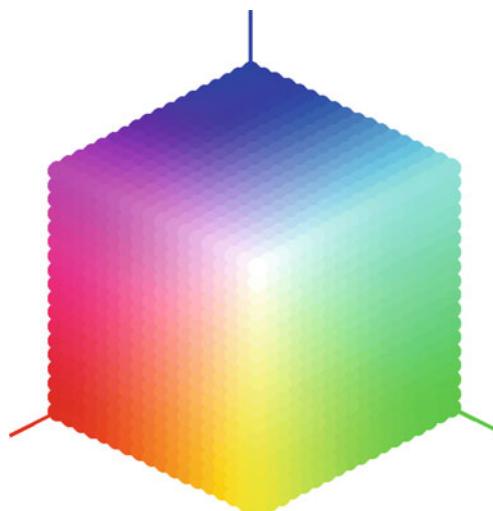

Printers, on the other hand, create colors using inks that are deposited on paper, in which case the manner in which they create color is called subtractive color mixing. The inks selectively absorb wavelengths of incident light and reflect

the remainder. As a beam of light passes through an absorbing medium, the amount of light absorbed is proportional to the intensity of the incident light times the coefficient of absorption (at a given wavelength). This is often referred to as *Beer-Lambert-Bouguer law* and is given by:

$$A(\lambda) = \log_{10} \varepsilon(\lambda)c(\lambda)l(\lambda) \quad (11)$$

where $\varepsilon(\lambda)$ denotes absorptivity, $c(\lambda)$ denotes the concentration, and $l(\lambda)$ denotes the path length for the beam of light. Stated differently, the higher the concentration or thickness or absorptivity of a certain absorptive material, the higher is absorption – the intensity of reflected or transmitted beam of light will be reduced [20]. The simplest model for printer inks is called the *block-dye model*, an idealized system where, for example, cyan ink absorbs all the red but none of the green or blue, with rectangular shapes for absorptivity as a function of wavelength.

In a subtractive-color setup, different thicknesses of the three primary inks may be deposited on top of each other to result in a final color to the observer. The colorant amounts required to print a stimulus designated by RGB emissions are given by $Y = 1 - X$, where $Y \in \{C, M, Y\}$ and $X \in \{R, G, B\}$, all normalized to unity. Real primary inks, however, do not correspond to these ideal functions and, hence, more sophisticated models need to include not just the spectral absorptions/reflectances of the inks, but the density (or area) of the inks and the characteristics of the media (paper) involved. The Kubelka-Munk equations describe the absorption and scattering of light as it passes through layers of ink and the substrate, for example, paper. Various extensions are used in practice that account for the shortcomings of the basic Kubelka-Munk analysis, considering issues such as nonlinearities in ink deposition, interactions between inks, etc.,

Color Spaces, Fig. 4 RGB color cube commonly used in display applications

Color Spaces, Table 1

Color mixing matrix for additive primaries

| Primary used | Color displayed | | | | | | | |
|--------------|-----------------|-------|------|------|--------|---------|-------|-------|
| | Red | Green | Blue | Cyan | Yellow | Magenta | White | Black |
| Red | 1 | 0 | 0 | 0 | 1 | 1 | 1 | 0 |
| Green | 0 | 1 | 0 | 1 | 1 | 0 | 1 | 0 |
| Blue | 0 | 0 | 1 | 1 | 0 | 1 | 1 | 0 |

Color Spaces, Table 2

Color mixing matrix for subtractive primaries

| Primary used | Color displayed | | | | | | | |
|--------------|-----------------|-------|------|------|--------|---------|-------|-------|
| | Red | Green | Blue | Cyan | Yellow | Magenta | White | Black |
| Cyan | 0 | 1 | 1 | 1 | 0 | 0 | 0 | 1 |
| Yellow | 1 | 1 | 0 | 0 | 1 | 0 | 0 | 1 |
| Magenta | 1 | 0 | 1 | 0 | 0 | 1 | 0 | 1 |

[8, 20]. In subtractive color mixing, the primaries are typically cyan (C), yellow (Y), and magenta (M). The color mixing matrix for subtractive color is shown in Table 2.

Much like RGB color systems, where the reference white made a difference in the appearance of a certain color, depending upon the kind of paper and inks used for printing, the rendered color can be significantly different from one printer to another.

Most printers use a “K” channel, denoting black ink, primarily because a black generated by mixing cyan, yellow, and magenta is not black enough in appearance. Additionally, to complicate matters, in order to print black, a printer would need to lay cyan, magenta, and yellow inks on top of each other, making ink drying a cause for concern and additionally the limits of ink absorption by the substrate, for example, paper. Additionally, using 1 unit of black ink instead of 1 unit each of cyan, yellow, and magenta inks can lead to significant cost savings.

HSL/HSV Color Model

In order to make the representation of colors intuitive, colors may be ordered along three inde-

pendent dimensions corresponding to the perceptual correlates of lightness, hue, and chroma. In device-dependent color spaces, there are many commonly used variants of these perceptual correlates: HSV is by far the most common. H stands for the perceptual correlate of hue; S stands for the saturation of a color, defined by the chroma of a color divided by its luminance (the more desaturated the color the closer it is to gray); and V stands for value (a perceptual correlate of lightness). This color model is commonly used in image processing and editing software. However, the HSV color model has two visualization representations, one of which is a cylinder with black at the bottom and pure full-intensity colors on the top, and the other is a representation by a cone, with black at the apex and white on the base. The equations used to convert RGB data into the HSV color space are given by:

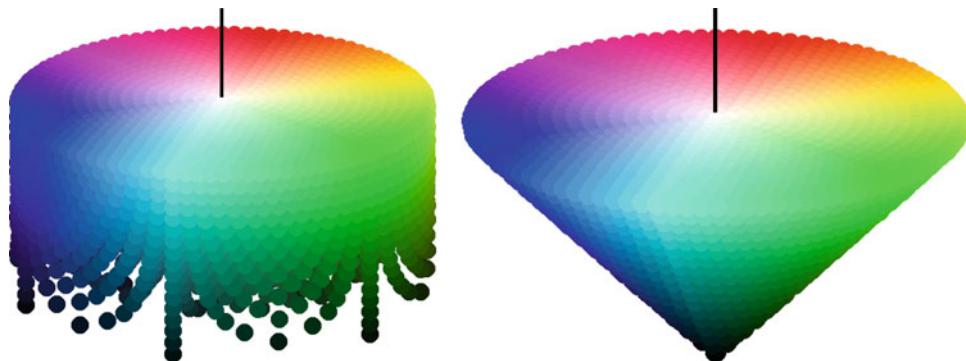

$$V = \max \quad (12)$$

$$S = \begin{cases} 0 & \text{if } V = 0 \\ (V - \min) / V & \text{if } V > 0 \end{cases} \quad (13)$$

$$H = \begin{cases} 0 & \text{if } S = 0 \\ 60(G - B) / (\max - \min) & \text{if } (\max = R \text{ and } G \geq B) \\ 60(G - B) / (\max - \min) + 360 & \text{if } (\max = R \text{ and } G < B) \\ 60(B - R) / (\max - \min) + 120 & \text{if } \max = G \\ 60(R - G) / (\max - \min) + 240 & \text{if } \max = B \end{cases} \quad (14)$$

where \max and \min denote the maximum and minimum of the (R, G, B) triplet. These two representations are shown in Fig. 5. From the figure, it is apparent that saturation is not dependent on the intensity of the signal. It is, however, often useful in image processing applications to have an indicator of saturation given by a function of the intensity of the signal, resulting in a conical-

shaped HSV color space (Fig. 5). When the conical representation is preferred, S is given by $(\max - \min) / (2^N - 1)$ where $2^N - 1$ denotes the largest possible value for R, G, or B. Other variants of the HSV color space also exist and are used as an intuitive link to RGB color spaces (HSB, or HLS denoting various correlates of hue, saturation, and brightness/lightness).

Color Spaces, Fig. 5 The HSV color model represented as a cylinder and as a cone

Other Color Spaces

Color spaces designed for editing and communication needs are typically formulated such that colors are encoded/transmitted in the color space of a reference device. Colors spaces fitting such a description include the sRGB color space, the YCC, YUV, YIQ color transmission spaces, the SWOP CMYK color space, Adobe RGB, and ProPhoto RGB, to list a few.

A popular mechanism to standardize colors across electronic devices such as printers, monitors, and the Internet is the use of the sRGB color space. Originally, this was proposed by Hewlett-Packard and Microsoft, and was later standardized by the International Electrotechnical Commission under IEC 61966-2-1 [12]. There are two primary parts to the sRGB standard: the viewing conditions and the necessary colorimetric definitions and transformations. The sRGB reference viewing environment corresponds to conditions typical of monitor display viewing conditions and thus may not be as well suited for print material, due to the various proprietary gamut mapping algorithms in most printers that take advantage of each printer's color gamut. The colorimetric definitions provide the transforms necessary to convert between the sRGB color space and the CIEXYZ tristimulus color space as defined for a standard 2° observer. More specifically, the standard is written for a standard reference monitor that has Rec. 709 primaries and a D65 white point. An overview of the technical advantages and challenges of the sRGB color space may be found in Refs. [21, 26]. As

was mentioned earlier, color spaces for video directly make use of the gamma-corrected signals, denoted R' , G' , B' , from camcorders, without any attempt to correlate to the linear signals used in color science, such as those in (1). For still imaging as well as video, this problem can be mitigated by the use of the transform built into the sRGB standard, which includes a function for transforming from nonlinear signals I' to linear ones. On a scale of 0.0–1.0, for each of $I = R, G, B$, the following function is applied:

$$\begin{cases} I = I'/12.92, & \text{if } I' < 0.04045; \\ I = ((I' + 0.055)/1.055)^{2.4} & \text{otherwise.} \end{cases} \quad (15)$$

In the video industry, a common mode of communication is the YCbCr color space (YPbPr in the analog domain) that converts RGB signal information into an opponent luma-chroma color space. A nonlinear transfer function is applied to linear-light R, G, B values and a weighted sum of the resulting R', G', B' values is used in the Y, Cb, and Cr signals. In the television domain, these signals have dynamic ranges (on an 8-bit scale) of 16–235 for the luma signal and 16–240 in the Cb and Cr signals. This is to allow for signal noise and potential signal processing noise, giving some head- and foot-room. The weights are different depending upon the color space that the data is being created for. For example, encoding R', G', B' signals with a 16–235 dynamic range into a color space defined by the NTSC primaries (often referred to as ITU-R BT.601), is

given by:

$$\begin{bmatrix} Y \\ Cb \\ Cr \end{bmatrix} = \begin{bmatrix} 0.299 & 0.587 & 0.114 \\ -0.169 & -0.331 & 0.500 \\ 0.500 & -0.419 & -0.081 \end{bmatrix} \begin{bmatrix} R' \\ G' \\ B' \end{bmatrix} + \begin{bmatrix} 0 \\ 128 \\ 128 \end{bmatrix} \quad (16)$$

whereas when using HDTV (referred to as ITU-R BT.709) primaries, is given by:

$$\begin{bmatrix} Y \\ Cb \\ Cr \end{bmatrix} = \begin{bmatrix} 0.213 & 0.715 & 0.072 \\ -0.117 & -0.394 & 0.511 \\ 0.511 & -0.464 & -0.047 \end{bmatrix} \begin{bmatrix} R' \\ G' \\ B' \end{bmatrix} + \begin{bmatrix} 0 \\ 128 \\ 128 \end{bmatrix}. \quad (17)$$

A useful reference for further details on this topic is a book by Keith Jack [14]. The Y channel typically contains most of the information in the image, as defined by spatial frequencies, and is hence sampled at much higher rates than the chroma signals. This greatly helps in the ability of the transmission system to compress luma and chroma data with low overheads when compared to luma-only systems. To aid compression formats, color images in the JPEG and JPEG2000 file formats also convert the R' , G' , B' information into the YCbCr color space prior to compression.

In the printing industry, a commonly specified color space is the SWOP (Specifications for Web Offset Publications) CMYK color space. The SWOP CMYK [2] is a proofing specification that has a well-established relationship between the CMYK input to a standard printer and its CIELAB values (an approximation of the perceptual coordinates of a color) and for a standardized dataset. Specifying images in the SWOP CMYK color space allows the printing house and the content creator to preview images on a common baseline prior to printing. Most image editing software available nowadays allows the user to preview images in the SWOP CMYK color space.

Open Problems

Depending upon the application, color spaces have their individual, optimized uses. Device-independent color models like the CIEXYZ, CIELAB, CIELUV, and their derivatives are used most often to communicate color either between devices or between different color processing teams across the world. The International Color Consortium (ICC) has been extremely successful in standardizing device-independent color spaces between displays, printers, and capture devices [9, 13]. The color profiles that are stored and communicated in ICC profiles use an intermediate profile connection space (PCS) such as CIEXYZ or CIELAB. ICC profiles also store color transformation profiles to and from different color devices (say, from an input device such as a scanner to CIEXYZ, and from CIEXYZ to an output device such as a printer). For example, an sRGB ICC profile incorporates the color space transform from sRGB to the PCS and a SWOP CMYK ICC profile would incorporate the color space transform from the PCS to the CMYK output color space for a printer. Furthermore, depending upon the rendering intent (how the colors need to be represented on the output device), different transformations may be specified in the ICC profile. Interested readers are referred to more detailed discussions of this subject such as the comprehensive books by Hunt [10], BillMeyer and Saltzman [1], Kuehni [16], Fairchild [19], Sharma [23], and Green and MacDonald [8].

Definition

Compressive sensing refers to parsimonious sensing, recovery, and processing of signals under a sparse prior.

Background

The design of conventional sensors is based heavily on the Shannon-Nyquist sampling theorem which states that a signal \mathbf{x} band limited to W Hz is determined completely by its discrete time samples provided the sampling rate is greater than $2W$ samples per second. This theorem is at the heart of modern signal processing as it enables signal processing in the discrete time

or digital domain without any loss of information. However, for many applications, the Nyquist sampling rate is high as well as redundant and unnecessary. As a motivating example, in modern cameras, the high resolution of the CCD sensor reflects the large amount of data sensed to capture an image. A 10 megapixel camera, in effect, takes 10 million linear measurements of the scene. Yet, almost immediately after capture, redundancies in the image are exploited to compress the image significantly, often by compression ratios of 100:1 for visualization and even higher for detection and classification tasks. This suggests immense wastage in the overall design of the conventional camera.

Compressive sensing (CS) refers to a sampling paradigm where additional structure on the signal is exploited to enable sub-Nyquist sampling rates. The structure most commonly associated with CS is that of signal sparsity in a transform basis. As an example, the basis behind most image compression algorithms is that images are sparse (or close to sparse) in transform bases such as wavelets and DCT. In such a scenario, a CS camera takes *under-sampled* linear measurements of the scene. Given these measurements, the image of the scene is recovered by searching for the image that is sparsest in the transform basis (wavelets or DCT) while simultaneously satisfying the measurements. This search procedure can be shown to be convex. Much of CS literature revolves around the design of linear measurement matrices, characterizing the number of measurements required and the design of image/signal recovery algorithms.

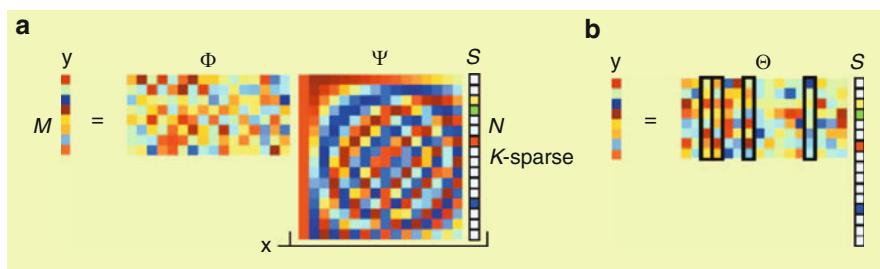

Theory

Compressive sensing [1–3] enables reconstruction of sparse signals from under-sampled linear measurements. A vector \mathbf{s} is termed K sparse if it has at most K nonzero components, or equivalently, if $\|\mathbf{s}\|_0 \leq K$, where $\|\cdot\|_0$ is the ℓ_0 norm or the number of nonzero components. Consider a signal (e.g., an image or a video) $\mathbf{x} \in \mathbb{R}^N$, which is sparse in a basis Ψ , that is, $\mathbf{s} \in \mathbb{R}^N$, defined as $\mathbf{s} = \Psi^T \mathbf{x}$, is sparse. Examples of the sparsifying basis Ψ for images include DCT and wavelets. The main problem of interest is that of sensing the signal \mathbf{x} from linear measurements. With no additional knowledge about \mathbf{x} , N linear measurements of \mathbf{x} are required to form an invertible linear system. In a conventional digital camera, an identity sensing matrix is used so that each pixel is sensed directly. For sensing reflectance fields, optimal linear sensing matrices have been designed [4].

The theory of compressive sensing shows that it is possible to reconstruct \mathbf{x} from M linear measurements even when $M \ll N$ by exploiting the sparsity of $\mathbf{s} = \Psi^T \mathbf{x}$. Consider a measurement vector $\mathbf{y} \in \mathbb{R}^M$ obtained using an $M \times N$ measurement matrix Φ , such that

$$\mathbf{y} = \Phi \mathbf{x} + e = \Phi \Psi \mathbf{s} + e = \Theta \mathbf{s} + e, \quad (1)$$

where e is the measurement noise (see Fig. 1) and $\Theta = \Phi \Psi$. The components of the measurement vector \mathbf{y} are called the *compressive measurements* or compressive samples. For $M < N$,

Compressive Sensing, Fig. 1 (a) Compressive sensing measurement process with a random Gaussian measurement matrix Φ and discrete cosine transform (DCT) matrix Ψ . The vector of coefficients \mathbf{s} is sparse with

$K = 4$. (b) Measurement process with $\mathbf{y} = \Phi \mathbf{x}$. There are four columns that correspond to nonzero s_i coefficients; the measurement vector \mathbf{y} is a linear combination of these columns. (Figure from [6])

estimating \mathbf{x} from the linear measurements is an ill-conditioned problem. However, when \mathbf{x} is K sparse in the basis Ψ , then CS enables recovery of \mathbf{s} (or alternatively, \mathbf{x}) from $M = O(K \log(N/K))$ measurements, for certain classes of matrices Θ . The guarantees on the recovery of signals extend to the case when \mathbf{s} is not exactly sparse but compressible. A signal is termed compressible if its sorted transform coefficients decay according to power law, that is, the sorted coefficient of \mathbf{s} decay rapidly in magnitude [5].

Restricted Isometry Property (RIP)

The condition for stable recovery for both sparse and compressible signals is that the matrix Θ satisfies the following property. Given S -sparse vector \mathbf{s} , $\exists \delta_S$, $0 < \delta_S < 1$ such that

$$(1 - \delta_S) \|\mathbf{s}\|_2 \leq \|\Theta \mathbf{s}\|_2 \leq (1 + \delta_S) \|\mathbf{s}\|_2. \quad (2)$$

Stable recovery is guaranteed when (2) is satisfied for $S = 2K$. This is referred to as the *restricted isometry property* (RIP) [2,7]. In particular, when Ψ is a fixed basis, it can be shown that using a randomly generated sub-Gaussian measurement matrix Φ ensures that Θ satisfies RIP with a high probability provided $M = O(K \log(N/K))$. Typical choices for Φ (or equivalently Θ) are matrices whose entries are independently generated using the Rademacher or the sub-Gaussian distribution.

Signal Recovery

Estimating K -sparse vectors that satisfy the measurement equation of (1) can be formulated as the following ℓ_0 optimization problem:

$$(P0) : \min \|\mathbf{s}\|_0 \text{ s.t. } \|\mathbf{y} - \Phi \Psi \mathbf{s}\|_2 \leq \epsilon, \quad (3)$$

with ϵ being a bound for the measurement noise e in (1). While this is a NP-hard problem in general, the equivalence between ℓ_0 and ℓ_1 norm for such systems [8] allows us to reformulate the problem as one of ℓ_1 norm minimization.

$$(P1) : \hat{\mathbf{s}} = \arg \min \|\mathbf{s}\|_1 \text{ s.t. } \|\mathbf{y} - \Phi \Psi \mathbf{s}\| \leq \epsilon. \quad (4)$$

It can be shown that, when $M = O(K \log(N/K))$, the solution to the (P1) – $\hat{\mathbf{s}}$ – is, with overwhelming probability, the K -sparse solution to (P0). In particular, the estimation error can be bounded as follows:

$$\|\mathbf{s} - \hat{\mathbf{s}}\|_2 \leq C_0 \|\mathbf{s} - \mathbf{s}_K\| / \sqrt{K} + c_1 \epsilon, \quad (5)$$

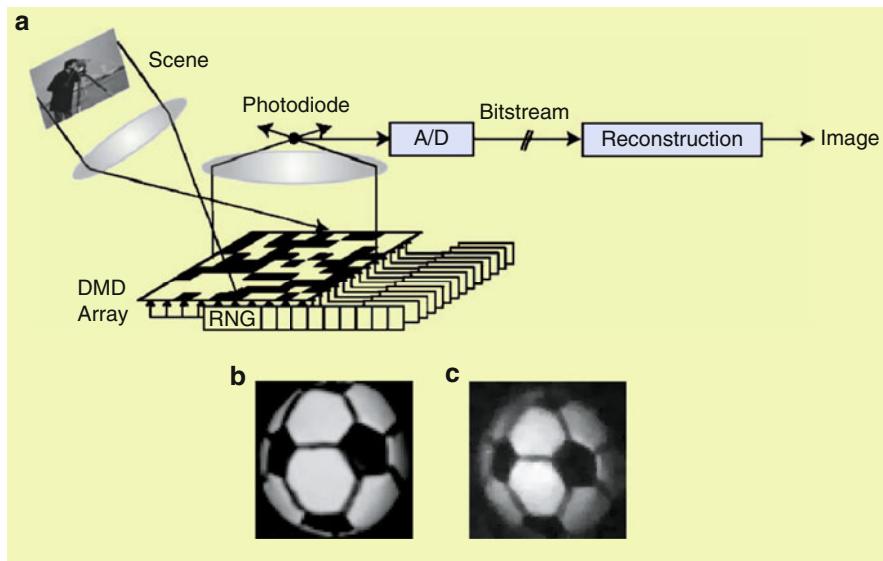

where \mathbf{s}_K is the best K -sparse approximation of \mathbf{s} .

There exist a wide range of algorithms that solve (P1) to various approximations or reformulations [9, 10]. One class of algorithms model (P1) as a convex problem and recast it as a linear program (LP) or a second order cone program (SOCP) for which there exist efficient numerical techniques. Another class of algorithms employ greedy methods [11] which can potentially incorporate other problem-specific properties such as structured supports [12].

Hardware Implementations

Compressive sensing has been successfully applied to sense various visual signals such as images [13, 14], videos [15], and light transport matrices [16]. The single-pixel camera (SPC) [13] for CS of images is designed as follows. The SPC consists of a lens that focuses the scene onto a digital micro-mirror device (DMD), which takes the place of the CCD array in a conventional camera. Each micro-mirror can be oriented in one of two possible angles. Micro-mirrors that are in the same angle/direction are focused onto a photodetector (hence, the single pixel) using a second lens (see Fig. 2). Each measurement that is obtained corresponds to an inner product of the scene with a set of 1s and 0s corresponding to the state of the micro-mirrors. By flipping the micro-mirrors randomly according to a Bernoulli distribution, multiple compressive measurements are obtained.

The SPC is most useful when sensing is costly. One such example is in sensing at wavelengths beyond the visible spectrum, where exotic and costly materials are needed to detect light. For such applications, the cost of building a focal plane array of even VGA resolution is

Compressive Sensing, Fig. 2 (a) Single-pixel, compressive sensing camera. (b) Conventional digital camera image of a soccer ball. (c) 64×64 black-and-white image of the same ball ($N = 4,096$ pixels) recovered from

$M = 1,600$ random measurements taken by the camera in (a). The images in (b) and (c) are not meant to be aligned. (Figure from [6])

prohibitive. However, the SPC needs only a single photodiode tuned to the spectrum of interest, with otherwise minimal changes to the underlying architecture.

Implications for Computer Vision

Novel Sensors

Compressive sensing enables a new sensing design that measures random linear projection of a scene and subsequently reconstructs the image of the scene using these measurements. The reconstructed image is no different from one captured from a suitably placed camera, barring reconstruction artifacts. However, compressive cameras enable parsimony in sensing – which can be extremely useful in problems where sensing is costly. This could be due to storage, as in the *data deluge* problem in large sensor networks. Compressive sensing is extremely valuable in time-sensitive applications such as medical imaging, sensing and modeling fluid dispersions, time-varying reflectance fields, and, in general, high-speed imaging. Finally, sensing

could be costly due to adverse effects caused by the process of sensing. In electron microscopy, there are fundamental limitations on the number of images of a thin layer of tissue that comes as the tissue is progressively destroyed in the process of imaging. In all such applications, where sensing is costly in some manner, CS offers better trade-offs over traditional linear sensing.

Tailoring Vision Algorithms for Compressive Data

In many cases, it is beneficial to work on the compressive measurements directly without reconstructing the images. As an example, in background subtraction, the silhouettes are spatially sparse and in many applications far sparser than the original images (in a transform basis). Given a static background image \mathbf{x}_s , silhouettes are recovered by identifying $(\mathbf{y} - \Phi\mathbf{x}_s)$ as compressive measurements of the silhouettes [17]. This can lead to silhouette recovery at extremely high compression ratios. Another example is in video CS for dynamic textures, where the linear dynamical system parameters of the scene can

be recovered by a suitably designed acquisition device [15].

Beyond Sparse Models

While the theory of CS relies on assumptions of sparsity or compressibility of the signal in a transform basis, it can be extended to signals that exhibit additional structures. One such idea is that of model-based CS [12] wherein the signal exhibits sparsity in a space of models which encompasses models such as block sparsity, union of subspaces, and wavelet tree models. Another idea is in the use of non-sparse models such as Markov random fields [18] for CS – with the eventual goal of using the Ising model for sensing images and background subtracted silhouettes. Such progress hints at interesting avenues for future research governed by the use of rich models in existing vision literature for the task of sensing.

Machine Learning and Signal Processing on Compressive Data

Restricted isometry property (see (2)) for random matrices implies that, for K -sparse signals, distances are approximately preserved under random projections. A host of machine learning and signal processing algorithms depend on pairwise distances of points as opposed to their exact location. For such algorithms, almost identical results can be obtained by applying them to randomly projected data as opposed to the data in the original space [19, 20]. This has tremendous advantages as the random projected data lies on a much lower-dimensional space and can be directly obtained from a compressive imager. Such ideas have been applied for detection and classification of signals in compressed domain [21].

Synonyms

Symmetry detection; Symmetry-based X

Definition

Symmetry is a mathematical concept as well as a widely used word for describing observed patterns. Formally:

Definition 1 Let S be a proper subset of R^n . Then an isometry (a distance preserving mapping) g is a symmetry of S if and only if $g(S) = S$.

Computational symmetry is a branch of research using computers to model, analyze, synthesize, and manipulate symmetries in digital form [41].

Background

Symmetry is a pervasive phenomenon presenting itself in all forms and scales, from galaxies to microscopic biological structures, in nature and man-made environments. Much of one's understanding of the world is based on the perception and recognition of recurring patterns that are generalized by the mathematical concept of symmetries [12, 14, 85]. Humans and animals have an innate ability to perceive and take advantage of symmetry in everyday life [22, 73, 80, 84], while harnessing this powerful insight for

Electronic Supplementary Material: The online version of this article (https://doi.org/10.1007/978-3-030-63416-2_640) contains supplementary material, which is available to authorized users.

machine intelligence remains a challenging task for computer scientists.

Interested readers can find several influential symmetry-related papers below to gain a historic perspective: the wonderful exposition on the role of symmetry in “Biological Shape and Visual Science” by Blum in 1973 [6]; in 1977, the “Description and Recognition of Curved Objects” reported by Nevatia and Binford, where bilateral symmetry of an object about different axes is examined [65]; the method of detecting angle/side regularities of closed curves and plateaus in one-dimensional patterns by Davis, Blumenthal, and Rosenfeld [7, 15]; the introduction of the term *skewed symmetry* by Takeo Kanade in 1981 [29]; the exposition on “Smoothed Local Symmetries and Their Implementation” by Brady and Asada [8]; the theory of (RBC) proposed by Biederman in 1985 [4]; “Perceptual Grouping and the Natural Representation of Natural Form” using superquadrics as restricted (GC) by Pentland in 1986 [72]; “Perceptual Organization and Visual Recognition” by Lowe [60], where the non-coincidental appearance of symmetry in the real world was noted; and the “Symmetry-seeking Models for 3D Object Reconstruction” (1987) illustrated by Terzopoulos, Witkin, and Kass [78].

A computational model for symmetry is particularly pertinent to computer vision, computer graphics, robotics, and machine intelligence in general, because symmetry is:

- *Essential*: intelligent beings perceive and interact with the chaotic real world in the most efficient and effective manner by capturing its structures – the generators of symmetry groups;
- *Ubiquitous*: both the physical and digital worlds are filled with various forms of symmetry patterns, albeit they are rarely perfectly presented;
- *Compact*: the recognition of symmetries is the recognition of redundancy and thus the first step toward optimization in representation, computation, and storage;

- *Aestho-physiological*: from a butterfly to an elephant, from a teacup to a skyscraper, symmetry or deviation from symmetry has been a time-honored principle for design (by nature or by human) that can guide machine perception, detection, recognition, and synthesis of the real world computationally.

Theory

From the spirit of Felix Klein's Erlangen program [23] that described geometry as the study of a space that is invariant under a given transformation group to the Gestalt principles of perception [1], symmetries and group theory play an important role in describing the geometry and appearance of an object. Informally, one may think of symmetry as expressing the notion that a figure or an object is made from multiple copies of smaller units that are interchangeable. Mathematically, this notion is formalized by examining the effect of transformations on the object in a certain space such that its sub-parts permute.

More formally, in a metric space M , a *symmetry* $g \in G$ of a set $S \subseteq M$ is an isometry (a distance preserving transformation) that maps S to itself (an automorphism), $g(S) = S$. The transformation g keeps S setwise invariant while permuting its parts. All symmetries of S , G , form an algebraic structure: *group* $\{G, *\}$, closed under transformation composition $*$, called the *symmetry group* of S [14].

Basic Concepts Definitions of symmetry and group theory can be found in most general mathematic textbooks on modern algebra. In particular the following books are recommended: *Geometry* by Coxeter [13]; *Generators and Relations for Discrete Groups* by Coxeter and Moser [14]; *Symmetry* by Weyl [85]; *The Symmetries of Things* by Conway, Burgiel, and Goodman-Strauss [12]; and *Tilings and Patterns* by Grünbaum and Shephard [24]. Some key concepts and computationally relevant definitions from [49] are provided below:

Definition 2 A symmetry g for a set $S \in R^n$ is a *primitive symmetry* if and only if (1) $g \neq e$

where e is an identity mapping and (2) if $g = g_1g_2$, $g_1 \neq e$, $g_2 \neq e$, and neither g_1 nor g_2 is a symmetry of S .

In 2D Euclidean space R^2 , for example, there are four types of *primitive symmetries* $g(S) = S$ [12, 14, 85]. They are, given an image $f(x, y)$ in Fig. 1:

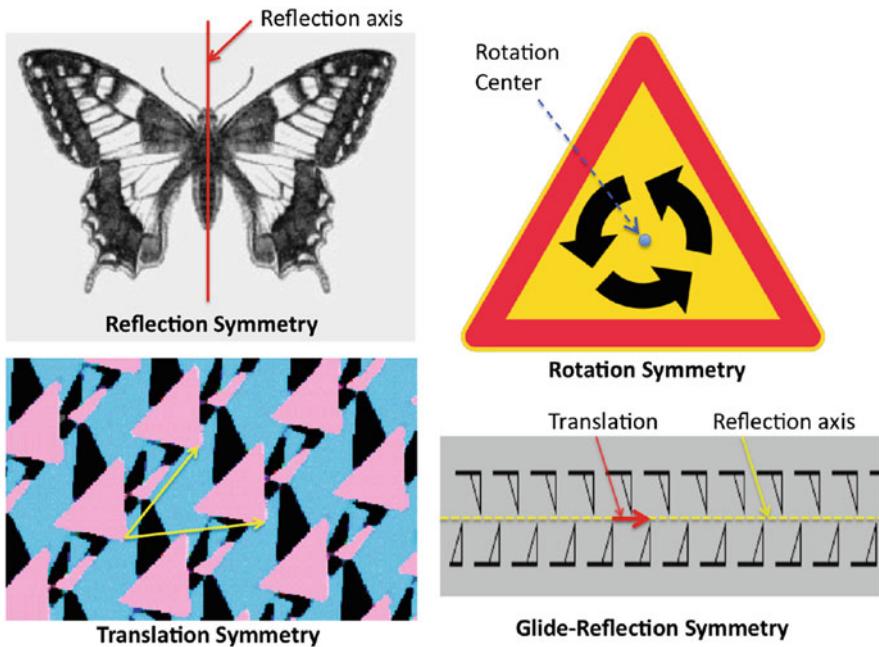

1. *Reflection*: $f(x, y) = f(-x, y)$, its reflection axis remains invariant under the reflection.
2. *Rotation*: $f(x, y) = f(r \cos(2\pi/n), r \sin(2\pi/n))$, $r = \sqrt{(x^2 + y^2)}$, n is an integer ($n = 3$ in the top-right of Fig. 1); its rotation center point remains invariant under the rotation.
3. *Translation*: $f(x, y) = f(x + \Delta x, y + \Delta y)$, for some $\Delta x, \Delta y \in R$, no invariant points on the plane exist under a translation symmetry.
4. *Glide Reflection*: $f(x, y) = f(x + \Delta x, -y)$, for some $\Delta x \in R$, no invariant points exist. A glide reflection g can be expressed as $g = tr$, where t is a translation and r is a reflection whose axis of reflection is along the direction of the translation. Neither t nor r alone is a symmetry of S ; thus g is a *primitive symmetry* of S by definition.

Definition 3 Let G be a non-empty set with a well-defined binary operation $*$ such that for each ordered pair $g_1, g_2 \in G$, $g_1 * g_2$ is also in G . $(G, *)$ is a **group** if and only if:

1. There exists an *identity* element $e \in G$ such that $e * g = g = g * e$ for all $g \in G$;
2. Any element g in G has an *inverse* $g^{-1} \in G$ such that $g * g^{-1} = g^{-1} * g = e$.
3. The binary operation $*$ is associative: $a * (b * c) = (a * b) * c$ for all $a, b, c \in G$.

Using the composition of transformations on R^n as the binary operation $*$, one can prove that *symmetries of a subset $S \subset R^n$ form a group*, which is called the **symmetry group** of S . Figure 2 and Table 1 illustrate the four distinct types of discrete symmetry groups in R^2 .

Definition 4 All the symmetries of R^n form the **Euclidean group** E .

Computational Symmetry, Fig. 1 An illustration of images with the four distinct primitive symmetries, respectively, in 2D Euclidean space. Reflection symmetry has the reflection axis as its point-wise invariance. Rotation symmetry has the center of rotation as its invariant

point. Glide reflection $g = t_{1/2}r$ is composed of a translation $t_{1/2}$ that is $1/2$ of the smallest translation symmetry t and a reflection r with respect to a reflection axis along the direction of the translation t . There are no invariant points under translation and glide-reflection symmetries

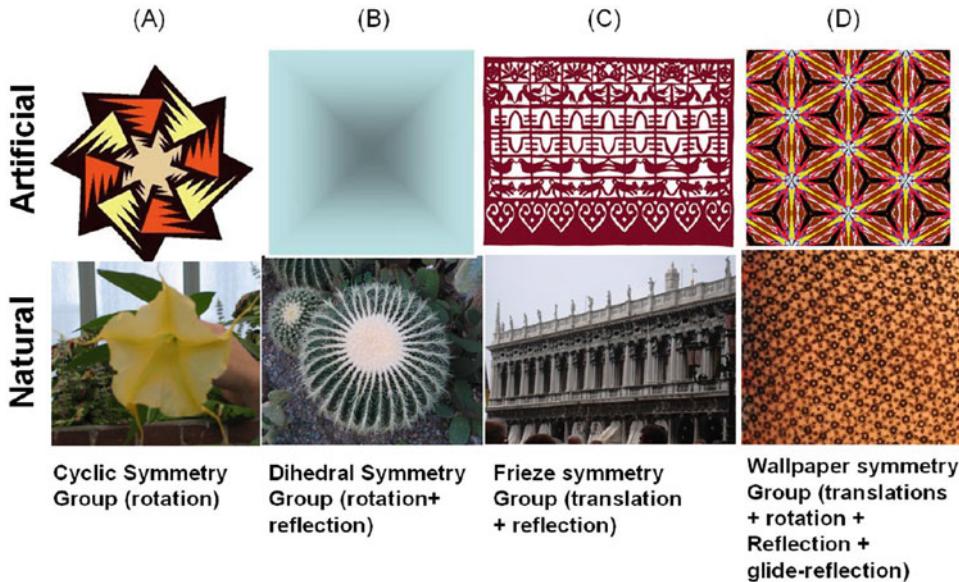

Definition 5 A point group G is a symmetry group that leaves a single point fixed. In other words, $G = G_x$, where G_x is the stabilizer subgroup on x .

Definition 6 A space group is a group G of operations that leave the infinitely extended, regularly repeating lattice pattern $L \subset R^n$ invariant while for all nontrivial $g \in G$, i.e., $g \neq e$, and $x \in R^n$, $g(x) \neq x$.

Crystallographic Groups An n -dimensional periodic pattern is formed by repeating a unit pattern in equal intervals along $k \leq n$ directions. A mature mathematical theory for symmetries of periodic patterns in n -dimensional Euclidean space has been known for over a century [3, 16–18], namely, the crystallographic groups [13, 24, 85]. An important mathematical discovery is the answer to the first part of Hilbert's 18th problem [62]: regardless of dimension n and despite an infinite number of possible instantiations of periodic patterns,

the number of distinct symmetry groups for periodic patterns in any Euclidean space R^n is always finite. For 2D monochrome patterns, there are 7 frieze-symmetry groups translating along one direction (strip patterns) [13] (Fig. 2c) and 17 wallpaper groups covering the whole plane [16, 24] (Fig. 2d). In 3D, there are 230 different space groups [27] generated by 3 linearly independent translations (regular crystal patterns).

Frieze-Symmetry Group A frieze pattern is a 2D strip in the plane that is periodic along one dimension. Any frieze pattern P is associated with one of the seven unique symmetry groups (Fig. 3). These seven symmetry groups, denoted by crystallographers as $l1, lg, ml, l2, mg, lm, mm$ [13], are called the *frieze groups*. Without loss of generality, assuming the direction of translation symmetry of a frieze pattern is horizontal, the frieze pattern can then exhibit five different types of symmetries (Fig. 3a):

Computational Symmetry, Fig. 2 Sample images of symmetry categorized by their respective ideal symmetry groups: column (a) cyclic group containing rotation symmetries only, (b) dihedral group (reflection and rotation), (c) frieze group (translation plus reflection), and (d) wallpaper group (translation, rotation, reflection, and

glide reflection). The top row contains synthetic patterns, while the bottom row shows photos of real-world scenes (bottom-right is an image of a transverse slice of skeletal muscle magnified with a transmitter microscope 800,000 times)

Computational Symmetry, Table 1 Discrete symmetry groups in R^2 (see Fig. 2 for sample images)

1. Horizontal translation;
2. Twofold rotation;
3. Horizontal reflection (reflection axis is placed horizontally);
4. Vertical reflection;
5. Horizontal glide reflection composed of a half-unit translation followed by a horizontal reflection.

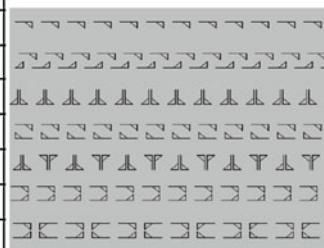

The primitive symmetries in each group (the Inner structure of a frieze group) and the relationship among the seven frieze groups (interstructure of frieze groups) are depicted in Fig. 3a and 3b, respectively. Each frieze pattern is associated with one of the seven possible frieze groups,

subject to the combination of these five primitive symmetries in the pattern (Fig. 3a).

Wallpaper Symmetry Group A wallpaper pattern is a 2D periodic pattern extending along two linearly independent directions [13, 74] (Fig. 4). Any wallpaper pattern is associated with 1 of the 17 wallpaper groups. Wallpaper group theory [24] states that all translationally symmetric patterns P_r can be generated by a pair of linearly independent, shortest (among all possible) vectors t_1, t_2 applied to a minimum tile. The orbits of this pair of translation symmetry generator vectors form a 2D *quadrilateral lattice*, which simultaneously defines all 2D tiles (partitions the

space into its smallest generating regions by its translation subgroup) and a topological lattice structure relating all tiles (Fig. 4a).

Figure 5 illustrates the 3D Euclidean group and some of its important subgroups.

Motifs of Wallpaper Patterns

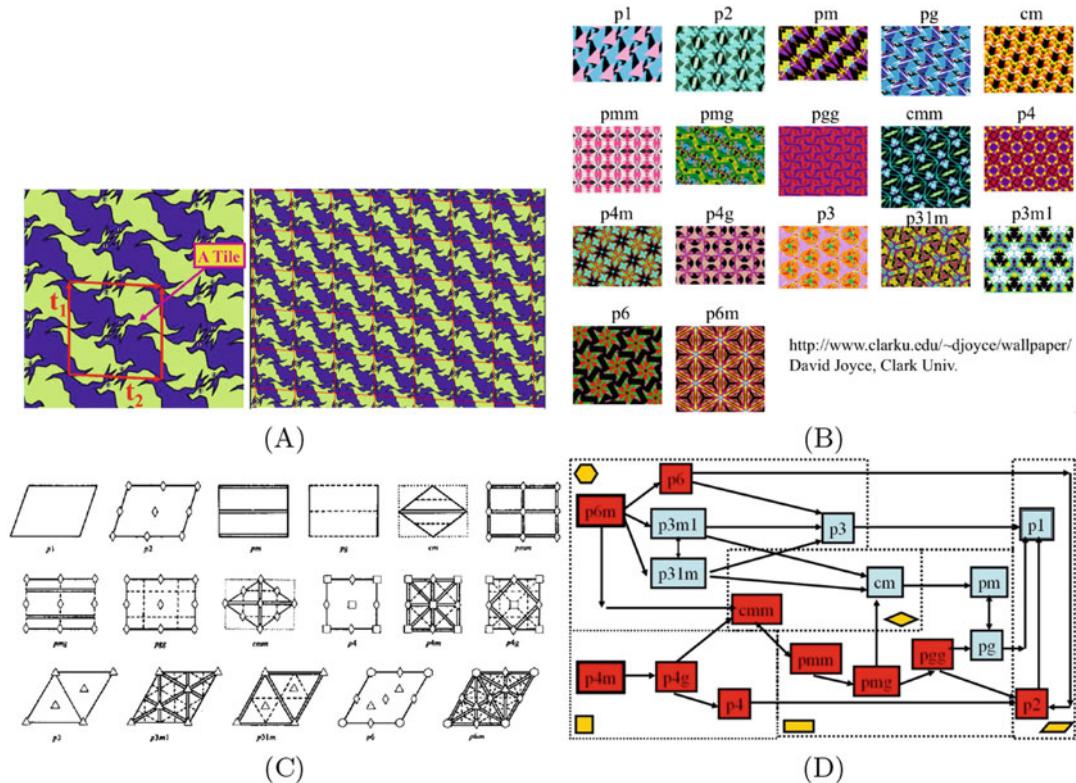

Definition 7 A *motif* of a wallpaper pattern is a tile that is cut out by a lattice unit centered on the fixed point of the largest stabilizer group.

When the translational subgroup of a periodic pattern is determined, it fixes the size, shape, and orientation of the unit lattice but leaves open the question of where the unit lattice should be anchored in the pattern. Any parallelogram of the same size and shape carves out an equally good tile that can be used to tile the plane. However, from a perception point of view, some parallelograms produce tiles that are better descriptors of

the underlying symmetry of the overall pattern than others. For example, if the whole pattern has some rotation symmetries, a tile located on the rotation centers can represent the global symmetry property of the wallpaper pattern instantly (Fig. 4a). Such *motifs*, as representative tiles of a periodic pattern, can be defined mathematically (and discovered computationally [43, 47]).

Applications

Automatic symmetry detection of primitive symmetries (reflection, rotation, translation, glide reflection) has been a lasting topic in the history of computer vision. The earliest attempt at an algorithmic treatment of bilateral reflection symmetry detection predates computer vision itself [5]. Interested readers can find a long list of published symmetry detection algorithms in [49]. The first quantitative benchmark on

Computational Symmetry, Fig. 4 (a) A tile and a 2D lattice (red) determined simultaneously by the generators t_1, t_2 of the translation subgroup. (b) Sample wallpaper patterns associated with the 17 distinct wallpaper groups. <http://vision.cse.psu.edu/research/symComp13/index.shtml>
<http://vision.cse.psu.edu/research/symComp/index.shtml>

Given the fact that automatic, general symmetry detection in computer vision is challenging, the first symmetry-based reCAPTCHA was proposed and tested in [20]. Subsequently, a neural net was trained to mimic human symmetry perception with moderate success [21].

Some sample applications of computational symmetry in computer vision and computer graphics include:

Facial asymmetry CVPR 2020 best paper award was given to Wu, Rupprecht, and Vedaldi for *Unsupervised Learning of Probably Symmetric Deformable 3D Objects from Images in the Wild* [88], where 2D reflection symmetry from a single image is used to recover 3D shapes

Computational Symmetry, Fig. 5 The 3D Euclidean group and its subgroup hierarchy, originally depicted in Figure 3.4 of [40]. G_{id} is the *identity group* of size 1, a.k.a. the *trivial symmetry group*: the symmetry group of an *asymmetrical state* [49]. Most past work in computer vision and human vision focuses on reflection symmetries only (dihedral group of size 2) [49]. More recent work addresses machine perception of discrete *planar symmetry groups* colored in red. Zooming into $G_{wallpaper}$, the subgroup hierarchy of the 17 distinct two-dimensional crystallographic groups (symmetry groups of *all* possible periodic patterns in 2D) is shown in Fig. 4d. Similarly, zooming into G_{frieze} , the subgroup hierarchy of the seven one-dimensional crystallographic groups (symmetry groups of *all* possible periodic patterns along one dimension) is shown in Fig. 3b

of human faces. Bilateral facial symmetry has been used before for view morphing [76] in 3D by Seitz and Dyer. Quantified facial asymmetry has been proposed and validated as a biometric [53, 54] and an expression and gender cue [52, 63, 64], respectively.

Symmetry groups for periodic patterns The first general-purpose, automatic frieze and wallpaper group classification algorithm on real images was published in [43, 47], followed by the classification of *skewed symmetry groups*, in particular wallpaper groups and rotation symmetry groups from affinely and projectively distorted images [31, 44]. Aiming at capturing the translation subgroup of a wallpaper group, several algorithms [26, 68, 70, 82] were developed for lattice detection (Fig. 4a) from various

locally and/or globally distorted, unsegmented real images [VIDEO-1, VIDEO-2].

Texture Texture replacement in real photos [81], static and dynamic near-regular texture analysis, synthesis [VIDEO-3], replacement/superimposition and tracking [35, 36, 50, 51, 57, 58], and image “de-fencing” [42, 66] have become a popular subject for various photo/video editing applications [VIDEO-4].

Urban scenes This is a playground for computational symmetry applications including facade matching between aerial and street views [39, 86], automatic geo-tagging [75], architectural facade in-painting [30], multi-view 3D geometry [28], and urban scene and architectural image analysis, synthesis, and 3D reconstruction [11, 30, 67, 75, 87].

Multitarget tracking Spatiotemporal multitarget tracking has utilized the topological invariant property of the 2D lattice, induced by the translation subgroup of the wallpaper groups [36, 71] [VIDEO-5A, 5B, 6]. Subsequently, multitarget tracking and symmetry pattern detection were used for topology-varying spatiotemporal patterns [37] [VIDEO-7].

General symmetry group detection and image segmentation, grouping, categorization The well-known *reflection symmetry* was generalized and treated computationally as a special case of curved glide reflection for the first time in *curved glide-reflection symmetry detection* [33]. Skewed rotation symmetry group detection [32, 33] captures deformed rotation symmetries in images. Symmetry-guided segmentation, grouping, and fabric categorization are done in [25, 34, 77, 89]. More recently, symmetry detection was relaxed to detect *recurring patterns* from a single image unsupervised [38] [VIDEO 8]. In addition, symmetry was used for transformation estimation in [2, 61, 83].

Biomedical applications Some sample applications include the following: human gait analysis [46, 47], automatic detection of midsagittal

plane in pathology brain images [45] for neural image retrieval [48,59] and tumor detection [90], quantified symmetry that has also been used to measure symmetry of moving objects such as molecules [91,92], pathological and degenerative volumetric neuroradiology images [55, 56, 79], and the firing fields of the grid cells of rats in the context of computational neuroscience [9].

Experimental Results

VIDEO-1 [26] The method and some results for finding texture regularity (deformed lattice) are shown through many real image examples

VIDEO-2 [68] The process of deformed lattice detection as a spatial tracking problem using mean-shift belief propagation is illustrated on several challenging real image examples

12001KBVIDEO-3 [51] The idea of near regular texture analysis and a synthesis example are displayed in this SIGGRAPH fast-forward video

VIDEO-4 [42] A sample image de-fencing result (by the first image de-fencing algorithm) is illustrated

VIDEOS-5A, 5B [35, 36] Dynamic near regular texture tracking as deformed lattice on video as a Markov Random Field Model, an effective superimposing on video is demonstrated

VIDEO-6 [35, 36] Tracking underwater patterns and texture replacement are shown

VIDEO-7 [37] It shows the tracking of topologically varying patterns (PSU marching band videos) with instant recognition of symmetry types

VIDEO-8 [38] The dynamic process of how to GRASP recurring patterns unsupervised is demonstrated on a real photo

Definition

Constrained optimization refers to the minimization of an objective function subject to hard constraint(s).

Background

Many computer vision problems have been resolved by mathematical optimization, where we try to optimize some criteria, called objective function, with or without hard constraint(s) that must be satisfied. This chapter focuses on constrained optimization, i.e., optimization problems involving hard constraint(s).

In general, constrained optimization is much more difficult than unconstrained one because algorithms must guarantee not only the convergence of the objective function to be minimized but also the satisfaction of given hard constraints. On the other hand, it has been recognized that the use of hard constraints brings various benefits, such as facilitating the choice of involved parameters and incorporating physical properties/structure directly on the solution, as addressed, for example, in the scenario of imaging inverse problems [1, 7, 12].

In computer vision applications, the size of optimization problems tends to be very large. In addition, we often adopt nonsmooth functions in

optimization to exploit a priori knowledge, e.g., sparsity and low-rankness. Hence, it is important to efficiently and flexibly manage various types of constraints under such nonsmooth optimization scenarios. This can be done by leveraging the notion of *metric projection* (or projection) together with the so-called proximal splitting algorithms [8, 14]. In what follows, we introduce such techniques with several applications.

Theory and Method

Basic Tools

A function $f : \mathbb{R}^N \rightarrow (-\infty, \infty]$ is said to be convex if $\forall \mathbf{x}, \mathbf{y} \in \mathbb{R}^N$ and $\lambda \in (0, 1)$, $f(\lambda \mathbf{x} + (1 - \lambda)\mathbf{y}) \leq \lambda f(\mathbf{x}) + (1 - \lambda)f(\mathbf{y})$. A set $C \subset \mathbb{R}^N$ is called convex if $\forall \mathbf{x}, \mathbf{y} \in C$ and $\lambda \in (0, 1)$, $\lambda \mathbf{x} + (1 - \lambda)\mathbf{y} \in C$.

We introduce the metric projection (or projection) onto a closed convex set C as follows:

$$P_C(\mathbf{x}) := \underset{\mathbf{z} \in C}{\operatorname{argmin}} \|\mathbf{x} - \mathbf{z}\|, \quad (1)$$

which maps the input vector \mathbf{x} to the vector $P_C(\mathbf{x}) \in C$ that is nearest from \mathbf{x} . This operation is a key in constrained optimization because a wide range of useful hard constraints can be written as (the intersection of) closed convex sets.

We also introduce the proximity operator (or proximal mapping) [2] of a convex function f as follows:

$$\operatorname{prox}_{\gamma f}(\mathbf{x}) := \underset{\mathbf{z}}{\operatorname{argmin}} f(\mathbf{z}) + \frac{1}{2\gamma} \|\mathbf{x} - \mathbf{z}\|^2, \quad (2)$$

where $\gamma > 0$. We call f proximable if the proximity operator of f can be computed efficiently.

Let us define the indicator function of a closed convex set C as

$$\iota_C(\mathbf{x}) := \begin{cases} 0, & \text{if } \mathbf{x} \in C, \\ \infty, & \text{otherwise.} \end{cases} \quad (3)$$

Then, the proximity operator of ι_C equals to the metric projection onto C , i.e.,

$$\begin{aligned}\text{prox}_{\gamma\iota_C}(\mathbf{x}) &= \underset{\mathbf{z}}{\operatorname{argmin}} \iota_C(\mathbf{z}) + \frac{1}{2\gamma} \|\mathbf{x} - \mathbf{z}\|^2 \\ &= \underset{\mathbf{z} \in C}{\operatorname{argmin}} \|\mathbf{x} - \mathbf{z}\| = P_C(\mathbf{x})\end{aligned}$$

This implies that proximal splitting algorithms can be a powerful choice for constrained optimization.

Projection Examples

A number of examples of frequently used constraints represented by closed convex sets and the associated projection calculations are shown below.

- **Nonnegative orthant.** The definition is \mathbb{R}_+^N and its projection is given by

$$P_{\mathbb{R}_+^N}(\mathbf{x}) = \max\{\mathbf{x}, 0\}. \quad (4)$$

- **Box constraint.** The definition is $[\alpha_i, \beta_i]_{i=1}^N$ ($\alpha_i < \beta_i$), and its projection is given by

$$P_{[\alpha_i, \beta_i]_{i=1}^N}(\mathbf{x}) = [\min\{\max\{x_i, \alpha_i\}, \beta_i\}]_{i=1}^N.$$

- **Linear constraint.** The definition is $S_{\mathbf{A}, \mathbf{b}} := \{\mathbf{x} \in \mathbb{R}^N | \mathbf{Ax} = \mathbf{b}\}$ ($\mathbf{A} \in \mathbb{R}^{M \times N}$ is a full row-rank matrix), and its projection is given by

$$P_{S_{\mathbf{A}, \mathbf{b}}}(\mathbf{x}) = \mathbf{x} - \mathbf{A}^\top (\mathbf{A}\mathbf{A}^\top)^{-1}(\mathbf{Ax} - \mathbf{b}). \quad (6)$$

- **Half space.** The definition is $H_{\mathbf{a}, b} := \{\mathbf{x} \in \mathbb{R}^N | \mathbf{a}^\top \mathbf{x} \leq b\}$ ($\mathbf{a} \in \mathbb{R}^N$), and its projection is given by

$$P_{H_{\mathbf{a}, b}}(\mathbf{x}) = \mathbf{x} - \frac{\max\{\mathbf{a}^\top \mathbf{x} - b, 0\}}{\|\mathbf{a}\|^2} \mathbf{a}. \quad (7)$$

- **ℓ_2 ball.** The definition is $B_{\ell_2}^{\mathbf{b}, \varepsilon} := \{\mathbf{x} \in \mathbb{R}^N | \|\mathbf{x} - \mathbf{b}\| \leq \varepsilon\}$, and its projection is given by

$$P_{B_{\ell_2}^{\mathbf{b}, \varepsilon}}(\mathbf{x}) = \mathbf{b} + \frac{\varepsilon}{\max\{\|\mathbf{x} - \mathbf{b}\|, \varepsilon\}}(\mathbf{x} - \mathbf{b}). \quad (8)$$

- **ℓ_1 ball.** The definition is $B_{\ell_1}^{\mathbf{b}, \varepsilon} := \{\mathbf{x} \in \mathbb{R}^N | \|\mathbf{x} - \mathbf{b}\|_1 \leq \varepsilon\}$, and its projection can be computed by fast algorithms [9, 10].

Problem Formulation and Algorithm

Consider a generic constrained convex optimization problem:

$$\min_{\mathbf{x}} \sum_{k=1}^K g_k(\mathbf{A}_k \mathbf{x}) \text{ s.t. } \begin{cases} \mathbf{A}_{K+1} \mathbf{x} \in C_1 \\ \vdots \\ \mathbf{A}_{K+L} \mathbf{x} \in C_L \end{cases}, \quad (9)$$

where g_k are proximable convex functions, C_l are projectable closed convex sets, and \mathbf{A}_k are matrices. Using the indicator functions of C_l , we can immediately rewrite the problem as

$$\min_{\mathbf{x}} \sum_{k=1}^K g_k(\mathbf{A}_k \mathbf{x}) + \sum_{l=1}^L \iota_{C_l}(\mathbf{A}_{K+l} \mathbf{x}). \quad (10)$$

This problem can further be reformulated into the following variable-splitting form:

$$\min_{\mathbf{x}, \mathbf{z}} \sum_{k=1}^K g_k(\mathbf{z}_k) + \sum_{l=1}^L \iota_{C_l}(\mathbf{z}_{K+l}) \text{ s.t. } \mathbf{z} = \mathbf{Ax}, \quad (11)$$

where $\mathbf{z} = (\mathbf{z}_1^\top \cdots \mathbf{z}_{K+L}^\top)^\top$ and $\mathbf{A} = (\mathbf{A}_1^\top \cdots \mathbf{A}_{K+L}^\top)^\top$. What is important here is that each proximable (projectable) function has own independent variable \mathbf{z}_i ($i = 1, \dots, K+L$). In general, the sum of two proximable function $g_1 + g_2$ is not proximable. This is also the case for the projection onto $C_1 \cap C_2$. The variable-splitting structure in (11) circumvents the above difficulty and thus enables us to leverage proximal splitting algorithms for solving the problem.

Let us explain the case of ADMM (alternating direction method of multipliers) [3, 11], known as a popular proximal splitting algorithm. ADMM solves convex optimization problems of the form:

$$\min_{\mathbf{x}, \mathbf{z}} f(\mathbf{x}) + g(\mathbf{z}) \text{ s.t. } \mathbf{z} = \mathbf{Bx}, \quad (12)$$

where f and g are convex functions and \mathbf{B} is a matrix. The original algorithm of ADMM is given as follows: for given $\gamma > 0$, $\mathbf{y}^{(0)}$, and $\mathbf{z}^{(0)}$, iterate

$$\begin{cases} \mathbf{x}^{(n+1)} = \operatorname{argmin}_{\mathbf{x}} f(\mathbf{x}) + \frac{1}{2\gamma} \|\mathbf{z}^{(n)} - \mathbf{Bx} - \mathbf{y}^{(n)}\|^2 \\ \mathbf{z}^{(n+1)} = \operatorname{prox}_{\gamma g}(\mathbf{Bx}^{(n+1)} + \mathbf{y}^{(n)}) \\ \mathbf{y}^{(n+1)} = \mathbf{y}^{(n)} + \mathbf{Bx}^{(n+1)} - \mathbf{z}^{(n+1)} \end{cases} \quad (13)$$

Then, by letting $f(\mathbf{x}) := 0$, $g(\mathbf{z}) := \sum_{k=1}^K g_k(\mathbf{z}_k) + \sum_{l=1}^L \iota_{C_l}(\mathbf{z}_{K+l})$ and $\mathbf{B} := \mathbf{A}$, Prob. (11) can be seen as an instance of Prob. (12), and thus we can apply ADMM, leading to the following algorithm: for given $\gamma > 0$, $\mathbf{y}_i^{(0)}$, and $\mathbf{z}_i^{(0)}$ ($i = 1, \dots, K + L$), iterate

$$\begin{cases} \mathbf{x}^{(n+1)} = \operatorname{argmin}_{\mathbf{x}} \frac{1}{2\gamma} \sum_{i=1}^{K+L} \|\mathbf{z}_i^{(n)} - \mathbf{A}_i \mathbf{x} - \mathbf{y}_i^{(n)}\|^2 \\ \text{for } i = 1, \dots, K \\ \mathbf{z}_i^{(n+1)} = \operatorname{prox}_{\gamma g_i}(\mathbf{A}_i \mathbf{x}^{(n+1)} + \mathbf{y}_i^{(n)}) \\ \mathbf{y}_i^{(n+1)} = \mathbf{y}_i^{(n)} + \mathbf{A}_i \mathbf{x}^{(n+1)} - \mathbf{z}_i^{(n+1)} \\ \text{for } i = K + 1, \dots, K + L \\ \mathbf{z}_i^{(n+1)} = P_{C_{i-K}}(\mathbf{A}_i \mathbf{x}^{(n+1)} + \mathbf{y}_i^{(n)}) \\ \mathbf{y}_i^{(n+1)} = \mathbf{y}_i^{(n)} + \mathbf{A}_i \mathbf{x}^{(n+1)} - \mathbf{z}_i^{(n+1)} \end{cases} \quad (14)$$

The update of \mathbf{x} is reduced to a quadratic minimization and thus can be solved in closed form. The update of \mathbf{z} is decoupled for each \mathbf{z}_i , where we only require the computation of the proximity operator of g_k or the projection onto C_l . We should remark that it is better to adopt the primal-dual hybrid gradient method [5] instead of ADMM when the matrix inversion associated with the update of \mathbf{x} is computationally expensive.

Application

Robust Principal Component Analysis

Principal component analysis (PCA) has played a central role of extracting and analyzing the intrinsic low-dimensional structure underlying high-dimensional data. PCA assumes that a given data matrix $\mathbf{M} \in \mathbb{R}^{M \times N}$, composed of N data vectors of size M , can be well approximated by

a low-rank matrix (or a few number of principal component vectors). However, PCA is known to be very sensitive to outliers because error in the data matrix is assumed to be Gaussian.

In order to resolve this problem, robust principal component analysis (RPCA) [4] was proposed. RPCA decomposes a given data matrix \mathbf{M} into a low-rank matrix \mathbf{L} and a sparse error matrix \mathbf{S} by solving the following convex optimization problem:

$$\min_{\mathbf{L}, \mathbf{S} \in \mathbb{R}^{M \times N}} \|\mathbf{L}\|_* + \lambda \|\mathbf{S}\|_1 \text{ s.t. } \mathbf{M} = \mathbf{L} + \mathbf{S}, \quad (15)$$

where $\|\cdot\|_*$ is the nuclear norm (the sum of the singular values of \cdot) and $\|\cdot\|_1$ is the ℓ_1 norm (the sum of the absolute values of all the entries of \cdot). The nuclear norm and the ℓ_1 norm are well-known low-rank and sparsity promoting convex functions, respectively. Since the sparse matrix \mathbf{S} serves as removing outliers, RPCA has been applied to many low-level computer vision problems, such as foreground-background separation, specular highlight removal [15], image classification [17], and preprocessing in photometric stereo [16].

Prob. (15) is a nonsmooth optimization problem with a linear constraint, where each term in the objective function is proximable, and so it can be solved by Alg. (14). First, Prob. (15) can be reformulated as

$$\min_{\mathbf{L}, \mathbf{S} \in \mathbb{R}^{M \times N}} \|\mathbf{L}\|_* + \lambda \|\mathbf{S}\|_1 + \iota_{\{\mathbf{M}\}}(\mathbf{L} + \mathbf{S}), \quad (16)$$

where $\{\mathbf{M}\}$ is the closed convex set consisting only of \mathbf{M} . Then, by introducing auxiliary variables $\mathbf{Z}_1, \mathbf{Z}_2, \mathbf{Z}_3$, we have a variable-splitting form of Prob. (16) as follows:

$$\begin{aligned} \min_{\mathbf{L}, \mathbf{S}, \mathbf{Z}} & \|\mathbf{Z}_1\|_* + \lambda \|\mathbf{Z}_2\|_1 + \iota_{\{\mathbf{M}\}}(\mathbf{Z}_3) \text{ s.t. } \begin{pmatrix} \operatorname{vec}(\mathbf{Z}_1) \\ \operatorname{vec}(\mathbf{Z}_2) \\ \operatorname{vec}(\mathbf{Z}_3) \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{I} & \mathbf{O} \\ \mathbf{O} & \mathbf{I} \\ \mathbf{I} & \mathbf{I} \end{pmatrix} \begin{pmatrix} \operatorname{vec}(\mathbf{L}) \\ \operatorname{vec}(\mathbf{S}) \end{pmatrix}. \end{aligned} \quad (17)$$

Clearly, this is an instance of Prob. (11). The resulting algorithm is

$$\begin{cases} \mathbf{L}^{(n+1)} = \frac{1}{3}(2(\mathbf{Z}_1^{(n)} - \mathbf{Y}_1^{(n)}) - \mathbf{Z}_2^{(n)} + \mathbf{Y}_2^{(n)}) \\ \quad + \mathbf{Z}_3^{(n)} - \mathbf{Y}_3^{(n)}) \\ \mathbf{S}^{(n+1)} = \mathbf{Z}_1^{(n)} - \mathbf{Y}_1^{(n)} + \mathbf{Z}_3^{(n)} - \mathbf{Y}_3^{(n)} - 2\mathbf{L}^{(n+1)} \\ \mathbf{Z}_1^{(n+1)} = \text{prox}_{\gamma \|\cdot\|_*}(\mathbf{L}^{(n+1)} + \mathbf{Y}_1^{(n)}) \\ \mathbf{Z}_2^{(n+1)} = \text{prox}_{\lambda \gamma \|\cdot\|_1}(\mathbf{S}^{(n+1)} + \mathbf{Y}_2^{(n)}) \\ \mathbf{Z}_3^{(n+1)} = P_{\{\mathbf{M}\}}(\mathbf{L}^{(n+1)} + \mathbf{S}^{(n+1)} + \mathbf{Y}_3^{(n)}) \\ \mathbf{Y}_1^{(n+1)} = \mathbf{Y}_1^{(n)} + \mathbf{L}^{(n+1)} - \mathbf{Z}_1^{(n+1)} \\ \mathbf{Y}_2^{(n+1)} = \mathbf{Y}_2^{(n)} + \mathbf{S}^{(n+1)} - \mathbf{Z}_2^{(n+1)} \\ \mathbf{Y}_3^{(n+1)} = \mathbf{Y}_3^{(n)} + \mathbf{L}^{(n+1)} + \mathbf{S}^{(n+1)} - \mathbf{Z}_3^{(n+1)} \end{cases}, \quad (18)$$

where the proximity operators of the nuclear norm and the ℓ_1 norm can be computed by applying soft-thresholding to the singular values of $\mathbf{L}^{(n+1)} + \mathbf{Y}_1^{(n)}$ and the entries of $\mathbf{S}^{(n+1)} + \mathbf{Y}_2^{(n)}$, respectively. The projection onto $\{\mathbf{M}\}$ is simply given by $P_{\{\mathbf{M}\}}(\mathbf{X}) = \mathbf{M}$.

Constrained Signal Reconstruction

Signal reconstruction from incomplete and/or degraded observation is a fundamental problem in computer vision and related fields, such as medical imaging, microscopy, tomography, spectral imaging, and computational photography.

Consider the following observation model:

$$\mathbf{v} = \Phi \bar{\mathbf{u}} + \mathbf{n}, \quad (19)$$

where $\bar{\mathbf{u}}$ is a latent signal to be reconstructed, Φ is a matrix representing some observation process, \mathbf{n} is a sensor noise, and \mathbf{v} is an observation vector. For example, in compressive imaging scenarios [6, 13], the matrix Φ expresses the compressive measurement process (e.g., random coded sampling), and we try to reconstruct the latent image $\bar{\mathbf{u}}$ from the compressive measurements \mathbf{v} .

Such a problem is often reduced to convex optimization problems of the form:

$$\min_{\mathbf{u}} \mathcal{R}(\Psi \mathbf{u}) + \frac{\lambda}{2} \|\Phi \mathbf{u} - \mathbf{v}\|^2 \quad (20)$$

where the first term is a regularization term, modeling some desirable properties on the signal of interest, and the second term is an ℓ_2 data-fidelity term, enforcing consistency with the observation \mathbf{v} , and $\lambda > 0$ is a balancing parameter. Here we

assume that \mathcal{R} is a proximable convex function and Ψ is some linear transform.

On the other hand, we can also consider a constrained counterpart of (20) as follows:

$$\min_{\mathbf{u}} \mathcal{R}(\Psi \mathbf{u}) \text{ s.t. } \|\Phi \mathbf{u} - \mathbf{v}\| \leq \varepsilon, \quad (21)$$

where $\varepsilon > 0$ controls the degree of data-fidelity. The above constrained formulation (21) has a clear advantage over the unconstrained one (20), that is, ε can be determined based only on the noise intensity, whereas λ depends both on the noise intensity and the regularization choice.

By using the definition in (8), Prob. (21) can be rewritten as

$$\min_{\mathbf{u}} \mathcal{R}(\Psi \mathbf{u}) + \iota_{B_{\ell_2}^{\mathbf{v}, \varepsilon}}(\Phi \mathbf{u}), \quad (22)$$

which is an instance of Prob. (10). Thus, the problem can be solved by Alg. (14), resulting in

$$\begin{cases} \mathbf{u}^{(n+1)} = (\Psi^\top \Psi + \Phi^\top \Phi)^{-1}(\Psi^\top (\mathbf{z}_1^{(n)} - \mathbf{y}_1^{(n)}) \\ \quad + \Phi^\top (\mathbf{z}_2^{(n)} - \mathbf{y}_2^{(n)})) \\ \mathbf{z}_1^{(n+1)} = \text{prox}_{\gamma \mathcal{R}}(\Psi \mathbf{u}^{(n+1)} + \mathbf{y}_1^{(n)}) \\ \mathbf{z}_2^{(n+1)} = P_{B_{\ell_2}^{\mathbf{v}, \varepsilon}}(\Phi \mathbf{u}^{(n+1)} + \mathbf{y}_2^{(n)}) \\ \mathbf{y}_1^{(n+1)} = \mathbf{y}_1^{(n)} + \Psi \mathbf{u}^{(n+1)} - \mathbf{z}_1^{(n+1)} \\ \mathbf{y}_2^{(n+1)} = \mathbf{y}_2^{(n)} + \Phi \mathbf{u}^{(n+1)} - \mathbf{z}_2^{(n+1)} \end{cases}. \quad (23)$$

Definition

Convolutional sparse coding is the method of learning sparse representations $\{\mathbf{x}_j\}$ of a signal \mathbf{s} , which is reconstructed from the sparse representations' convolution with a set of linear filters $\{\mathbf{d}_j\}$ (also known as templates or dictionaries):

$$\mathbf{s} = \sum_j \mathbf{d}_j * \mathbf{x}_j \quad (1)$$

The signal can be an image, an audio clip, a sequence of words, or even a video clip.

Background

Representation learning forms a cornerstone of modern machine learning. Representing the data in the relevant feature space is critical to obtaining good performance in challenging machine learning tasks in speech, computer vision, and natural language processing.

Sparse Coding

Sparse coding is one of the most widely used models for inverse problems in signal processing [5]. It is a representation learning method which aims at finding a sparse representation of the input data in the form of a linear combination of basic templates. Given a signal $s \in \mathbb{R}^n$, sparse coding is a representation learning method which aims at finding a sparse representation of the signal in the form of a linear combination (with coefficients $\mathbf{x} = [x_1, x_2, \dots, x_k]^\top$) of basic templates (i.e., dictionary $D = [D_1, D_2, \dots, D_k]$):

$$s = D\mathbf{x} = \sum_{i=1}^k x_i D_i \quad (2)$$

where $\mathbf{x} \in \mathbb{R}^k$, $D \in \mathbb{R}^{n \times k}$. Using sparse coding for images usually requires flatten the image as a vector s . However, this model fails to incorporate natural domain-specific invariances such as shift invariance and results in highly redundant dictionary elements, which makes inference in these models expensive.

Convolutional Sparse Coding

These shortcomings can be remedied by incorporating invariances into the sparse coding model, and such models are known as convolutional models. Convolutional models are ubiquitous in machine learning for image, speech, and sentence representations [3, 9, 11], and in neuroscience for modeling neural spike trains [4, 10]. Deep convolutional neural networks are a multilayer extension of these models with nonlinear activa-

tions. Such models have revolutionized performance in image, speech, and natural language processing [8, 11].

The model of convolutional sparse representations is proposed for translation-invariant sparse representations. Specifically, the unstructured dictionary D is specified with a set of linear filters $\{\mathbf{d}_j\}$. Given a signal $s \in \mathbb{R}^{n \times n'}$, convolutional sparse coding finds a sparse representation of the signal in the form of a summation of activation maps $\{\mathbf{x}_j\}$ convolution with filters $\{\mathbf{d}_j\}$:

$$s = \sum_j \mathbf{d}_j * \mathbf{x}_j. \quad (3)$$

Theory

Solving Convolutional Sparse Coding Through Optimization

Given m independent samples of the input signal $\{s^{(i)}\}$, a square loss reconstruction criterion is usually employed for learning the convolutional sparse coding model in (3)

$$\begin{aligned} & \underset{\{\mathbf{d}_j\}, \{\mathbf{x}_j^{(i)}\}}{\operatorname{argmin}} \sum_{i=1}^m \left\| s^{(i)} - \sum_{j \in [L]} \mathbf{d}_j * \mathbf{x}_j^{(i)} \right\|_2^2 \\ & + \lambda \sum_{i=1}^m \sum_j \|\mathbf{x}_j^{(i)}\|_1 \quad \text{such that } \|\mathbf{d}_j\| = 1 \end{aligned} \quad (4)$$

The constraints ($\|\mathbf{d}_j\| = 1$) are required to avoid the scaling ambiguity between the filters and the activation maps; without the constraints, the scaling can be exchanged between the filters \mathbf{d}_j and the activation maps $\mathbf{x}_j^{(i)}$. The regularization term $\lambda \sum_{i=1}^m \sum_j \|\mathbf{x}_j^{(i)}\|_1$ is used to promote sparsity on $\mathbf{x}_j^{(i)}$. The filters or dictionaries \mathbf{d}_j are shared across different samples $s^{(i)}$. Due to shift invariance of the convolutional operator, shifting a filter \mathbf{d}_j by some amount, and applying a corresponding negative shift on the activation $\mathbf{x}_j^{(i)}$, leaves the objective in (4) unchanged.

A popular heuristic for solving (4) is based on alternating minimization [2], where the filters

\mathbf{d}_j are optimized, while keeping the activations $\mathbf{x}_j^{(i)}$ fixed and vice versa. Each alternating update can be solved efficiently (since it is linear in each of the variables). However, the method is computationally expensive in the large sample setting since each iteration requires a pass over all the samples, and in modern machine learning applications, the number of samples can run into billions. Moreover, alternating minimization has multiple spurious local optima, and reaching the global optimum of (4) is NP-hard in general. This problem is severely amplified in the convolutional setting due to additional symmetries, compared to the usual dictionary learning setting (without the convolutional operation).

Solving Convolutional Sparse Coding Through Spectral Methods

Tensor methods have emerged as a powerful paradigm for consistent learning of many latent variable models such as topic models, independent component analysis, and dictionary learning [1,7]. Model parameters are estimated via CP decomposition of the observed higher-order input moments.

In [6], the authors extend tensor decomposition framework to models with invariances, such as convolutional dictionary models. The tensor decomposition algorithm used in [6] is based on the popular alternating least squares (ALS) method, but with additional shift invariance constraints on the factors. The authors demonstrate that each ALS update can be computed efficiently using simple operations such as fast Fourier transforms and matrix multiplications. The algorithm converges to models with better reconstruction error and is much faster, compared to the popular alternating minimization heuristic, where the filters and activation maps are alternately updated.

Definition

Cook-Torrance model is an analytic BRDF model that describes the wavelength dependent reflectance property of a surface based on the principles of microfacet theory.

Background

Accurate descriptions of how light reflects off a surface are a fundamental prerequisite for computer vision and graphics applications. Real world materials exhibit characteristic surface reflectance, such as glossy or specular highlights, anisotropy, or off-specular reflection, which need to be modeled for such applications. The surface reflectance of a material is formalized by the notion of the Bidirectional Reflectance Distribution Function (BRDF) [1], which describes the reflected response of a surface in a certain exitant direction to illumination from a certain incident direction over a hemisphere of directions.

Analytical reflection models attempt to describe certain classes of BRDFs using a mathematical representation involving a small number of parameters. The Cook-Torrance model [2] is an analytic isotropic BRDF model that falls under the category of a physics-based model and is based on the microfacet theory of inter-reflection of light at rough surfaces. It extends the Torrance-Sparrow reflectance model, originally developed in the field of applied optics [3], for modeling wavelength dependent

effects of reflection. The model predicts both the directional distribution as well as spectral composition of reflected light.

Theory

Given a light source, a surface, and an observer, the Cook-Torrance model describes the intensity and spectral composition of the reflected light reaching the observer. The geometry of reflection is shown in Fig. 1. An observer is looking at a point P on a surface. V is the unit vector in the direction of the viewer, N is the unit normal to the surface, and L is the unit vector in the direction of a specific light source. H is the normalized half-vector between V and L given as

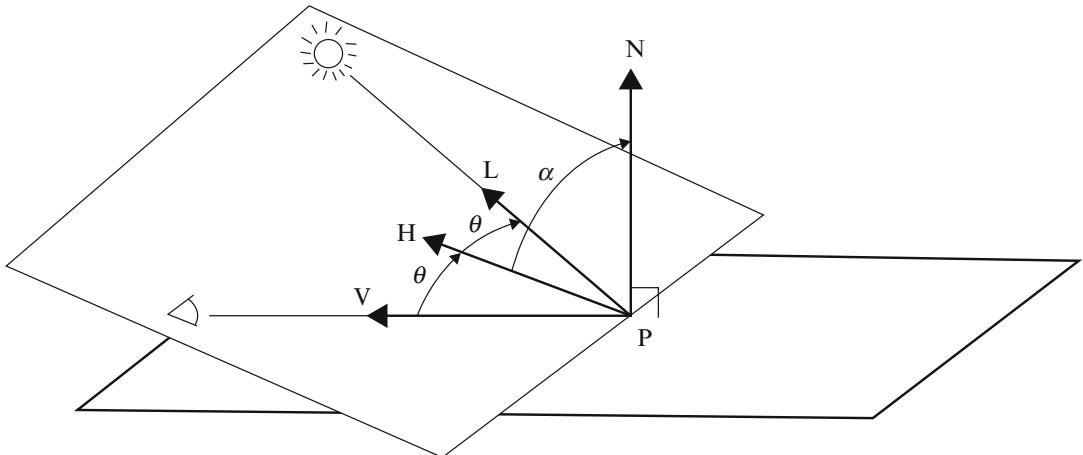

$$H = \frac{L + V}{\|L + V\|}, \quad (1)$$

and is the unit normal of a microfacet that would reflect light specularly from L to V . α is the angle between H and N , and θ is the angle between H and V , so that $\cos \theta = V \cdot H = L \cdot H$.

The main components of the reflectance model are the directionally dependent diffuse and specular reflection terms, and a directionally independent ambient term. The specular component R_s represents light that is reflected from the surface of the material. The diffuse component R_d originates from internal scattering (in which the incident light penetrates beneath the surface of the material) or from multiple surface reflections (which occur if the surface is sufficiently rough). The directional reflectance is thus given as $R = sR_s + dR_d$ where $s + d = 1$. The model also includes a directionally independent ambient term R_a to approximate the effects of global illumination.

The total intensity of the light reaching the observer is the sum of the reflected intensities from all light sources plus the reflected intensity from any ambient illumination. The basic reflectance model then becomes

$$I_r = I_{ia} R_a + \sum_l (sR_s + dR_d) I_{il} (N \cdot L_l) d\omega_{il}. \quad (2)$$

Cook-Torrance Model, Fig. 1 The geometry of reflection [2]

This formulation accounts for the effect of light sources with different intensities and different projected areas which may illuminate a scene. The next two sub-sections consider the directional and wavelength dependence of the reflectance model.

Directional Distribution

The ambient R_a and diffuse R_d components of the model reflect light independent of the viewing direction. However, the specular component R_s does depend on the viewing direction. The angular spread of the specular component can be described by assuming that the surface consists of microfacets, each of which reflects specularly [3].

Only facets whose normal is in the direction H contribute to the specular component of reflection from L to V . The specular component is given as

$$R_s = \frac{F}{\pi} \frac{D \cdot G}{(N \cdot L)(N \cdot V)}, \quad (3)$$

where D is the facet slope distribution function, G is the geometric masking and shadowing attenuation term, and F accounts for Fresnel reflectance. The Fresnel term F describes the fraction of light that is reflected from each smooth microfacet. It is a function of incidence angle and wavelength of incident light and is discussed in the next section.

Microfacet Distribution

The facet slope distribution function D represents the fraction of the facets that are oriented in the direction H . Various facet slope distribution functions have been considered by Blinn [4] including the Gaussian model:

$$D = ce^{-(\alpha/m)^2}, \quad (4)$$

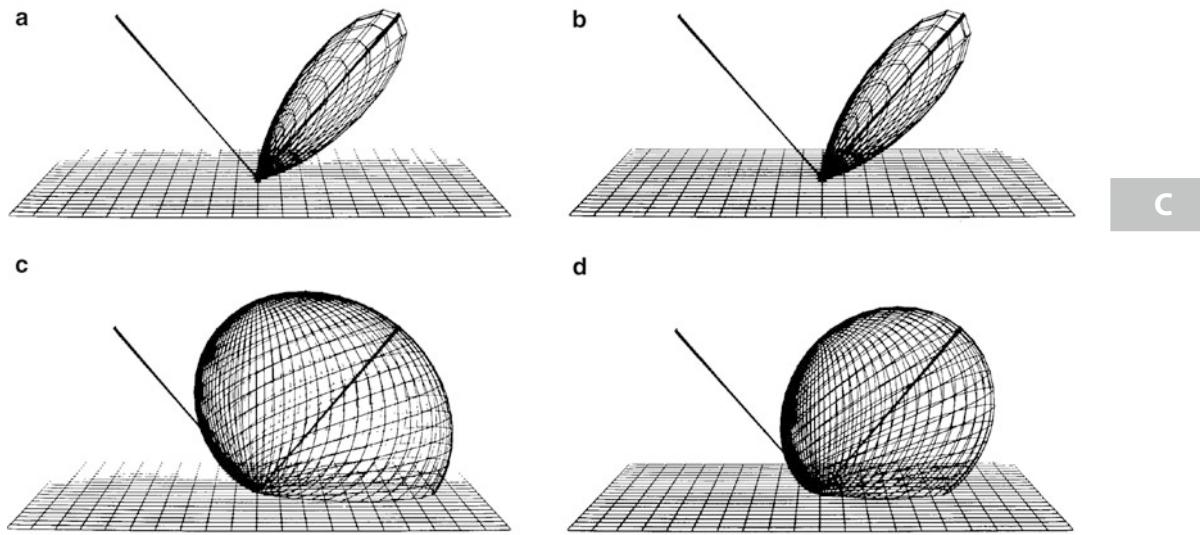

where c is the normalization constant.

Beckmann described a model that originated from the study of scattering of radar waves from rough surfaces [5], and is applicable to a wide range of surface conditions ranging from smooth to very rough. For rough surfaces, the Beckmann distribution is

$$D = \frac{1}{m^2 \cos^4 \alpha} e^{-[(\tan \alpha)/m]^2} \quad (5)$$

In both the facet slope distribution functions, the spread of the specular component depends on the root mean square (rms) slope m . Small values of m signify gentle facet slopes and give a distribution that is highly directional around the specular direction, while large values of m imply steep facet slopes and give a distribution that is spread out with off-specular peak modeled by the Beckmann distribution (see Fig. 2).

For general surfaces with two or more scales of surface roughness, the slope m can be modeled

Cook-Torrance Model, Fig. 2 (a) Beckmann distribution for $m = 0.2$, (b) Gaussian distribution for $m = 0.2$, (c) Beckmann distribution for $m = 0.6$, (d) Gaussian distribution for $m = 0.6$ [2]

by using a convex weighted combination of two or more distribution functions [6]:

$$D = \sum_j w_j D(m_j), \quad (6)$$

where m_j is the rms slope and w_j the weight of the j th distribution respectively.

Geometric Attenuation The geometrical attenuation factor G accounts for the shadowing and masking of one facet by another and is discussed in detail in [3, 4]. The following expression is derived for G for microfacets in the shape of v-shaped grooves (see Fig. 3):

$$G = \min \left\{ 1, \frac{2(N \cdot H)(N \cdot V)}{(V \cdot H)}, \frac{2(N \cdot H)(N \cdot L)}{(V \cdot H)} \right\}. \quad (7)$$

Spectral Composition

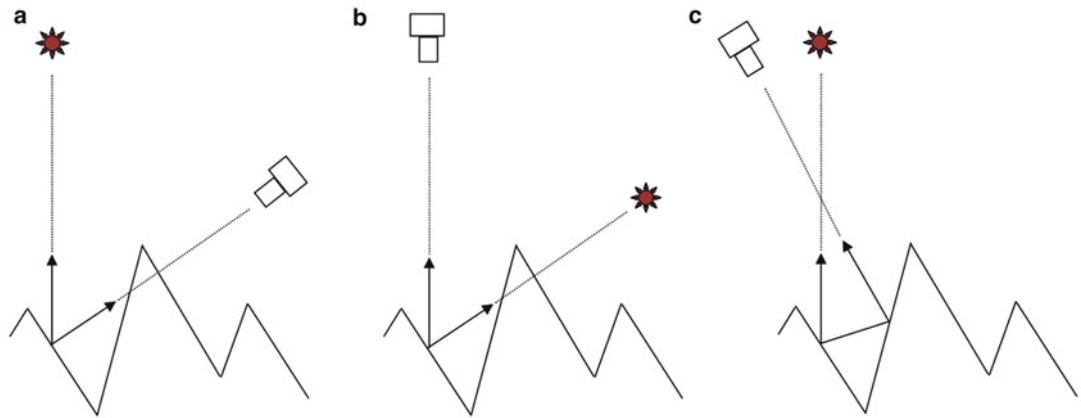

The ambient, diffuse, and specular reflectances all depend on wavelength. R_a , R_d , and the F term of R_s may be obtained from the appropriate reflectance spectra for the material. Reflectance spectra of thousands of materials can be found in

the literature [7–10]. The reflectance data are usually for illumination at normal incidence. These values are normally measured for polished surfaces and must be multiplied by $1/\pi$ to obtain the bidirectional reflectance for a rough surface. Most materials are measured at only a few wavelengths in the visible range (typically around 10–15), so that values for intermediate wavelengths must be interpolated.

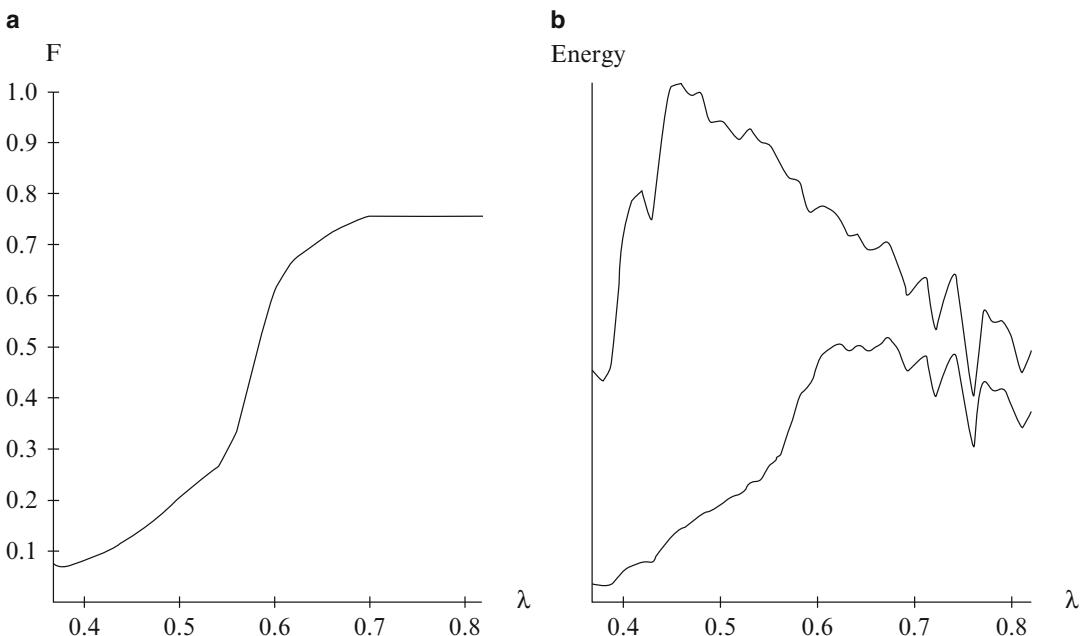

The spectral energy distribution of the reflected light is found by multiplying the spectral energy distribution of the incident light by the reflectance spectrum of the surface. An example of this is shown in Fig. 4. The spectral energy distributions of the sun and a number of CIE standard illuminants are available in [11].

Fresnel Reflectance

The reflectance F may be obtained theoretically from the Fresnel equation [12]. This equation expresses the reflectance of a perfectly smooth, mirrorlike surface in terms of the index of refraction n (for both metals and dielectrics) and the extinction coefficient k (for metals only) of the surface and the angle of incidence of illumination θ . The Fresnel equation for unpolarized incident light and a dielectric material ($k = 0$) is

standard illuminant D6500. Bottom curve: Spectral energy distribution of light reflected from a copper mirror illuminated by D6500 [2]

$$F = \frac{1}{2} \frac{(g - c)^2}{(g + c)^2} \left\{ 1 + \frac{[c(g + c) - 1]^2}{[c(g - c) + 1]^2} \right\}, \quad (8)$$

where $c = \cos \theta = V \cdot H$ and $g^2 = n^2 + c^2 - 1$. The dependence of the reflectance on wavelength and the angle of incidence implies that the color of the reflected light changes with the incidence

angle, from color of the material at normal incidence to color of the illuminant at grazing incidence.

In general, both n and k vary with wavelength, but their values are frequently not known. On the other hand, experimentally measured values of the reflectance at normal incidence are frequently known. To obtain the spectral and

angular variation of F , the following practical approach is adopted: If n and k are known, the Fresnel equation is used. If not, but the normal reflectance is known, the Fresnel equation is fit to the measured normal reflectance for a polished surface. For nonmetals or dielectrics, for which $k = 0$, this immediately gives an estimate of the index of refraction n . For metals, for which k is generally not 0, k is set to 0 to get an effective value for n from the normal reflectance. The angular dependence of F is then available from the Fresnel equation. The above procedure yields the correct value of F for normal incidence and a good estimate of its angular dependence,

which is only weakly dependent on the extinction coefficient k .

To illustrate this procedure, consider a dielectric material ($k = 0$) at normal incidence. $\theta = 0$, so $c = 1$, $g = n$ and Eq. 8 reduces to

$$F_0 = \frac{(n - 1)^2}{(n + 1)^2}. \quad (9)$$

Solving for n gives the equation

$$n = \frac{1 + \sqrt{F_0}}{1 - \sqrt{F_0}}. \quad (10)$$

Values of n determined in this way can then be substituted into the original Fresnel equation to obtain the reflectance F at other angles of incidence. The procedure may then be repeated at other wavelengths to obtain the spectral and directional dependence of the reflectance.

RGB Values

The laws of trichromatic color reproduction are finally used to convert the spectral energy distribution of the reflected light to the appropriate RGB values for a particular display device. Every color sensation can be uniquely described by its location in a three dimensional color space. One such color space is called the XYZ space. A point in this space is specified by three coordinates, the color's XYZ tristimulus values. Each spectral energy distribution is associated with a point in the XYZ color space and thus with tristimulus values. If two spectral energy distributions are associated with the same tristimulus values, they produce the same color sensation and are called metamers. The goal, then, is to find the proportions of RGB that produce a spectral energy distribution that is a metamer of the spectral energy distribution of the reflected light.

These proportions are determined by calculating the XYZ tristimulus values that are associated with the spectral energy distribution of the reflected light [11], and then calculating the RGB values (with a linear transform from XYZ followed by a non-linear transform based on display gamma curve) that produce a spectral energy distribution with these tristimulus values [13].

Application

Being a physics-based reflectance model, the Cook-Torrance model has been widely used in computer vision and graphics to model the appearance of real world materials. It has been shown to well approximate the reflectance of many measured isotropic BRDFs in the MERL database [14] ranging from metals, plastics, rubber and fabrics [15] (see Fig. 5). It has also been successfully applied in computer vision to the problem of uncalibrated photometric stereo

[18], and in computer graphics to model the measured surface reflectance of human skin [16, 17] (see Fig. 6).

Corner Detection

Michael Maire

California Institute of Technology, Pasadena,
CA, USA

Related Concepts

- ▶ Edge Detection

Definition

Corner detection is the process of locating points in an image whose surrounding local neighborhoods contain edges of different orientations that intersect at those points.

Background

A corner can be viewed as a special type of interest point. Interest points [1] are distinct local image regions with well-defined positions that are robust to various image deformations, such as changes in viewpoint or lighting. Many corner detection algorithms relax the strict requirement of edge intersection and, for example, instead locate centroids of windows containing high edge energy in multiple directions.

Theory

Most corner detection algorithms operate by scoring local image patches [2–6]. Nonmaximum suppression and thresholding steps can then be applied to localize corners by selecting the peak responses and retaining only those deemed sufficiently salient.

An early approach to corner detection scores patches based on their similarity to neighboring patches [7]. Comparing a patch centered on a corner to patches offset by several pixels in any direction should produce a low similarity score as the edges incident at the corner do not align once shifted. In contrast, patches in uniform regions are identical to their neighboring patches. Comparing patches using the sum of squared differences (SSD) yields score:

$$S_{u,v}(x, y) = \sum_{x_i} \sum_{y_i} \left[I(x_i + u, y_i + v) - I(x_i, y_i) \right]^2 \quad (1)$$

for comparing the patch in image I centered at pixel (x, y) to the one offset by u in the x -direction and v in the y -direction. The summation is over the pixels (x_i, y_i) belonging to the patch. An optional weighting factor can be used to decrease the importance of the outer patch region with respect to the center. Since patches centered on edge pixels which are not corners exhibit a large SSD when displaced orthogonal to the edge, but no difference when displaced along it, a robust measure of corner strength C takes the minimum over all possible displacements:

$$C(x, y) = \min_{u,v} S_{u,v}(x, y) \quad (2)$$

In the limit of small displacement, the difference in (Eq. 1) can be approximated by image derivatives:

$$\begin{aligned} & I(x_i + \Delta x, y_i + \Delta y) - I(x_i, y_i) \\ &= I_x(x_i, y_i) \Delta x + I_y(x_i, y_i) \Delta y \end{aligned} \quad (3)$$

yielding:

$$S(x, y) = [\Delta x \ \Delta y] \begin{bmatrix} \sum_{x_i, y_i} (I_x(x_i, y_i))^2 & \sum_{x_i, y_i} I_x(x_i, y_i) I_y(x_i, y_i) \\ \sum_{x_i, y_i} I_x(x_i, y_i) I_y(x_i, y_i) & \sum_{x_i, y_i} (I_y(x_i, y_i))^2 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} \quad (4)$$

Define:

$$A(x, y) = [\nabla I \nabla I^T] \Big|_{(x, y)} \quad (5)$$

The eigenvalues λ_1 and λ_2 of $A(x, y)$ describe the behavior of the local neighborhood of point (x, y) . This region is uniform if λ_1 and λ_2 are both small, an edge if exactly one of λ_1, λ_2 is large, and a corner if both are large.

The Harris corner detector [4] translates this observation into a measure of corner strength given by:

$$C(x, y) = \lambda_1 \lambda_2 - k(\lambda_1 + \lambda_2)^2 \quad (6)$$

where k is a parameter. Shi and Tomasi [8] instead use:

$$C(x, y) = \min(\lambda_1, \lambda_2) \quad (7)$$

Lindeberg [5] extends the Harris detector to operate across multiple scales and adds automatic scale selection.

Wang and Brady [9] define corners in terms of curvature using the score:

$$C(x, y) = \nabla^2 I - k|\nabla I|^2 \quad (8)$$

where k is again a constant user-defined parameter (Fig. 1).

Forstner and Gulch [3] take a different approach to corner localization by finding points p whose distance to edges in their local neighborhood is minimal. Specifically,

$$p = \operatorname{argmin}_{(x', y')} \sum_{(x_i, y_i)} D((x_i, y_i), (x', y')) \quad (9)$$

where D is the distance from point (x', y') to the line passing through (x_i, y_i) with orientation

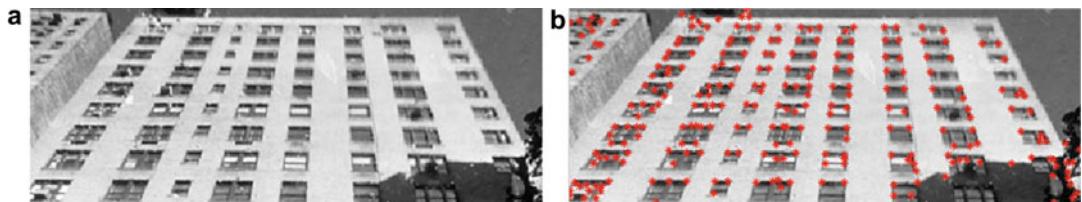

orthogonal to the gradient at (x_i, y_i) . The distance is further weighted by the gradient magnitude. A similar technique can be used to locate junctions with respect to discrete contour fragments [10].

Application

Interest points, including corners, have found use in a variety of computer vision applications such as image matching, object detection and tracking, and 3D reconstruction. The ability to localize interest points in different views of the same object makes matching and tracking feasible. By design, corner and other interest point detectors respond at locations with rich structure in the surrounding image neighborhood. Thus, these positions are natural choices at which to compute informative feature vectors that describe local image content. The ability to associate these descriptors with interest points further facilitates matching and detection algorithms. In general, the choice of feature descriptor to compute at corners can be application specific and may or may not be coupled with the choice of corner detection algorithm.

While a goal of corner and interest point detectors is to localize the same physical sites across different views, in practice this is only accomplished in a statistical sense. There is usually a significant chance of both missed and spurious detections. Consequently, algorithms built on these components must be robust to errors in detecting individual corners, and instead rely on average detector performance. A typical approach is to utilize a large number of corners or interest points per image for added redundancy.

It is not strictly necessary to use corners or interest points in the process of extracting feature

Corner Detection, Fig. 1 Corners detected using the Harris operator followed by nonmaximum suppression and thresholding

descriptors from images. Alternatives include computing features at sampled edge points or on regions from a segmentation of the image. The sliding window detection paradigm exhaustively scans the image, computing features over all possible image windows.

Cross Entropy

Ying Nian Wu

Department of Statistics, UCLA, Los Angeles, CA, USA

Definition

Cross entropy is a concept in information theory to measure the independence of two probability distributions.

Theory

For two distributions $p(x)$ and $q(x)$ defined on the same space, the cross entropy is defined as

$$\begin{aligned} H(p, q) &= E_p[-\log q(X)] \\ &= E_p[-\log p(X)] \\ &\quad + E_p[\log(p(X)/q(X))] \\ &= H(p) + KL(p, q), \end{aligned}$$

where $H(p) = E_p[-\log p(X)]$ is the entropy of p and $KL(p, q) = E_p[\log(p(X)/q(X))]$ is the Kullback-Leibler divergence from p to q . The Kullback-Leibler divergence is also called relative entropy.

The cross entropy method is a Monte Carlo method for rare event simulation and stochastic optimization [2].

Curvedness

Related Concepts

► Geodesics, Distance Maps, and Curve Evolution

Definition

Curvature is a fundamental concept of differential geometry that represents local “curvedness” of some object such as a curve, a surface, and a Riemannian space.

Background

Dealing with the shape of an object is a fundamental issue of computer vision. It is necessary, for example, to represent the two-dimensional or

three-dimensional shape of an object, to extract the object shape from various types of images, and to measure similarity between two object shapes. The application of differential geometry to these problems is getting more and more common in modern computer vision. Curvature is one of the most fundamental concept of differential geometry, and its use can be seen throughout all sorts of related problems. This entry explains basic definitions of the curvature of a plane curve and a surface in Euclidean space and summarizes their applications to a few major applications. See [1] for the definition of curvatures of a Riemannian space.

Theory and Application

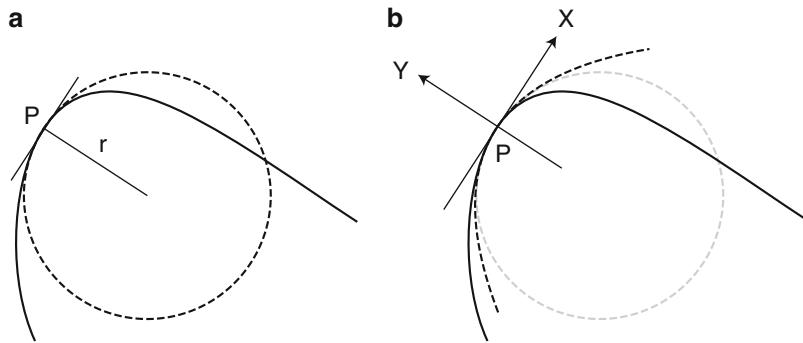

A plane curve C can be specified by the coordinates $(x(s), y(s))$ of each point, where s is a monotonic function of the arc length. Algebraically, the curvature $\kappa(s)$ of C at a point $(x(s), y(s))$ is defined as

$$k(s) = \frac{\dot{x}\ddot{y} - \dot{y}\ddot{x}}{(\dot{x}^2 + \dot{y}^2)^{3/2}}, \quad (1)$$

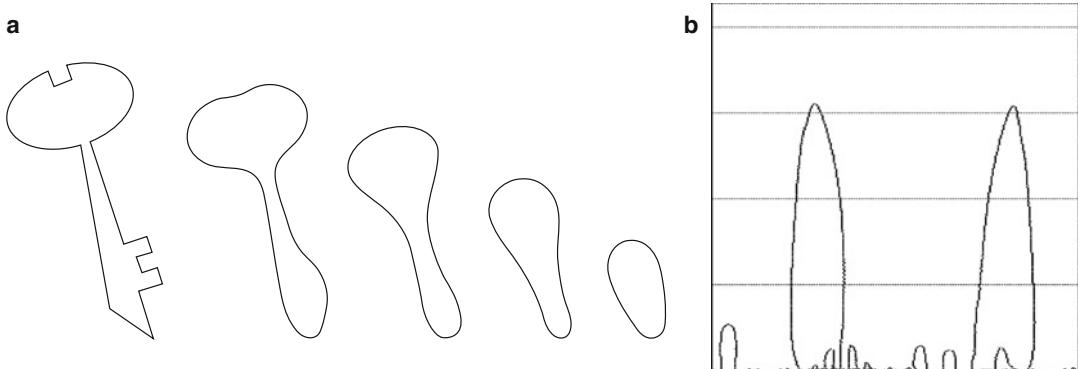

where $\dot{x} = dx/ds$, $\ddot{x} = d^2x/ds^2$, etc. Note that the denominator becomes 1 when s is the arc length itself. Let $\phi(s)$ be the orientation of the tangent to C at $(x(s), y(s))$, that is, $\tan \phi(s) = \dot{y}/\dot{x}$. If s is the arc length, the curvature can be represented as $k = \dot{\phi}(s)$.

Geometrically, the absolute value of κ is equal to the reciprocal of the radius r of the circle osculating the curve C at the point, that is, $|k| = 1/r$, as shown in Fig. 1a; r is called the radius of curvature. The curve C can also be locally approximated by a second-order polynomial curve. Consider the local coordinates XY defined by the tangent and the normal vectors to C , as shown in Fig. 2b. The approximating quadratic curve will be given as $Y = kX^2/2$. Note that there is freedom in the choice of the sign of the curvature; in its definition of Eq. (1), the sign depends on the parametrization of s .

The curvature of a plane curve is effectively used to analyze and/or represent two-dimensional

Curvature, Fig. 1 (a) A plane curve (solid line) and an osculating circle (broken line). The curvature κ at P is the reciprocal of the radius r of the circle. (b) The approximating quadratic curve at P (broken line)

Curvature, Fig. 2 (a) The curvature scale space of a shape. (b) $s - \sigma$ plot of the trajectories of the inflection points of the shape

shapes. In [2], the curvature primal sketch is proposed, in which significant changes in curvature along a curve are detected and used for shape representation. In [3], the concept of curvature scale space (CSS) is presented, where the zero-crossings of curvature (i.e., the inflection points of the curve) are used to represent the structure of the curve at varying levels of detail. This technique has been applied to various computer vision problems, such as feature extraction, shape retrieval, and object recognition [4].

The CSS technique is summarized as follows. Let $X(s; \sigma)$ and $Y(s; \sigma)$ be the convolutions of $x(s)$ and $y(s)$ with a Gaussian kernel $g(s, \sigma)$, respectively, that is, $X(s; \sigma) = x(s) * g(s, \sigma)$ and $Y(s; \sigma) = y(s) * g(s, \sigma)$. As shown in Fig. 2a, the curve given by $(X(s; \sigma), Y(s; \sigma))$ gradually becomes smoother, as σ increases. Figure 2b shows a $s - \sigma$ plot of the trajectories of the inflection points.

The horizontal axis indicates the normalized arc length s that is scaled to the range $[0-1]$.

The curvature of a plane curve serves as a basic measure of its smoothness. A smoother curve has smaller curvature at each point. Curve evolution like the one in CSS is used in many applications besides shape analysis/representation, where this property with curvature plays a central role.

The active contour model (ACM) [5] was developed to detect the contour of an object in an image by moving an elastic curve from a given initial position to nearby the object contour. This is performed by minimizing the sum of two energy terms, an external term modeling the similarity/dissimilarity to the image edges and an internal term modeling the “elasticity” of the curve. This latter term usually includes the arc length as well as the curvature of the curve to

obtain a smoother curve that is more desirable in practice. ACM was later reformulated as a problem of finding local geodesics in a space with Riemannian metric computed from the image, which is known as the geodesic active contour model [6]. The same smoothing property associated with (Euclidean) curvature also plays a key role there.

The evolution of a curve can be fully represented by specifying the normal speed of the curve, that is, the evolution speed measured along the normal vector at each point. Consider a closed curve evolving with speed equal to its curvature, where the sign of the curvature is chosen so that a circle would shrink inward. Its generalization to higher-dimensional space is known as the mean curvature flow. This curve evolution has the properties of “smoothing”; the curve evolves so that its high curvature parts are smoothed out in a finite time. It is shown that any closed curve will become a convex curve and then shrink to a point (Grayson’s theorem [7]).

The level set method (LSM) [8] is a numerical framework for computing such curve evolutions (as well as surface/manifold evolution), which has many advantages to previous methods, such as being able to handle topological changes of the curves. In LSM, a curve is represented as a zero-level curve of an auxiliary function ϕ as $\phi(x, y) = 0$. Then, the curve evolution with normal speed F is represented as $\partial\phi/\partial t = -F \perp \nabla\phi$, a time-dependent evolution equation of ϕ . The curvature κ of each point of the level curve is computed using ϕ as

$$k = \nabla \cdot \frac{\nabla\phi}{|\nabla\phi|} \quad (2)$$

where ∇ is the gradient operator $\nabla = (\partial/\partial x, \partial/\partial y)$. Thus, the mean curvature flow is represented as $\partial\phi/\partial t = -k \perp \nabla\phi$.

In some problems, the evolution equations of an image $I(x, y)$, which are similar to those of $\phi(x, y)$ above, are considered. An example is the diffusion equation [9] represented as $\partial I/\partial t = \nabla \cdot (c(x, y) \nabla I)$, which has many applications, for example, image denoising/restoration

[10] and image inpainting [11]. Although the choice of $c(x, y)$ depends on each application, it often has a term of the curvature of the level curves of $I(x, y)$, which can be also computed by Eq. (2) (When $c(x, y)$ is constant, the resulting image evolution coincides with the Gaussian blurring).

The curvature of a smooth surface S in a three-dimensional space is defined as follows. Consider the tangent plane to S at a point P of S (Fig. 3b). The normal vector of S at P should be perpendicular to the tangent plane. Then consider a plane containing this normal vector (Fig. 3c). The intersection of the plane with S yields a plane curve on it. The curvature of this plane curve at P , defined in the same manner as above, is called the normal curvature of S at P . The plane has a one-dimensional rotational freedom around the normal vector, and the normal curvature is defined for each of such planes.

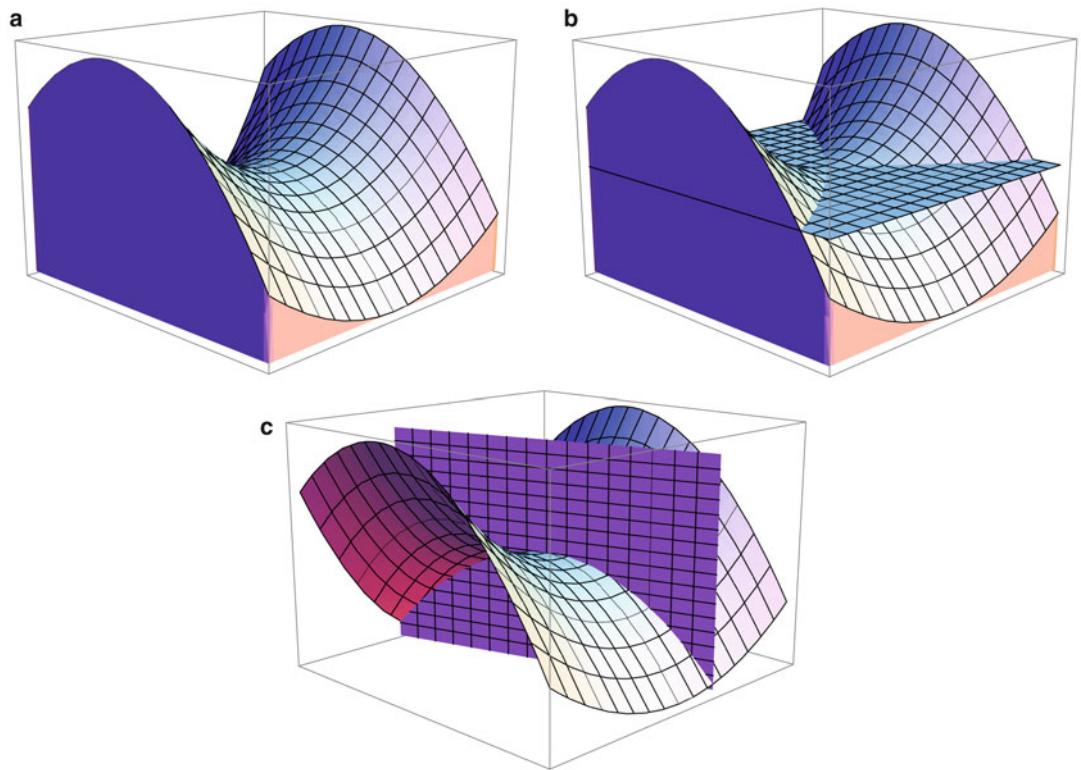

Let the maximum and minimum values of the normal curvature at P be k_1 and k_2 . They are called the principal curvatures of S at P . Consider a local coordinate frame XYZ whose origin is located at P and Z axis coincides with the normal vector. The surface is locally approximated by a second-order polynomial surface

$$Z = \frac{1}{2} [X \ Y] \mathbf{H} \begin{bmatrix} X \\ Y \end{bmatrix}, \quad (3)$$

where \mathbf{H} is a 2×2 symmetric matrix. Specifying a direction in the XY plane by a two-dimensional normalized vector \mathbf{v} ($\|\mathbf{v}\|^2 = 1$), the normal curvature for the direction \mathbf{v} is given by $\mathbf{v}^\top \mathbf{H} \mathbf{v}$. The eigenvalues of \mathbf{H} are the same as the principal curvatures k_1 and k_2 , and their associated eigenvectors the corresponding directions \mathbf{v} ’s. The Gaussian curvature of S at P is defined as a product of principal curvatures k_1 and k_2 ,

$$k = k_1 k_2, \quad (4)$$

and the mean curvature of S at P is defined as their mean,

Curvature, Fig. 3 (a) A surface S . (b) The tangent plane to S at a point P in the center. (c) A plane containing the normal vector of S at P . The intersecting curve on the plane gives the normal curvature of S at P

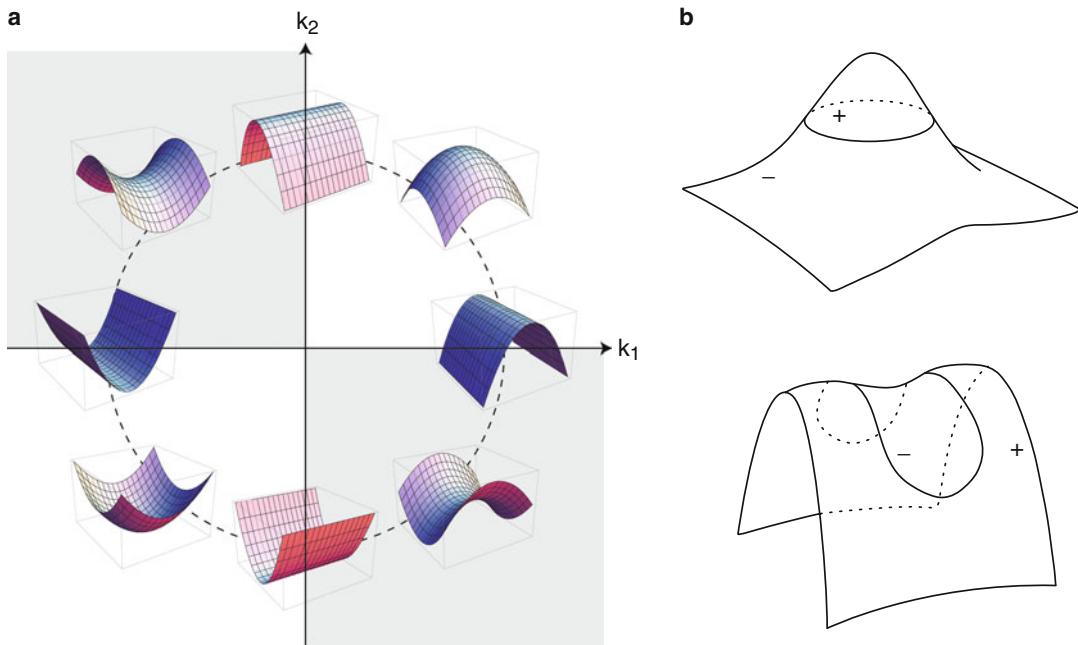

$$h = \frac{k_1 + k_2}{2}. \quad (5)$$

Local shapes of a surface are classified by the signs of the principal curvatures k_1 and k_2 , as shown in Fig. 4a [12]. A point at which k_1 and k_2 have the same sign, that is, the Gaussian curvature $\kappa > 0$, is called an elliptical point. If k_1 and k_2 have different signs, that is, $\kappa < 0$, then the point is called a hyperbolic point. If either k_1 or k_2 vanishes, that is, $\kappa = 0$, then the point is called a parabolic point. Using this classification, a smooth surface may be segmented into finite regions depending on the sign of the curvatures; Fig. 4b shows examples of the surface segmentation based on the Gaussian curvature signs.

This classification method is used in all sorts of applications. For example, it is used in the detection of features such as corners and edges in images, where the images or their variants

are regarded as the surface whose local shape is classified; see, for example, [13]. In [14], the shape of an object obtained as range data is represented based on its curvature. It is shown in [15, 16] that similar curvature-based shape representation can be computed from multiple images taken under different illumination directions but without detailed knowledge on the process of the image formation.

More advanced forms of curvatures, such as the curvature of higher-dimensional submanifolds and the Riemannian curvature tensors, are used in recent studies. In [17], several Riemannian metrics on the space of two-dimensional shapes are studied. In [18], biases of the maximum likelihood estimates derived for the problems of estimating some geometric structure from images (e.g., the epipolar geometry) are related to the curvature of the hypersurfaces given by the geometric structure.

Curvature, Fig. 4 (a) Classification of local shapes according to principal curvatures k_1 and k_2 . The first and third quadrants are where the surface point is elliptical,

and the second and fourth quadrants are where it is hyperbolic. (b) Examples of the surface segmentation based on the sign of the Gaussian curvature

Definition

Space curves are one-parameter manifolds immersed in Euclidean 3D space $\mathbf{r}(s) \subset \mathbb{E}^3$, where $s \in \mathbb{R}$. One requires differentiability to whatever order is necessary, and $\left\| \frac{\partial \mathbf{r}(s)}{\partial s} \right\|^2 \neq 0$.

It is convenient to require $\left\| \frac{\partial \mathbf{r}(s)}{\partial s} \right\|^2 = 1$, though this can always be achieved through a

reparameterization. Such curves are known as “rectified” or “parameterized by arc-length,” and one writes $\dot{\mathbf{r}}(s)$ for the partial derivative with respect to arc-length ($\mathbf{r}'(t)$ will be used if the parameter t is not arc-length). As discussed below, in addition one requires $\ddot{\mathbf{r}}(s) \neq 0$ for a generic space curve. The very notion of “rectifiable” is of course Euclidean. Curves in non-Euclidean spaces (affine, projective) have to be handled in appropriate ways.

C

Background

The classical theory of curves starts with Newton and Leibniz; it was brought in the form presented here in the course of the eighteenth and nineteenth century.

Theory

In differential geometry the “shape” of a curve is defined locally as a set of differential invariants that are algebraic combinations of derivatives $\{\dot{\mathbf{r}}, \ddot{\mathbf{r}}, \dddot{\mathbf{r}}, \dots\}$, and that are invariant with respect to Euclidean motions (notice that “congruencies” would assign the same shape to helices of opposite chirality). A complete set of such differential invariants, specified as a function of the parameter s (arc-length), allows one to construct the curve on the basis of this, up to arbitrary motions. Such a specification of the curve is known as its “natural equations.”

In performing coordinate-wise operations one has to refer to a fiducial frame, most conveniently an orthonormal basis. All equations will take on their simplest form in a frame that is especially fit to the curve. The classical Frenet-Serret frame is one way to achieve this. As one moves along the curve the frame will rotate in various ways. The simplest description expresses the instantaneous motion of the frame in terms of the frame itself. The differential invariants have geometrically intuitive interpretations in such a system. This insight is due to Elie Cartan, though already implicit in the classical formulation.

These are the basic insights of the classical theory. A short derivation with appropriate geometrical interpretations follows.

The first derivative of position $\mathbf{r}(s)$ with respect to arc-length s is (by construction) a unit vector known as the *tangent* to the curve, denoted $\mathbf{t}(s) = \dot{\mathbf{r}}(s)$. Geometrically the tangent is the direction of the curve, it is the limit of the difference of two points $\mathbf{r}(s_1) - \mathbf{r}(s_2)$ (with $s_1 > s_2$) of the curve divided by the chord-length, that is, $\|\mathbf{r}(s_1) - \mathbf{r}(s_2)\|$, as the points approach each other infinitesimally. Thus the expression $\mathbf{r}(s_0) + (s - s_0)\mathbf{t}(s_0)$ is a first order approximation, the tangent line, to the curve.

Because the tangent is a unit vector, one has $\mathbf{t} \cdot \mathbf{t} = 0$. (Note the Euclidean nature of this!) Thus the second-order derivative $\ddot{\mathbf{r}}$ is orthogonal to the tangent. We write $\ddot{\mathbf{r}} = k\mathbf{n}$, where the unit vector $\mathbf{n}(s)$ is the “normal” to the curve, and $k(s)$ the “curvature.” Notice that the normal would be undefined in the case the tangent did not change direction. For a generic space curve we have to require $k > 0$ throughout (though of course the choice of sign is arbitrary). This is different from planar curves for which a signed curvature makes sense. Thus planar curves may have points of inflection, whereas this notion makes no sense for space curves (Fig. 1).

The normal and the tangent define a plane, the so-called osculating plane of the curve. It is the limit of the plane spanned by three points of the curve as the points approach each other infinitesimally. One might say that, at least locally, the curve lies in its osculating plane (remember that “to osculate” means literally “to kiss”). The three points also define a circle (lying in the osculating plane), whose radius can be shown to be $1/k$. (An easy way to show this is to write down the second order Taylor development of the curve.) Thus, locally, the curve is like a circular arc of radius $1/k$ in the osculating plane, moving in the tangent direction. The curvature measures the degree to which the curve veers away from the tangent direction, into the direction of the normal. Notice that $\ddot{\mathbf{r}} \cdot \mathbf{n} = k$, and that the curvature is a scalar that does not depend upon the coordinate frame. The curvature is the first example of a differential invariant.

In Euclidean space \mathbb{E}^3 the tangent and the normal imply a third vector orthonormal to them both. It is $\mathbf{b} = \mathbf{t} \times \mathbf{n}$, known as the “binormal.” This is again a very Euclidean construction, the vector product being a Euclidean 3D concept. The orthonormal frame $\{\mathbf{t}, \mathbf{n}, \mathbf{b}\}$ is the Frenet-Serret frame. It is tightly connected to the curve and a complete basis of \mathbb{E}^3 . Thus it is perfectly suited to describe the third order derivative $\dddot{\mathbf{r}}$. The obvious move is to express $\ddot{\mathbf{n}}$ in terms of the tangent and the binormal (given the fact that the normal is a unit vector this should be possible). Thus one writes $\ddot{\mathbf{n}} = -\kappa\mathbf{t} + \tau\mathbf{b}$, where τ is another differential invariant known as the torsion of the curve. The reason for the term $-\kappa\mathbf{t}$ is that $\dot{\mathbf{t}} = \kappa\mathbf{n}$: the frame turns about the binormal with angular speed κ (Fig. 2). The third derivative itself then is $\dddot{\mathbf{r}} = -\kappa^2\mathbf{t} + \dot{\kappa}\mathbf{n} + \tau\kappa\mathbf{b}$.

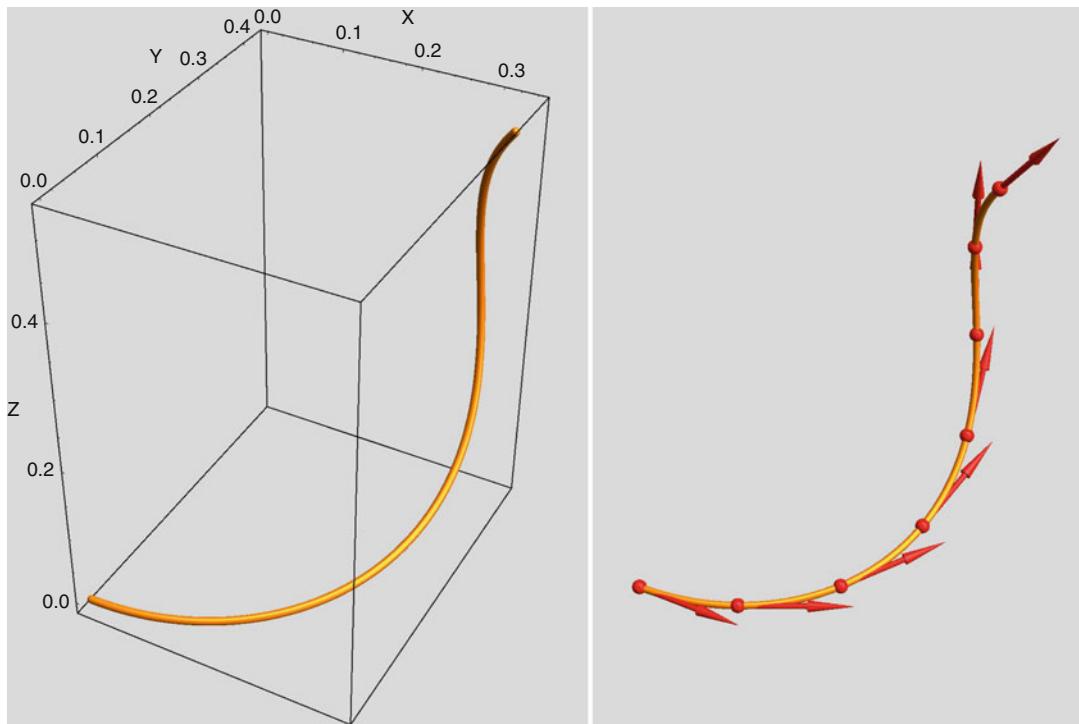

The torsion (sometimes called “second curvature”) has a simple geometrical interpretation. It is the angular rate of change of the attitude of the osculating plane.

Notice that the metrical structure of \mathbb{E}^3 is used in an essential manner in all constructions thus far. The classical theory of curves cannot be used in spaces with different structures, even in homogeneous spaces such as affine or projective spaces. Of course, a theory of curves can be developed for such spaces too, but the differential invariants, although often denoted “curvature” and “torsion,” will have meanings that are completely distinct from the curvature or torsion of curves in Euclidean space. The reader should be keenly aware of this, as non-Euclidean spaces occur frequently and naturally in computer vision and image processing applications, the best known being the affine and projective 3D spaces, as well as “graph space.”

The structure found thus far can be appreciated from a straightforward Taylor expansion:

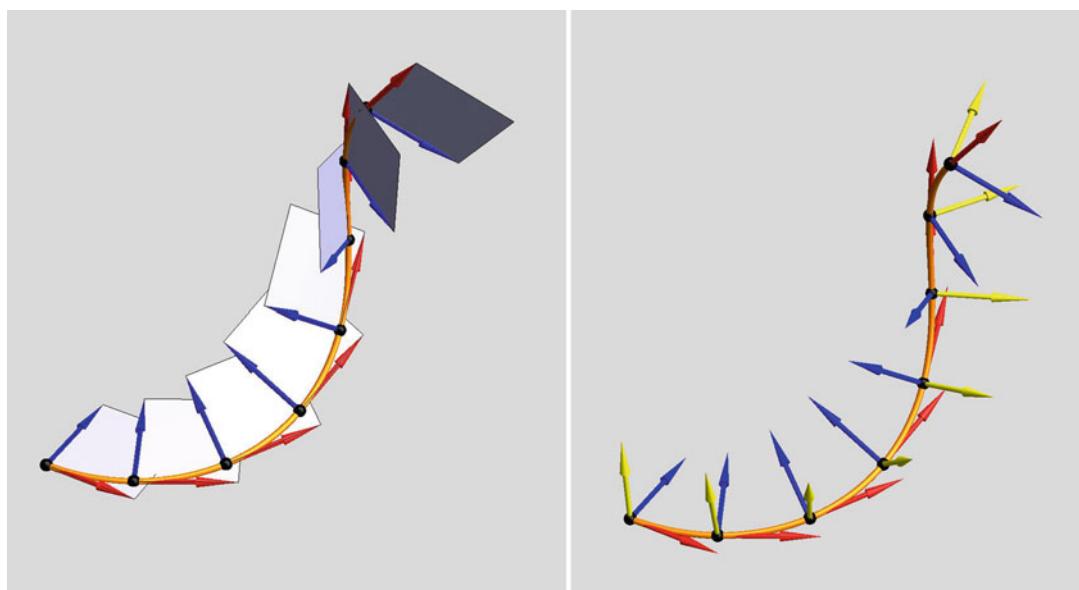

$$\mathbf{r}(s) = \mathbf{r}(0) + \dot{\mathbf{r}}s + \ddot{\mathbf{r}}\frac{s^2}{2!} + \ddot{\mathbf{r}}\frac{s^3}{3!} + O[s]^4, \quad (1)$$

which in terms of the Frenet-Serret frame is (the “canonical representation”):

Curves in Euclidean Three-Space, Fig. 1 At *left* generic space curve. It is curved throughout and “winds” in a single sense. This curve was defined via its natural

equations (see below), $\kappa(s) = 1 + 3s$, $\tau(s) = 1 + 5s$, $0 < s < 1$. At *right* the field of tangents along the curve

Curves in Euclidean Three-Space, Fig. 2 At *left* the field of osculating planes along the space curve. Notice how it rotates, revealing the curve to be a “twisted” one.

At *right* the field of Frenet frames along the curve. Again, notice how it rotates as it moves along the curve

$$\begin{aligned} \mathbf{r}(0) + & \left(s + \kappa^2 \frac{s^3}{3!} + \dots \right) \mathbf{t} \\ & + \left(\kappa \frac{s^2}{2!} + \dot{\kappa} \frac{s^3}{3!} + \dots \right) \mathbf{n} + \left(\kappa \tau \frac{s^3}{3!} + \dots \right) \mathbf{b}, \end{aligned} \quad (2)$$

from which the habitus of the curve is readily gleaned: The projection on the osculating plane is (approximately) a parabolic arc, on the normal ($\mathbf{n} \times \mathbf{b}$) plane a cusp, and on the tangential ($\mathbf{b} \times \mathbf{t}$) plane an inflection (Figs. 3 and 4).

Notice that the third order includes a term in the rate of change of curvature, not merely the torsion. The meaning of this becomes evident from another geometrical construction. Four distinct points define a sphere, and in the limit one obtains the osculating sphere at a point of the curve. When the curve is twisted at the point ($\tau \neq 0$), the center of the osculating sphere is given by:

$$\mathbf{c}_{osc} = \mathbf{r}(s) + \frac{1}{\kappa(s)} \mathbf{n}(s) - \frac{\dot{\kappa}(s)}{\kappa(s)^2 \tau(s)} \mathbf{b}(s), \quad (3)$$

and its radius of curvature $\rho_{osc}(s)$ by:

$$\rho_{osc} = \sqrt{\rho^2(s) + \left(\frac{\dot{\rho}(s)}{\tau(s)} \right)^2}, \quad (4)$$

Curves in Euclidean Three-Space, Fig. 3 At left a view from the binormal, at right a view from the normal direction. From the binormal direction the curve shows its curvature, from the normal direction one sees an inflection

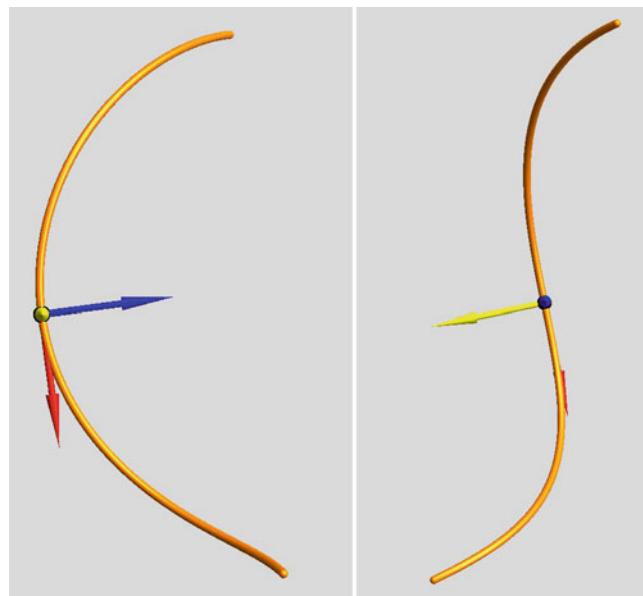

where ρ is the radius of the osculating circle. Thus only at “vertices” of the curve ($\dot{\kappa} = 0$) is the osculating circle a great circle of the osculating sphere. The osculating sphere always cuts the osculating plane in the osculating circle though.

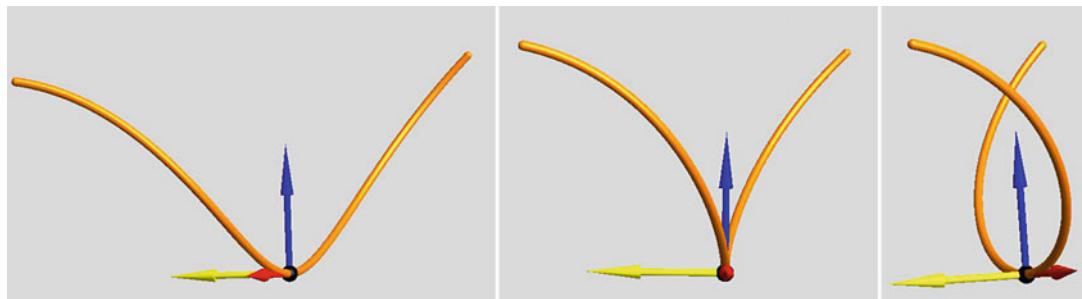

The geometrical structure is formulated rather elegantly by the Frenet-Serret formulas (notice the antisymmetry of the matrix):

$$\begin{pmatrix} \dot{\mathbf{t}} \\ \dot{\mathbf{n}} \\ \dot{\mathbf{b}} \end{pmatrix} = \begin{pmatrix} 0 & +\kappa & 0 \\ -\kappa & 0 & +\tau \\ 0 & -\tau & 0 \end{pmatrix} \begin{pmatrix} \mathbf{t} \\ \mathbf{n} \\ \mathbf{b} \end{pmatrix}. \quad (5)$$

The “natural equations” simply specify $\kappa(s)$ and $\tau(s)$. Using the Frenet-Serret equations one constructs the curve by integration, specifying an arbitrary initial Frenet-Serret frame. Thus the curvature and torsion specify the curve up to arbitrary Euclidean motions.

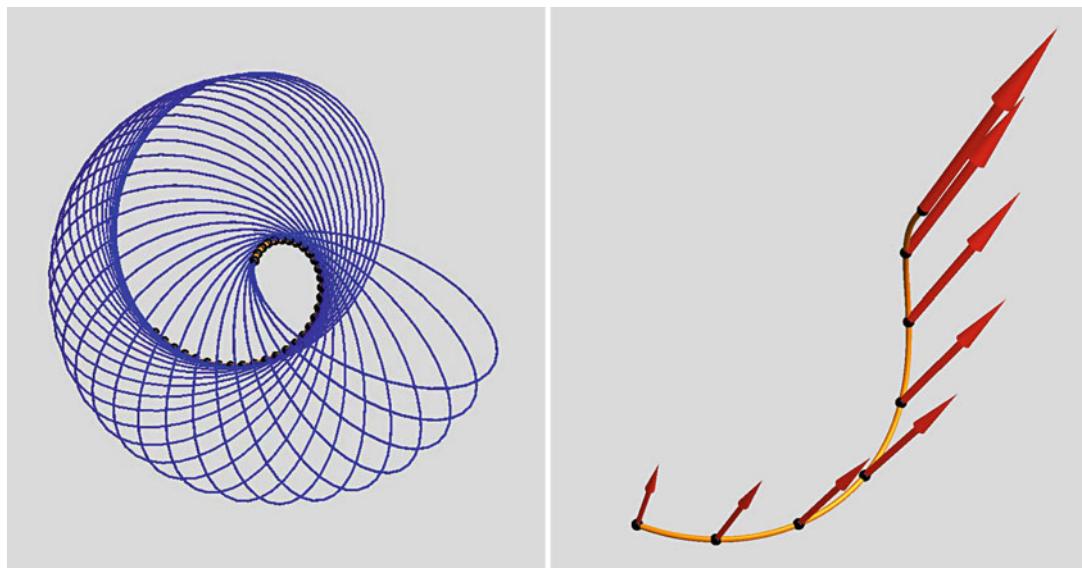

A useful formalism that extends this is due to Darboux (Fig. 5). The “Darboux vector” is defined as $\mathbf{d} = \tau \mathbf{t} + \kappa \mathbf{b}$. Now one has $\dot{\mathbf{t}} = \mathbf{d} \times \mathbf{t}$, $\dot{\mathbf{n}} = \mathbf{d} \times \mathbf{n}$, and $\dot{\mathbf{b}} = \mathbf{d} \times \mathbf{b}$, thus the Darboux vector is the angular velocity of the “moving trihedron” $\{\mathbf{t}, \mathbf{n}, \mathbf{b}\}$. One immediately concludes that the curvature is the rate of turning about the binormal and the torsion the rate of turning about the tangent. This nicely “explains” the

C

Curves in Euclidean Three-Space, Fig. 4 At center a view from the tangent direction. In this view the curve appears as a cusp. At left and right views from nearby directions

Curves in Euclidean Three-Space, Fig. 5 At left osculating circles along the curve. At right the Darboux vector field along the curve

geometrical meaning of the differential invariants κ (the curvature) and τ (the torsion).

The Darboux formalism is by far the simplest to commit to memory. It completely sums up the structure of generic space curves in Euclidean three-space. The Darboux vector also lets one handle degenerate cases easily, for instance that of planar curves (binormal constant), or straight curves (or rather, lines; tangent constant). Finally, the Frenet-Serret equations are written in an easily remembered (because of the cyclic **t-n-b-** structure) form:

$$\dot{\mathbf{t}} = \mathbf{d} \times (\mathbf{n} \times \mathbf{b}), \quad (6)$$

$$\dot{\mathbf{n}} = \mathbf{d} \times (\mathbf{b} \times \mathbf{t}), \quad (7)$$

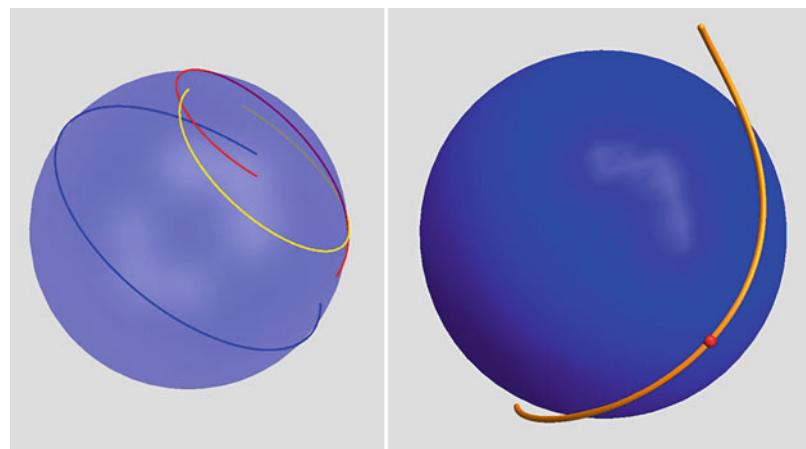

$$\dot{\mathbf{b}} = \mathbf{d} \times (\mathbf{t} \times \mathbf{n}). \quad (8)$$

There are a number of geometrical structures related to a curve that are of occasional use. A few of these are discussed below.

So-called spherical images are spherical curves – that are curves on the surface of the unit sphere – related to a curve (Fig. 6). One naturally considers the tangent, normal, and binormal spherical images that are the curves $\mathbf{t}(s)$, $\mathbf{n}(s)$, and $\mathbf{b}(s)$ (notice that these curves are not rectified!). Notice that for straight lines the tangent spherical

Curves in Euclidean Three-Space

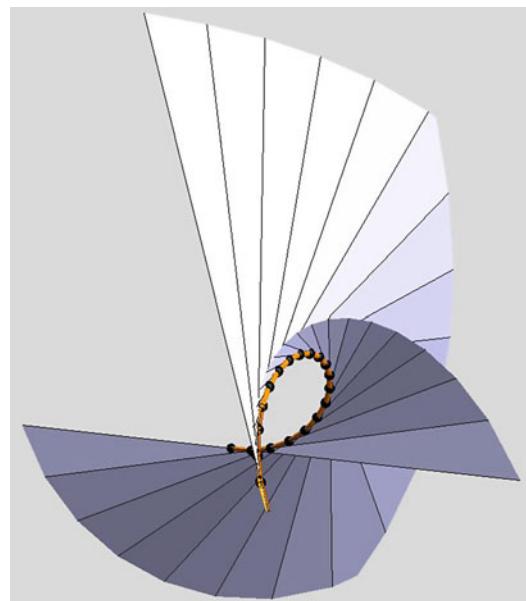

Fig. 6 At left the spherical images associated with the curve (red: tangent image; blue: normal image; yellow: binormal image). At right an osculating sphere at the curve

images degenerate to a point, whereas the other spherical images are undefined. For planar curves the tangent and normal spherical images are degenerated to arcs of great circles, whereas the binormal spherical image degenerates to a point. Special points of the spherical images, like inflections or cusps, relate to special points of the original curve. For some problems of a physical nature it is the spherical image, rather than the curve itself that is of primary interest. An example is that of specularities on tubular surfaces like human hairs.

The surfaces described by the lines defined by the tangent, normal, binormal, and Darboux vector are also of occasional interest. These are – by construction – ruled surfaces, though not necessarily developable ones. Their singular features, like the edge of regression in the case of developable surfaces or the line of striction in the case of skew surfaces, have useful geometrical relations to the curve. The best known example is the surface of tangent lines, which happens to be developable, with the curve itself as the edge of regression, and the surface of normal lines, which is commonly used to describe surface strips (Fig. 7).

Special points on the curve may also be studied by direct means of course. Perhaps the most obvious instance is that of a torsion zero (Fig. 8). At a torsion zero the chirality of the curve changes. Whereas the curve generically osculates, but also pierces its osculating plane, the curve merely osculates, but fails to pierce the

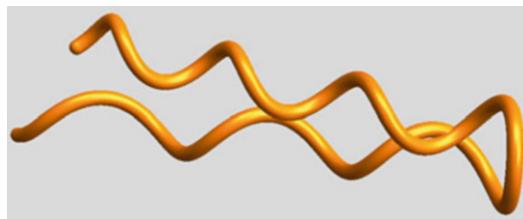

Curves in Euclidean Three-Space, Fig. 7 The surface described by the tangents to the curve is a developable surface, the curve being its edge of regression

osculating plane, it being “deflected” by it. Such special points are often introduced by design in telephone cords, and many vines also have frequent torsion zeroes in their tendrils

Additional Problems

This entry describes the Euclidean differential geometry of space curves. In many problems

Curves in Euclidean Three-Space, Fig. 8 Example of a torsion zero. Notice the opposite chirality of the parts of the curves at either side of the torsion zero (which is at the right in this picture)

the context is different from Euclidean though. Because the differential invariants introduced here are specific for the Euclidean transformation group, one needs to develop the differential geometry from scratch. Examples frequently occur in computer vision, for instance, and one often works in spaces with mere affine, or even projective structure. Spaces with even less structures are common. A common case

involves “isotropic differential geometry” in “graph spaces.”

Data Augmentation

Ying Nian Wu

Department of Statistics, UCLA, Los Angeles,
CA, USA

Definition

Data augmentation is a Markov chain Monte Carlo algorithm for sampling from a Bayesian posterior distribution

Background

Data augmentation was originally developed by Tanner and Wong [10] as a stochastic counterpart of the EM algorithm [1], and it is closely related to the Gibbs sampler [2]. Thus, the basic setup of data augmentation is similar to the EM algorithm.

Theory

Let y be the observed data and z be the missing data or latent variable. Let $p(y, z|\theta)$ be the probability distribution of the complete data (y, z) , with θ being the unknown parameter. The marginal distribution of the observed data y is $p(y|\theta) = \int p(y, z|\theta)dz$. Let $p(\theta)$ be the prior distribution of θ . The goal is to draw Monte

Carlo samples from the posterior distribution $p(\theta|y) \propto p(\theta)p(y|\theta)$.

The data augmentation algorithm is an iterative algorithm. It starts from an initial value θ_0 . Let (θ_t, z_t) be the values of θ and z sampled in the t -th iteration. Then in the $(t+1)$ -st iteration, it goes through the following two steps:

Imputation step: Sample $z_{t+1} \sim p(z|y, \theta_t)$.

Posterior step: Sample $\theta_{t+1} \sim p(\theta|y, z_{t+1})$.

$p(z|y, \theta)$ is the predictive distribution for imputing the missing data z given y and θ . $p(\theta|y, z)$ is the posterior distribution of the complete-data model. The data augmentation algorithm capitalizes on the fact that both the $p(z|y, \theta)$ in the imputation step and $p(\theta|y, z)$ in the posterior step are often easy to sample from.

In correspondence to the EM algorithm, the imputation step corresponds to the E-step, and the posterior step corresponds to the M-step. The data augmentation algorithm can also be viewed as a two-component Gibbs sampler for sampling from $p(z, \theta|y)$, but the emphasis of the data augmentation algorithm is that it augments the missing data or latent variable z to simplify the computation. In that sense, it is related to the auxiliary variable algorithm [3], the most prominent example being the Swendsen-Wang algorithm [9].

The rate of convergence of the data augmentation algorithm is determined by a quantity called Bayesian fraction of missing information [5]. It is the Bayesian version of the fraction of missing information that determines the rate of convergence of the EM algorithm [1].

Meng and van Dyk [7] observed that for the same marginal model $p(y|\theta)$, it is possible to construct a class of complete-data models $p_a(y, z|\theta)$ indexed by a working parameter a so that $\int p_a(y, z|\theta) dz = p(y|\theta)$ for all a . One may then optimize the fraction of missing information over the working parameter a in order to devise the EM or data augmentation algorithm with the optimal rate of convergence.

Inspired by Meng and van Dyk [7], Liu, Rubin and Wu observed that when augmenting the data from y to (y, z) , it is possible to expand the parameter θ to θ, α so that the complete model becomes $p(y, z|\theta, \alpha)$, where both θ and α are identifiable in the complete-data model, but $\int p(y, z|\theta) dz = p(y|\theta)$ so that the parameter α disappears in the observed-data model [6]. Based on this observation, they proposed a parameter-expanded EM (PX-EM) algorithm which has faster convergence rate than the original EM algorithm. Liu and Wu (2000) [4] proposed a parameter-expanded data augmentation (PX-DA) algorithm which has a faster convergence rate than the original data augmentation algorithm. Independently, Meng and van Dyk [8] proposed a similar algorithm called marginal augmentation.

Application

The data augmentation algorithm and its extensions can be used for sampling of posterior distributions from a wide range of Bayesian models. Practically for any EM algorithm for maximum likelihood estimation, there is a corresponding data augmentation algorithm for posterior sampling. In fact, the imputation step of the data augmentation algorithm can be easier to implement than the E-step of the EM algorithm because it is often easier to sample from a distribution than calculating the expectation in closed form.

Information fusion

Definition

Data fusion refers to combining data from multiple sources for achieving better understanding of a phenomenon of interest. Applications abound in engineering and applied sciences, including wireless sensor networks, computer vision, and biometrics.

Background

In several fields, combining different sets of information has taken place, although a more systematic study for the fusion of data is emerging since a decade [1]. The human brain is an example of a complex system which integrates data or signals from different sensory preceptors in the body. Building a machine-based system that can meaningfully integrate data from different sources for better understanding of a phenomenon of interest is the challenge faced in many fields. Since data emerges from different sensors with varying accuracy and coverage factors, benefits of data fusion include improved system reliability and/or redundancy, extended coverage, and possible shorter response time. Applications in human-machine interface area include robots in industrial automation, surveillance in military and commercial fields, battlefield management, medical diagnostics, biometrics, satellite imaging, image understanding, computer vision, target detection and tracking, wireless sensor networks, and wireless communications.

Application

In many vision-related applications, a single sensor will not provide complete information with respect to the scene that is being sensed. Also, sensors may have different fields of views and different sensors, such as IR and optical, may have different resolution capabilities. Better results are obtained when data from sensors are combined in an appropriate manner. For imaging applications, fusion of images can be done at various levels, viz., pixel, feature, and decision. In general, the latter two entail some loss of information as the fusion is performed after extraction of information from the original images. Pixel-level fusion methods include Laplacian pyramid, discrete wavelet transforms, and support vector machines [2]. In decision/classification systems, combining features or decisions may be appropriate when sensors are geographically dispersed, thereby requiring distributed processing at sensor sites.

In video surveillance applications involving tracking of objects or persons of interest, fusion of data from multiple images would be needed [3]. Similar situations arise in military applications involving tracking of maneuvering enemy aircrafts. Track-to-track fusion of target position estimates derived from individual sensor data is a possible approach [4,5].

Detection and estimation of targets using a set of geographically dispersed multiple sensors necessitate distributed signal processing at sensor sites [6,7]. Although individual sensors process sensed information and possibly make inference regarding the presence or absence of a target (or a phenomenon of interest), a final determination that is based on the collective information is usually made at a central site called the fusion center. It is conceivable that, in some applications, one of the sensors could be the fusion center making the final decision. Thus, the traditional signal detection (estimation) paradigm is naturally extended to the situation of distributed processing. The terminology “distributed detection,” “decentralized detection,” or “distributed decision fusion” refers to such situations. Depending on the flow of information from the sensors to the fusion center and between the sensors, several configurations of sensor suites are possible: serial or tandem, parallel, and tree [8]. Formulation of Neyman-Pearson and Bayes optimization criteria leads to fundamental theoretical solutions in this area. Statistical correlation among sensor observations can lead to some unexpected results as shown first in [9]. Recent result shows how correlation might be helpful in some signal configurations for both centralized and decentralized detection scenarios [10]. Asymptotic solutions involving a very large number of sensors as well as computational approaches for obtaining optimal solutions are available [6–8,11]. Recently, there is interest in the estimation of parameters using processed data from multiple sensors [12].

In earlier works on distributed detection problems, the communication channels between the sensors and the fusion center were assumed ideal or error-free. However, with the pervasiveness of wireless sensor networks, the assumption of error-free links is not quite true. The inclusion

of error-prone links in the distributed signal processing systems has further broadened the literature to provide practically achievable as well as theoretically possible solutions [13,14]. Channel-aware solution paradigm leads to several sub-optimal solutions depending on the availability of knowledge of channel information. Although some similarity to traditional diversity reception in signal communication exists, the decentralized detection in wireless sensor network is distinctly different in the sense that the decisions made by the sensors regarding a phenomenon of interest need not all be identical unlike the case of diversity reception. Thus, the maximal ratio combining, which is optimal for diversity reception, is generally inferior in wireless sensor network case. Depending on the noisiness of the channel, combining based on individual sensor decisions arrived at the fusion center can outperform other suboptimal combiners based on received sensor data at the fusion center.

Cognitive radio has evolved over the last two decades. Cognitive radio now could be a simple receiver which senses and adapts to different signal modulations to a more complex modem where the radio is able to sense the non-presence of a user in a spectral frequency range, thereby adapting its operating frequency to be in that range for achieving signal connectivity [15]. The problem faced by a secondary user is the detection of the presence or absence of a primary licensed user through spectrum sensing. The spectrum sensing is done cooperatively by several secondary users in order to opportunistically access the spectrum, when it becomes available. Presence of distributed radios, inability of some radios not being able to sense the primary user due to shadowing or “hidden terminal” problem, limitations on communication capacity between the secondary radios and the radio acting as the fusion center, and availability of signal processing capability within the radios have set the stage for the application of decentralized detection concepts to cognitive radios [16, 17]. Shadowed signal receptions at multiple cognitive radios can lead to signal correlation thereby requiring signal processing schemes that don't assume statistical independence among observations at different radios [16].

Biometrics is used for authentication purposes in civilian and military applications. Biometrics for person identification could be fingerprints, facial image, voice, or iris. Use of several biometrics, when appropriately combined, can lead to better results than that can be obtained through any one biometrics. Also, multiple samples of any one biometrics can be combined for achieving better results. Combining data from multimodal biometrics is a challenging problem because of the need for proper normalization of biometrics scores before combining [18, 19]. The determination of optimal combining method needs to take into account possible correlation among different biometrics. Application of multivariate copula distributions for combining heterogeneous data for biometrics is discussed in [20]. The authors of another paper, also involving a multimodal biometric system, show that significant classification improvement can be achieved by employing social network analysis for the fusion of decisions from individual biometrics [21]. Challenges exist due to stringent requirements in surveillance applications where false accept rates and false reject rates need to be kept small. Moreover, biometrics identification systems need to be robust to the extent possible due to possible fake biometrics posed by latex fingers, face masks, etc. The fusion of biometric can be at various levels: data, features, and classifiers (decisions).

Definition

Deblurring is a process to recover sharp and clear images from blurry images.

Background

Blur usually occurs when taking a photo with long exposure time or with wrong focal length. This is because the lights captured for a pixel are mixed with the lights captured for the other pixels within a local neighborhood during the exposure period. Such effect is modeled by the blur kernel (a.k.a., point spread function) which describes how the lights are mixed during the exposure period. The goal of deblurring is to recover sharp and clear images of the scene from the captured blurred images. Deblurring,

however, is a severely ill-posed problem because the number of unknowns exceeds the number of equations that can be derived from the observed data.

The problem of deblurring can be further categorized into non-blind deblurring and blind deblurring according to whether the blur kernel is known or not. In non-blind deblurring, the blur kernel is given and is used to recover the latent image from a blurry image. The main problem of non-blind deblurring is how to estimate high-quality clear images with the given blur kernels. In blind deblurring, the kernel is unknown. This problem is quite more challenging as both the blur kernels and clear images are needed to be estimated. The conventional blind deblurring process usually consists of two interdependent steps: blur kernel estimation and latent image restoration. Thus, the non-blind deblurring can be regarded as an important step in blind deblurring. In addition, benefiting from the deep learning approach, the blind deblurring process can be achieved by directly estimating high-quality clear images from observed blurry images.

This chapter mainly reviews the single image motion deblurring methods.

Theory

The Image Formation Model

Mathematically, the blur process can be modeled by:

$$B(x) = \sum_{y \in \mathcal{N}(x)} I(x - y)k_x(y) + n(x), \quad (1)$$

where B denotes a blurry image, I denotes a sharp image, k_x denotes the blur kernel at pixel x , n denotes image noise, and $\mathcal{N}(x)$ denotes a local neighborhood centered at pixel x . If the blur kernel k_x is spatially variant, the blur model (1) is usually used to approximate those cases when the camera exhibits rotational motion or the scene has large depth disparity or contains a moving object during exposure period.

While the blur kernel is spatially varying, the variation of the blur kernel is spatially smooth. Lots of previous works simplify the problem by assuming that the blur kernel is spatially invariant to model the camera motion blur. Thus, the blur model will reduce to a convolution operation:

$$B = I \otimes k + n, \quad (2)$$

where \otimes denotes the convolution operator.

As (2) cannot effectively model the blur caused by camera-rotation, several methods [1,2] assume that the blurry image is the sum of lots projectively-transformed versions of sharp image:

$$B(x) = \sum_{\theta} I(\mathbf{H}_{\theta}x)k(\theta) + n(x), \quad (3)$$

where \mathbf{H}_{θ} denotes the homography induced at the camera pose θ .

Methodology

Image deblurring is a long-standing problem. This section mainly reviews the non-blind and blind deblurring.

Non-blind Deblurring

Early representative non-blind deblurring approaches mainly include the Richardson-Lucy algorithm [3, 4] and Wiener deconvolution [5]. However, these algorithms usually generate the results with undesirable artifacts such as ringing and amplification of image noise. To solve this problem, several algorithms develop different image priors to regularize the latent image in the restoration process. Such as total variation regularization [6], hyper-Laplacian prior [7], patch-based image prior [8], learning-based image prior [9, 10], etc. Among these methods, the methods using patch-based image priors or learning-based image priors have achieved state-of-the-art performance.

Blind Deblurring

As both blur kernels and latent images are unknown, most existing methods first estimate blur kernels and then use the non-blind deblurring methods as mentioned above to restore high-

quality clear images. Existing blind deblurring methods can be roughly categorized into hardware-based methods, statistical prior-based methods, and data driven-based methods.

Hardware-based methods To better solve blind deblurring, several methods design specific devices or experimental settings. Ben-Ezra and Nayer [11] and Tai et al. [12] propose a hybrid camera system which estimates the blur kernel through integration of optical flows from the auxiliary high-speed camera. In [13], Levin et al. develop prototype camera to estimate spatially variant blur kernels. The inertia sensors of cameras have also been explored to facilitate the blur kernel estimation [14–16].

Another line of research tackles blur kernel estimation by exploring additional information. For example, the noisy/blurry image pair by Yuan et al. [17] and two consecutively captured blurred images by Chen et al. [18]. With the estimated blur kernels, the clear images can be obtained by the those above non-blind deblurring methods. Using specific devices or additional information is able to simplify the blur kernel estimation process and achieves favorable performance in blind deblurring. However, designing specific devices or experimental settings is often expensive.

Statistical prior-based methods As blind deblurring is ill-posed, lots of methods explore the kinds of priors to make the problem well-posed so that the blur kernels can be efficiently estimated and then facilitate the clear image restoration. Chan and Wang [19] develop the total variation regularization to constrain both blur kernels and sharp images. Fergus et al. [20] and Whyte et al. [2] propose a multi-scale variational Bayesian framework to estimate the uniform blur kernels and non-uniform blur kernels, respectively. Shan et al. [21] use a parametric model to model the heavy-tail property of image gradients and develop an alternating optimization method to estimate the blur kernel. Levin et al. [22] show that the variational Bayesian inference method [20] is able to avoid trivial solutions while naive maximum a posterior based methods may not [21]. They

propose an improved maximum a posterior for the blur kernel estimation [22]. In addition, as the variational Bayesian approach is computationally expensive, Levin et al. [23] propose an efficient marginal likelihood optimization for blur kernel estimation and use the non-blind deblurring method based on a hyper-Laplacian prior [24] to restore clear images.

As the naive maximum a posterior based methods are likely to converge to trivial solution [22], some edge prediction-based methods [25, 26] have been proposed for blur kernel estimation. As demonstrated by [27], these edge prediction-based methods have been proven to be effective in real cases.

To overcome the limitations of the naive maximum a posterior-based methods and avoid the heuristic edge-prediction step, some effective image priors have also been introduced for blur kernel estimation, e.g., normalized sparsity prior [28], L0-regularized prior [29–31], internal patch recurrence [32], sparsity of dark channel prior [33], and so on.

Note that these above uniform deblurring methods can be straightforwardly extended to non-uniform deblurring according to some modifications [34].

Data driven-based methods The data driven approach is developed for blind deblurring. In [35], Zuo et al. develop a discriminative learning approach to adaptive learn priors for blur kernel estimation.

The deep learning approach is also employed to estimate blur kernels. In [36], Sun et al. develop a deep convolutional neural network to estimate the probabilistic distribution of motion blur at the patch level. Gong et al. [37] directly estimate the motion flow from the blurred image through a fully-convolutional deep neural network and use the estimated optical flow as the motion blur. Schuler et al. [38] and Pan et al. [39] develop deep convolutional neural networks to learn the key components that are used for blur kernel estimation. With the estimated blur kernel, these methods usually employ existing non-blind deblurring methods, e.g., [24], to restore clear images.

As the blur kernel estimation is complex, several algorithms develop end-to-end trainable deep convolutional neural networks to directly estimate clear images from blurry images, e.g., [40]. In spite of achieving decent results, the generalization ability of these methods is worth further investigation.

Application

The main application of deblurring is on image restoration and enhancement. Since blur is a common artifact in imaging system, its applications range from astronomy telescope, satellite imaging, medical imaging, and common customer level camera. The restored high-quality images can facilitate intelligent analysis in these fields and can be better visualized on high-definition devices.

Definition

Automatic face recognition is the problem of identifying a person from an image or a video. The problem of face recognition can be divided into face identification and face verification. The standard approach for training a CNN for solving these problems include four steps: face detection, alignment, representation, and classification (Fig. 1). Identification is the problem of assigning an identity to an image from a list of identities. From another perspective, this can be considered as trying to retrieve the best matching face from a gallery for a given probe image. On the other hand, face verification involves verifying whether two face images are of the same person. This is usually performed by computing the similarity between feature representations of the two faces. Both identification and verification have benefited immensely from developments in deep learning algorithms and more advanced CNN architectures.

Deep CNN-Based Face Recognition, Fig. 1 Standard approach for training a CNN for face verification and identification

Background

Datasets for Face Recognition

A face recognition system starts with detecting faces, then localizes landmarks which are used to align the faces to canonical views, and then classifies the detected faces. All three parts of the system require different level of information and data types. In this section, we explore some recently released public datasets targeted these.

In the wild face recognition at a large scale essentially started with the release of the Labeled Faces in the Wild (LFW) dataset [1]. Recent years have seen several large datasets being released to help the training of deep networks and to provide stronger benchmarks. Some examples of such include CelebA [2], CASIA-WebFace [3], UMDFaces [4], MS-Celeb-1M [5], VGGFace [6], VGGFace2 [7], DFW [8], etc. However, these are still constrained because they only contain still images of mainly celebrities. Such photos are typically frontal and taken under good lighting. However, evaluation datasets like IJB-A [9], IJB-B [10], IJB-C [11], IJB-S [12], and MegaFace [13] contain videos and images in varied conditions. To fill this gap, several video datasets have been proposed over the years. Among these, YouTube Faces (YTF) [14] and UMDFaces Video [15] are currently the largest publicly available annotated video datasets.

The most popular and the largest dataset for training and evaluating face detection models is

the WIDER FACE dataset [16]. Another standard benchmark is FDDB [17]. The IARPA Janus Benchmark datasets [9–11] also contain a large number of face annotations for evaluating face detection and recognition in completely unconstrained settings. Due to the difficulty in labeling and verifying facial keypoints in images, there are only a few large-scale public datasets available which include such annotations. These include Annotated Face in the Wild (AFW) [18], 300 faces-in-the-wild dataset [19], Labeled Face Parts in the Wild (LFPW) [20], and Annotated Facial Landmarks in the Wild (AFLW) [21].

In addition to these, there are some 3D datasets [22], age datasets [23, 24], attribute datasets [2, 25], and expression datasets [2].

Face Detection

Face detection is the process of finding a bounding box for each face in an image. This is often the first step in any face recognition or tracking system. Counting the number of people in a crowded scene [26, 27] can also benefit from robust face and head detection. Large real-world datasets like [16] and deep CNN-based representations have led to significant improvements in face detection performance. Most of the popular face detection methods have been adapted from general object detectors and can be classified as either proposal-based or single-stage detectors.

Proposal-based object detection methods start with a class-agnostic object proposal generator

like selective search [28], edge-boxes [29], or a region-proposal network (RPN) [30]. These proposals are then classified into object classes by a CNN. Proposal-based face detectors follow a similar approach and generate face proposals which are then classified as face vs non-face by a CNN. Examples of such face detectors include All-in-One Face [31], Hyperface [32], Finding Tiny Faces [33], and Supervised Transformer Network [34].

Unlike proposal-based detectors, single-stage object detectors do not contain an explicit proposal generation step. Such detectors typically include a single pass through a CNN and processing multi-scale image pyramid or multiple layers of a CNN. Single-shot multibox detector (SSD) [35] and YOLO [36, 37] are examples of recent single-stage object detectors. Several recent face detectors adapt these methods. These include DPSSD [38], SSH [39], CNN Cascade [40], ScaleFace [41], and S³FD [42].

After a face has been detected, the step in most face recognition pipelines in facial landmark detection and face alignment. Landmarks determine the most discriminative locations on a face. We refer the reader to the brief overview in [38] and a comprehensive review in [43] for a better coverage of the topic.

Theory

The loss function is an important factor in determining the performance of deep networks. Most face recognition networks are trained to perform a C -way classification of faces with the hope that the learned features can be used as discriminative representations. Many existing works use the standard cross-entropy loss with softmax for training face recognition networks. Variants of the cross-entropy loss aim to address issues like preference for high-quality images, early saturation, lack of margin between intra- and inter-class samples, etc. Some methods instead focus on directly optimizing the features for face verification. Metric learning approaches optimize the features to reduce intra-class separation and increase inter-class separation.

We start with a description of the standard softmax-based cross-entropy loss. Suppose there are M training samples in a batch. Let \mathbf{x}_i be the i^{th} face image in the batch with the label y_i and $f(\mathbf{x}_i)$ be the feature representation of the face. The feature representation is typically a deep CNN. The feature vectors are projected into logits using weights W and bias b . Then, the softmax loss is given by:

$$\mathcal{L}_{\text{Softmax}} = -\frac{1}{M} \sum_{i=1}^M \log \frac{e^{W_{y_i}^T f(\mathbf{x}_i) + b_{y_i}}}{\sum_{j=1}^C e^{W_j^T f(\mathbf{x}_i) + b_j}} \quad (1)$$

where C is the total number of classes, W_j is the j^{th} column of the weight matrix W , and b_j is the corresponding bias. Note that the bias term in (1) can be absorbed into the weights by appending 1 to $f(\mathbf{x}_i)$. Now, since $\mathbf{a}^T \mathbf{b} = \|\mathbf{a}\| \|\mathbf{b}\| \cos(\theta)$, where θ is the angle between \mathbf{a} and \mathbf{b} , the equation above can be rewritten as:

$$\mathcal{L}_{\text{Softmax}} = -\frac{1}{M} \sum_{i=1}^M \log \frac{e^{\|W_{y_i}\| \|f(\mathbf{x}_i)\| \cos(\theta_{y_i})}}{\sum_{j=1}^C e^{\|W_j\| \|f(\mathbf{x}_i)\| \cos(\theta_j)}} \quad (2)$$

At test time, a probe face \mathbf{x}_p is compared to a face in the gallery, \mathbf{x}_g , using cosine similarity:

$$s = \frac{f(\mathbf{x}_p)^T f(\mathbf{x}_g)^T}{\|f(\mathbf{x}_p)\|_2 \|f(\mathbf{x}_g)\|_2} \quad (3)$$

Crystal Loss [44] adds the following constraint

$$\|f(\mathbf{x}_i)\|_2 = \alpha, \forall i = 1, 2, \dots, M \quad (4)$$

to the objective in (1). The authors argue that the features obtained from networks trained with softmax loss strongly prefer high-quality/high-resolution images to low-quality images.

A-Softmax [45] incorporates an angular margin to the softmax formulation. This is based on the idea that at test time, we usually want dissimilar features to be angularly separated (since our distance metric is cosine distance). A-Softmax starts by normalizing the weight vectors $\|W_j\| = 1, \forall j$. Let $\|f(\mathbf{x}_i)\| = s$, and then the A-Softmax loss is given as:

$$\begin{aligned} \mathcal{L}_{\text{SphereFace}} &= -\frac{1}{M} \sum_{i=1}^M \log \frac{e^{s \cos(m\theta_{y_i,i})}}{e^{s \cos(m\theta_{y_i,i})} + \sum_{j \neq y_i} e^{s \cos(\theta_{j,i})}} \end{aligned} \quad (5)$$

where m is the size of the margin and $\theta_{y_i,i}$ is in the range $[0, \frac{\pi}{m}]$. However, training a CNN under this constraint is difficult. Therefore, the authors in [45] propose to generalize $\cos(\theta_{y_i,i})$ to a monotonic angle function $\psi(\theta_{y_i,i})$ which equals $\cos(\theta_{y_i,i})$ in $[0, \frac{\pi}{m}]$. So, A-softmax can be written as:

$$\begin{aligned} \mathcal{L}_{\text{SphereFace}} &= -\frac{1}{M} \sum_{i=1}^M \log \frac{e^{s\psi(\theta_{y_i,i})}}{e^{s\psi(\theta_{y_i,i})} + \sum_{j \neq y_i} e^{s \cos(\theta_{j,i})}} \end{aligned} \quad (6)$$

where $\psi(\theta)$ is a piecewise function:

$$\begin{aligned} \psi(\theta) = & (-1)^k \cos(m\theta) - 2k, \theta \in \left[\frac{k\pi}{m}, \frac{(k+1)\pi}{m} \right] \\ & \text{and } k \in [0, m-1] \end{aligned} \quad (7)$$

Large Margin Cosine Loss [46] uses an additive margin term instead of a multiplicative margin as used above. In addition to fixing $\|W_j\| = 1$ by L_2 normalization, the authors propose to fix $\|f(\mathbf{x}_i)\| = s$. This puts the learned features on a

hypersphere where they need to be separable in the angular space. Fixing the norm of the features is a commonly used technique, e.g., [44]. Adding the margin in (2) thus gives the formulation:

$$\begin{aligned} \mathcal{L}_{\text{CosFace}} &= -\frac{1}{M} \sum_{i=1}^M \log \frac{e^{s(\cos(\theta_{y_i,i})-m)}}{e^{s(\cos(\theta_{y_i,i})-m)} + \sum_{j \neq y_i} e^{s \cos(\theta_{j,i})}} \end{aligned} \quad (8)$$

The margin m and the feature scale s are interdependent.

Additive Angular Margin Loss [47] also starts by normalizing W_{y_i} and scaling the feature such that $\|f(\mathbf{x}_i)\| = s$. However, instead of directly adding an additive cosine margin as in (8), [47] proposes to use an additive angular margin. This is again done with the aim of increasing inter-class discrepancy and intra-class compactness. The proposed loss can be written as:

$$\begin{aligned} \mathcal{L}_{\text{ArcFace}} &= -\frac{1}{M} \sum_{i=1}^M \log \frac{e^{s(\cos(\theta_{y_i,i}+m))}}{e^{s(\cos(\theta_{y_i,i}+m))} + \sum_{j \neq y_i} e^{s \cos(\theta_{j,i})}} \end{aligned} \quad (9)$$

where m is the additive angular margin. Additionally, the authors also propose a loss which combines SphereFace (5), CosFace (8), and the proposed ArcFace (9):

$$\mathcal{L}_{\text{Combined}} = -\frac{1}{M} \sum_{i=1}^M \log \left(\frac{e^{s(\cos(m_1\theta_{y_i,i}+m_2)-m_3)}}{e^{s(\cos(m_1\theta_{y_i,i}+m_2)-m_3)} + \sum_{j \neq y_i} e^{s \cos(\theta_{j,i})}} \right) \quad (10)$$

where m_1, m_2 , and m_3 are the corresponding margins for SphereFace [45], ArcFace [47], and CosFace [46].

Several other loss functions have been proposed for training face recognition networks. However, space limitations do not allow a more detailed exposition of those methods. We refer the reader to the original papers for Noisy Softmax [48], Center Loss [49], Center Invariant Loss [50], Range Loss [51], Centralized

Coordinate Learning [52], Ring Loss [53], Triplet Loss [54].

Applications

In this section we describe some recent face recognition applications which utilize some of the techniques described above. We note that both face identification and verification can be

formulated as the same problem. In identification, given a probe image, the goal is to find the closest image from a gallery. This is achieved by computing the similarities between the feature representation of the probe image and feature representations of the gallery images. The image with the highest similarity with the probe images is given as output. In verification, the aim is to determine if a given pair of images belong to the same person. This is also achieved by computing the similarity between the feature representations of the two images. The basic operation in both identification and verification is to extract a feature representation and compare with representations of the other image/images. We focus on face verification in this section. Similar methods can be used for face identification too.

A typical face verification training and testing pipeline is shown in Fig. 2. A training set of aligned faces is used to train a deep network for C -way classification. The layer before the classification layer is used to extract a feature representation for a face at test time. Representations from two faces are compared using a similarity metric.

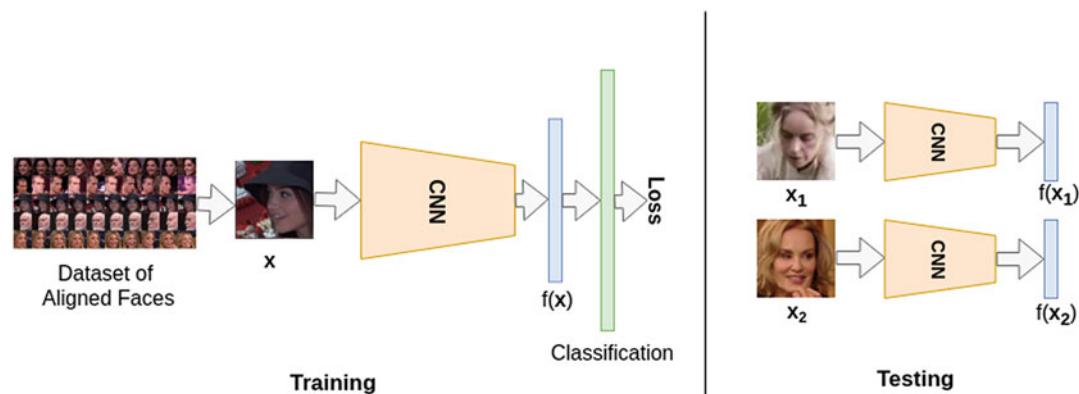

DeepID [55] proposes to train a deep network on a large number of classes to obtain discriminative features which can be used for face verification. It extracts features from 60 face patches from different scales, different regions, and RGB or gray channels. Features for each

patch and their flipped versions are extracted and concatenated into a 19,200 dimension feature. All neural networks are trained with softmax loss over a training dataset containing 10,177 identities.

DeepFace [56] uses explicit 3D modeling, starting from 2D keypoints, to apply a piecewise affine transformation for aligning faces. The aligned face is further warped to the image plane of a generic 3D face shape. After the alignment, DeepFace uses a nine-layer deep network with 120 million parameters to learn the face representation. The network is trained using a dataset of four million images from over 4,000 identities. This network is trained with the standard softmax cross-entropy loss.

FaceNet [54] uses a triplet loss to directly optimize the embedding instead of using the surrogate task of C -way classification. The authors claim that this leads to greater representational efficiency, and this feature embedding can improve face verification and clustering performance.

VGGFace [6] model uses a large dataset of over 2.6 million images from about 2,600 identities to train a CNN with softmax loss. The features obtained from this network are embedded using a triplet loss similar to [57].

Deep CNN-Based Face Recognition, Fig. 2 A face verification training and testing pipeline. A dataset of aligned faces is used to train a deep CNN with a classification loss.

At test time, features are extracted from two faces, and their similarity is computed to determine whether the two faces are of the same person

All-in-One Face [31] proposes a multi-task learning approach for face detection, keypoint detection, pose estimation, smile detection, gender classification, age estimation, and face recognition. The network contains several heads which are responsible for learning different functionalities. The idea is that each modality will benefit from other modalities. The separate heads are trained with the corresponding losses, and gradients from all heads are accumulated to train the trunk of the network. The face recognition/feature learning branch uses a standard softmax loss.

Fast and Accurate System [38] proposes a better face detector (DPSSD) and uses an ensemble of networks to extract features. The authors argue that a good face detector leads to better face verification performance by avoiding false positives and missing faces. Each network in the ensemble is a different architecture and is trained with a combination of three large datasets: UMDFaces [4], UMDFaces Videos [15], and MS-Celeb-1M [5]. Crystal loss [44] is used to train all networks. Such ensembles have also been used for recognizing disguised faces [58] and for clustering faces [59].

ArcFace [47] uses the Additive Angular Margin Loss and the large-scale and clean MS1MV2 dataset to achieve state-of-the-art performance on several face recognition and verification benchmarks. The MS1MV2 dataset is a refined version of the MS-Celeb-1M dataset and contains about 5.8M faces for 85,000 identities. ArcFace uses the popular ResNet-100 network architecture.

Some other recent methods include [60–68].

Open Problems

Though immense progress has been made in face recognition in the past few years, there are still several unanswered questions. With the ever-increasing size of training datasets, it is not clear if there is a saturation point, i.e., if there is a point at which additional data will not lead to performance improvements. A related problem

is the use of unlabeled data. Semi-supervised learning methods which use a little labeled data along with large amounts of unlabeled data need to be developed for face recognition.

Deep networks are still mostly trained with aligned faces and need aligned faces during testing. However, this cascade process introduces an unnecessary source of error. Are there ways which obviate the need for alignments? Can collecting larger datasets help? Are there better ways to align faces which do not require an additional step? These questions are important and there are no clear answers.

Another overlooked area is the presence of biases in the datasets which leads to recognition systems being biased. Most public datasets are of celebrities. These images are taken by professional photographers with good quality cameras. Networks learn to be biased to such data. Most datasets have been collected from a pre-defined list of people. Many of these people are Caucasian men. This introduces a gender and racial bias in the networks. There have been very few major attempts to remove such biases. Merler et al. [69] recently released a diversity dataset which is an important step toward this problem. An interesting question is how do we transfer knowledge from one kind of biased data to another such that we end up with a network which performs well for both categories.

These questions and more need to be answered for even better face recognition systems in the future and will give researchers something to work on for the next few years.

Definition

Deep generative models, or deep generator networks, refer to a family of deep networks that take in an input tensor \mathbf{z} and then output a

sample of certain patterns. In computer vision, such patterns could be specific object categories, such as cats, as shown in Fig. 1. The input tensor \mathbf{z} could be as simple as a randomly generated vector. The deep generative model can be trained with a set of images in an unsupervised way. Two popular algorithmic formulations are the generative adversarial networks (GANs) [9] and the variational auto-encoder (VAE) [14].

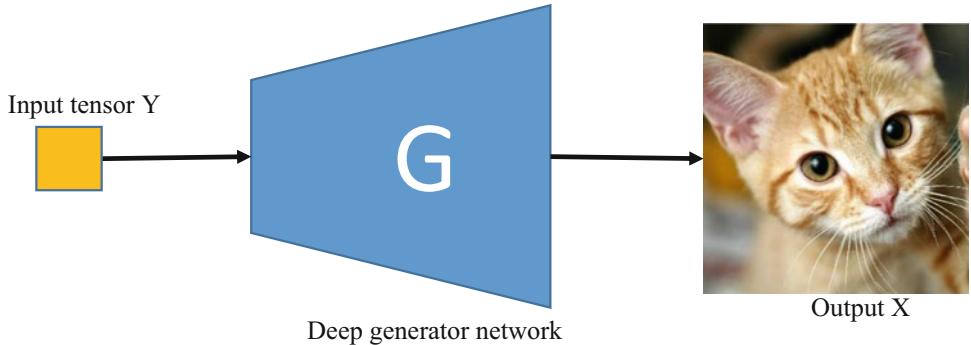

D

Background

Generative models are a family of statistical models that model the joint distribution $p(\mathbf{X}, \mathbf{Y}|\Theta)$ of an observable variable \mathbf{X} and a target (or hidden) variable \mathbf{Y} , where both \mathbf{X} and \mathbf{Y} could be multivariate and Θ represents the parameters of the model. It could be used for classification tasks if the target variable \mathbf{Y} represents the class labels. This is in contrast to *discriminative models* for classification, which directly models the conditional distribution $p(\mathbf{Y}|\mathbf{X}, \Theta)$.

Some of the traditional and notable generative models that have been widely adopted to solve computer vision problems include Gaussian mixture models (along with other mixture models), Hidden Markov models [17], Bayesian networks (BN) [16], Markov random fields [2], Latent Dirichlet Allocation (LDA) [4], Boltzmann machine [1] and its variants such as restricted Boltzmann machine [11], and deep belief networks [12], as well as energy-based models (EBMs) [15]. Most of these traditional generative models can all be unified under probabilistic graphical models. Once a generative model is formulated, *learning* and *inference* in such a model are two fundamental problems to be addressed.

Learning of these generative models is often carried out by maximizing a data likelihood over the parameters of the model. When the training data is complete, i.e., both \mathbf{X} and \mathbf{Y} are observed in each sample, such a maximization is often quite straightforward. Nevertheless, a more interesting problem is to learn the generative models with incomplete data, where the target variable is unknown in the training dataset. Under such a setting, one is not able to directly maximize the

Deep Generative Models, Fig. 1 A deep generative model (a generator network) takes a tensor as an input and outputs a sample following the distribution of certain patterns. The figure presents a generator network for cat images

joint data likelihood. Instead, we need to maximize the data likelihood $\mathcal{L}(\mathbf{X}|\Theta)$ of the observed data. Such a problem of maximum likelihood with incomplete data is often approached by the seminal Expectation-Maximization (EM) algorithm [6], where an E-step and an M-step are iteratively conducted to maximize the incomplete data likelihood.

The E-step, by its name, targets on obtaining the expectation of data likelihood over the distribution of the hidden or target variables. To achieve this, we must first conduct an *inference* step. That is to calculate the posterior probability $p(\mathbf{Y}|\mathbf{X}, \Theta_c)$ given the current parameter setting Θ_c . Then we may easily obtain an expectation

$$E(\Theta|\Theta_c) = \int_{\mathbf{Y}} p(\mathbf{X}, \mathbf{Y}|\Theta) p(\mathbf{Y}|\mathbf{X}, \Theta_c) d\mathbf{Y}. \quad (1)$$

Then the M-step would solve an optimization problem to maximize $E(\Theta|\Theta_c)$, i.e.,

$$\Theta_c^{\text{new}} = \arg \max_{\Theta} E(\Theta|\Theta_c). \quad (2)$$

These two steps would iterate until convergence. This iteration represents a surrogate maximization process and guarantees that $\mathcal{L}(\mathbf{X}|\Theta)$ would be monotonically non-decreasing. Since it is upper bounded, the process is guaranteed to converge. Ghahramani [8] derived a Bayesian EM algorithm leveraging probabilistic variational analysis.

Note that the inference of the posterior probability $p(\mathbf{Y}|\mathbf{X}, \Theta_c)$ would have an analytical

solution under limited cases, e.g., when the prior distribution $p(\mathbf{Y})$ and likelihood distribution $p(\mathbf{X}|\mathbf{Y})$ are conjugate. Such conjugate priors are common when the distributions are confined to the conjugate-exponential family [8]. However, for more general distributions, it is often intractable to calculate the posterior in closed form.

A common practice would be using Markov chain Monte Carlo (MCMC) method, such as the Gibbs sampling, to produce samples from this distribution and then compute the integral in Eq. 1 numerically. Hinton et al. [11] presented a method, namely, contrastive divergence to use one-step sampling to replace the full MCMC sampling. It could significantly speed up the learning process with a certain guarantee of convergence.

The explosive development of deep learning in the past 10 years has also led to new learning paradigms that are able to more conveniently learn generative models through standard back-propagation in deep neural networks. Two families of deep generative models are the generative adversarial networks (GANs) [9] and the variational auto-encoder (VAE) [14]. They approached to learning of the generative models in different ways.

GANs add another convolutional neural network (CNN) as a discriminator, which attempts to conduct a binary classification task so as to best differentiate the images produced by the generator network from the real images in training. In the meantime, the generator network is trained in

such a way to best fool the discriminator network. This forms a two-player game in the training stage. And asymptotically at the equilibrium, the distribution of images produced from the generator network would match the distribution of real images in training.

The mathematical foundation of VAEs is rooted in theory of variational inference and learning in probabilistic graphical models. This naturally pairs an encoder network with the generator network (a.k.a. the decoder network). The encoder maps an input image to a latent space and strives for following the posterior distribution in the training phase. The latent space by itself is constrained by a zero-mean Gaussian prior. The generator takes a sample from the latent space and maps it to an image.

This setting permits us to formulate the joint learning of the encoder and generator (decoder) as the maximization of a variational lower bound of the incomplete data likelihood. The whole optimization can hence be conducted via back-propagation. At convergence, the encoder maps to the inference process, while the generator again would function as a sampler which produces image samples that follow the distribution of the images in training.

Theory

Here, we present the core mathematical formulations of the generative adversarial networks and variational auto-encoders. These two core families of deep generative models have had many different variants, but the core theories remain the same.

Generative adversarial networks As shown in Fig. 2, GANs pair a generator network with a discriminative network and formalize the learning as a two-player adversarial game. Mathematically, if we denote the generator network as $\mathcal{G}(\cdot)$, the discriminative network as $\mathcal{D}(\cdot)$, and a sample from the training images to be x , then the following min-max problem is solved in GAN, i.e.,

$$\min_{\mathcal{D}} \max_{\mathcal{G}} [E_{x \sim p_{\text{data}}(x)} \{\log \mathcal{D}(x)\} + E_{z \sim p_z(\mathbf{z})} \{\log (1 - \mathcal{D}(\mathcal{G}(z)))\}]. \quad (3)$$

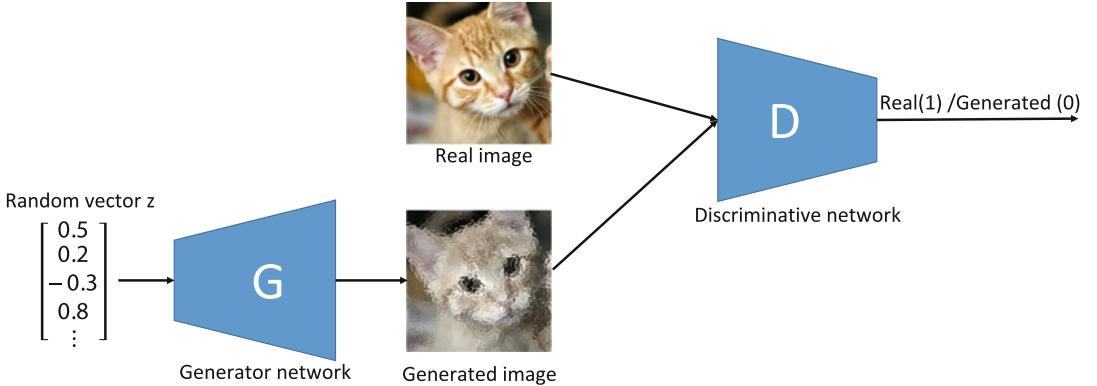

This is assuming that the discriminative network outputs a binary value with 1 indicating the input image is a real image and 0 being a generated image. The two steps of minimization and maximization are conducted alternatively by back-propagation through the two networks. The idea of adversarial training can be traced back to Tu's work [19] in training generative models with a discriminative method. But a more direct inspiration of the formulation of GANs is believed to be the noise contrastive estimator proposed by Gutmann and Hyvarinen [10].

Variational auto-encoder As shown in Fig. 3, VAEs use the generator \mathcal{G} to model the conditional likelihood probability $p_\theta(x|z)$, where θ is the parameter of the generator deep network. It is paired with an encoder network \mathcal{E} to model the conditional posterior probability $q_\phi(z|x)$, where ϕ is the parameter of the encoder network. The encoder network outputs a mean $\mu(x)$ and a variance $\sigma^2(x)$ of a Gaussian distribution given an input x , from which the latent vector z is sampled. We further impose a zero-mean and unit variance multivariate Gaussian prior on the latent vector z , i.e., $z \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$.

The learning paradigm of VAEs is established from the following equations [7], i.e.,

$$\begin{aligned} & \log p_\theta(x) - \mathcal{KL}[q_\phi(z|x) || p(z|x)] \\ &= E_{z \sim q_\phi(z|x)} [\log p_\theta(x|z)] \\ &\quad - \mathcal{KL}[q_\phi(z|x) || p(z)], \end{aligned} \quad (4)$$

where $p(z|x)$ is the true posterior of z given x and $\mathcal{KL}[\cdot || \cdot]$ is the KL divergence between two distributions. The left-hand side of Eq. 4 is what we want to maximize, as the first term on the left-hand side represents the data likelihood that needs to be maximized and the second term on the left side would be driven to zero as KL divergence is not less than zero. This would also naturally make $q_\phi(z|x)$ to the true posterior $p(z|x)$. So the optimal solution of maximizing

Deep Generative Models, Fig. 2 Generative adversarial networks: the generator network outputs an image given a random input vector and attempts to fool the dis-

the left-hand side is exactly the maximum data likelihood solution.

However, directly optimizing the left-hand side of Eq. 4 is not computable as the true posterior $p(z|x)$ is unknown. But with Eq. 4, we can equivalently maximize the right hand side of Eq. 4. This leads to the following optimization problem, i.e.,

$$\max_{\theta, \phi} E_{z \sim q_\phi(z|x)} [\log p_\theta(x|z)] - \mathcal{KL}[q_\phi(z|x) || p(z)]. \quad (5)$$

Both terms in Eq. 5 could be computed and optimized by stochastic gradient descent. Since p_θ and q_ϕ both are represented as a deep network, this further leads to, after using a reparameterization trick, an end-to-end stochastic gradient descent algorithm through the generator network \mathcal{G} to the encoder network \mathcal{E} .

Discussions GANs and VAEs both have their cons and pros. In general, GANs tend to generate sharper images but may encounter the mode collapse issue, where the generator got trapped in one mode of the data distribution and hence cannot generate diverse examples. In contrast, VAEs in general may produce diverse images, but the generated images tend to be more blurry. Fortunately, these two optimization paradigms could be combined to form the VAE-GAN family of generative models, which leverage both an

iscriminative network, which tries to correctly differentiate the generated images and real images

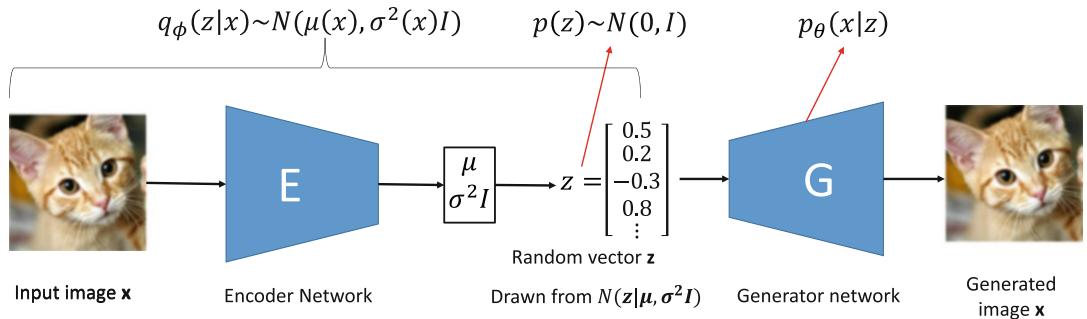

encoder network and a discriminative network to learn the generator network, so as to enjoy the benefits of both.

Applications

Deep generative models have been applied to solve many computer vision problems in real-world applications, due to their high capacity of fitting any data distributions and conveniently sample from the modeled distributions, ranging from image synthesis, image inpainting, image enhancement, image stylization, domain adaptation, semi-supervised recognition, etc. We selectively discuss some of them.

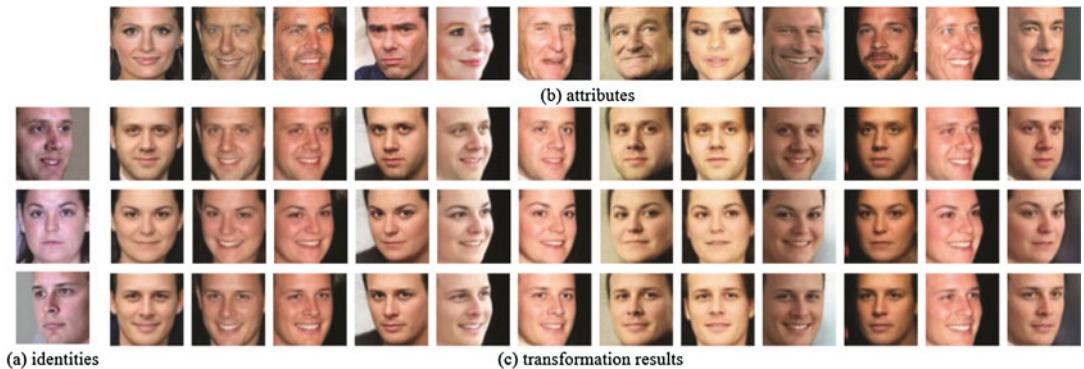

Due to its superb capability of sampling unseen image samples from the modeled image distributions, deep generative models have been widely applied for image synthesis, such as generating realistic face images [3, 13]. Bao et al. [3] proposed a hybrid structure exploiting ideas from both VAEs and GANs for generating faces while preserving their identities, even when those identities are not present in the training phase.

The central idea is to build two branches of encoders to obtain disentangled identity and attribute vectors from a face image. Figure 4 presents some open-set identity preserving face

Deep Generative Models, Fig. 3 Variational auto-encoder: VAEs pair the generator (decoder) network with an encoder network. Through a reparameterization, it allows end-to-end stochastic gradient descent to jointly

train the encoder and generator network. At convergence, the joint log data likelihood is maximized and $q_\phi(z|x)$ will be approaching to the true posterior $p(z|x)$

Deep Generative Models, Fig. 4 Open-set identity preserving face synthesis results using the identity of the faces in (a) and attributes from the randomly drawn faces in (b), to generate the face images in (c). Neither the face

images in (a) nor the face images in (b) appeared in the training dataset. Result images are by courtesy of Bao et al. [3] and from Figure 6 in their paper

synthesis results. One culmination of high-resolution and high-fidelity face generation results are produced from the award-winning StyleGAN [13], invented by researchers at NVIDIA Research. Some sample generated images from StyleGAN are presented in Fig. 5. Such vivid synthesized face images have caused people to worry about faked images in news, dubbed the name “Deep Fake.”

On the image enhancement side, deep generative models, especially GANs, have been adopted to effectively enhance astronomical images [18]. It has successfully helped modeling a lot of astronomical physical phenomena, including dark matters, gravitational lensing, and high-energy jet formation. It has also been

successfully applied to accelerate simulation and improve simulation fidelity in particle physics experiments. (https://en.wikipedia.org/wiki/Generative_adversarial_network)

Other real-world applications include but are not limited to

- fashion, art, and design, e.g., by creating photos of virtual models;
- video games, e.g., by efficiently synthesizing high-resolution textures;
- 3D reconstruction, e.g., by regressing depth maps through code slam [5], trained using VAEs;
- domain matching or transfer, e.g., using Cycle GAN [20].

Open Problems

Deep generative models have shown superb results in fitting image distributions and sampling from the modeled image distributions. It has been known that the sampled images from the modeled image distributions remain to be an interpolation of the training images, no matter how they differ from the training images. Such an interpolation is conducted in a highly nonlinear space with a compositional process. How we may build upon the success of deep generative models and endow future models the capability of extrapolation beyond the training data remains to be an open problem for us to explore.

Definition

The field of 3D vision covers a large range of techniques developed to estimate 3D information from one or multiple images, such as the absolute or relative pose of a camera and the 3D structure of the scene. For instance, among 3D vision problems, visual odometry and visual localization consist in estimating the pose of a camera in the environment, while stereo matching and multi-view stereo aim to reconstruct the 3D structure of the scene from different viewpoints. Conventional techniques developed to solve 3D vision tasks traditionally rely on low-level image features, such as sparse keypoints or dense photometric matching. These strategies are efficient under favorable conditions but tend to be sensitive to poorly textured scenes and usually do not encapsulate contextual and semantic information. Conversely, deep learning techniques are known for their ability to extract high-level features carrying relevant and useful information.

Deep learning based 3D vision attempts to take advantage of deep neural network architectures to improve the robustness and reliability of 3D vision tasks under challenging contexts.

Deep Visual Odometry/SLAM

Visual odometry (VO) consists in the joint estimation of the camera motion and the local structure of the scene using one or multiple cameras. Taking advantage of deep learning in the context of VO is particularly relevant to improve its robustness and applicability. Indeed, conventional techniques are still limited in their ability to reconstruct 3D at metric scale (in the monocular case) and remain particularly inefficient in texture-less environments where semantic cues can play a crucial role.

The first techniques applying deep learning to the relative pose estimation problem focus on the motion and depth estimation between two images. It is, for instance, the case of DeMoN [1] which iteratively refines the optical flow and the motion estimation of the sensor through a succession of encoder-decoder networks. This work led to the development of multiple analogous approaches dedicated to solve the motion and depth in an end-to-end manner. If these techniques are efficient, they are not specifically designed for visual odometry and tend to accumulate an important drift when a large sequence of images is processed.

More ad hoc solutions have been designed to cope with the drift issues by imposing temporal constraints in the motion estimation process. The first attempt to incorporate such an a priori is DeepVO [2] which proposes to employ a Recurrent Convolutional Neural Network (RCNN) to learn the motion dynamics of the sensor and to impose sequential information. The proposed technique is straightforward and can be described in two steps: features extraction and Recurrent Neural Network 6DOF pose estimation. For the features extraction, two successive RGB images are concatenated and processed through a Fully Convolutional Network. The extracted features are pushed into

an LSTM network for every new image in order to output the current pose of the camera. For training, the proposed cost function is the Mean Squared Error between the ground-truth pose and the predicted translation and orientation vectors. Despite its simplicity, this technique is functional and resolves the scale problem inherent to monocular odometry methods. However, the generalization of such a technique to multiple datasets has not yet been demonstrated. Finally, this technique only permits to estimate the motion of the camera while ignoring the depth estimation which is often explicitly solved in conventional VO/SLAM techniques. A follow-up of DeepVO, called UnDeepVO [3] proposes to solve together the motion and the depth in an unsupervised manner. Unsupervised approaches in the context of VO are very desirable since accurately labeled motion and depth data still requires expensive equipment, and, as a result, only a few are publicly available. To train UnDeepVO, a set of stereo images is sufficient since the network learns the spatial and temporal consistency by enforcing the photometric and pose constraints between two successive calibrated stereo views (via image warping and inter-poses relationships). The advantage of this approach is its ability to implicitly learn the scale information from the stereo images training set. As a result, the proposed technique demonstrates competitive results against traditional monocular algorithms. However, UnDeepVO only considers two successive monocular views and does not incorporate long-term temporal constraints; therefore, this strategy is conceptually closer to binocular depth and pose estimation techniques [1]. Moreover, the resulting depth map does not capture small details, and this technique has exclusively proved to be effective in the context of vehicular navigation which questioned its transferability to other scenarios.

While UnDeepVO requires a set of calibrated stereo images to be trained, SfMLearner [4] only needs monocular video sequences to learn visual odometry. To achieve this complex task, the photometric error between a target image and the warped surrounding views is utilized to train the network to predict the depth of the target

image as well as the poses between the target and the source images. This approach is particularly flexible since it can be trained from any arbitrary video sequence; however, it cannot recover the scale of the reconstruction since it fully relies on monocular data.

Despite promising results, the previously presented techniques remain practically limited by their data dependence, lack of transferability, speed, and accuracy. Recently, Zhou et al. [5] proposed a novel architecture to resolve some of the aforementioned limitations. Their strategy, entitled DeepTAM (for Deep Tracking and Mapping), is largely inspired by conventional direct SLAM approaches [6] where the tracking and mapping are addressed separately. The camera tracking process consists in an end-to-end network predicting both the optical flow (exclusively used to guide the training) and the pose of the camera with respect to the closest keyframe. On the other hand, the mapping is performed by a second end-to-end network inspired by plane-sweeping techniques [7] where the 3D information is accumulated as a cost volume and refined for every new keyframe. This tracking and mapping strategy happens to be particularly efficient in confined and low textured environments where conventional approaches tend to fail. Additionally, this method generalized well to various indoor datasets as a positive sign of transferability. As a limitation, DeepTAM requires smooth motions with sufficient overlapping between successive frames. Moreover, the generalization of this approach for large-scale mapping cannot be readily achieved due to the rigidity of the mapping process.

Aside from end-to-end approaches, multiple works propose to integrate priors computed from deep learning into the traditional SLAM pipeline. A representative work successfully coupling conventional SLAM with deep learning data is CNN-SLAM [8], where a conventional dense SLAM technique is enhanced using single image depth estimation through a Bayesian filtering strategy. The depth computed from the CNN network allows to solve the following limitations inherent to conventional techniques: pure

rotational cases (the depth cannot be computed without baseline), low textured environment, and metric scale estimation. Similarly, [9] proposes a novel unsupervised network for monocular depth estimation based on the computation of a virtual disparity map trained with a set of stereo images. The resulting single image depth prediction is used in a standard dense visual odometry framework in order to resolve the problem of metric scale estimation. The reported results demonstrate high performance with low-scale drift, making this approach competitive against stereo visual SLAM techniques.

D

Deep Visual Localization

Visual localization and absolute camera pose estimation refers to as the localization of a camera in a known scene (often modeled as a 3D map or a set of pictures) given an input image. It is an essential task to solve a large range of problems including, SLAM, augmented reality, and autonomous car navigation to cite just a few.

Conventional absolute camera pose estimation approaches usually operate in two distinct phases; first, a coarse appearance-based visual localization [10] is utilized in order to reduce the search range to a limited set of images. From this initial assumption, a robust 2D-3D point-based matching strategy is employed to estimate the position and orientation of the camera in the 3D map referential. In practice, this absolute pose estimation is achieved via a RANSAC perspective-n-point algorithm. Over the years, this two-stage strategy proved to be computationally efficient and accurate. However, the limitation of conventional approaches lies in the matching stage between the scene and the target image which remains complex due to a bundle of factors, including occlusions, different illumination conditions, appearance changes (e.g., weather conditions, day and night, etc.), repetitive structures, and strong viewpoint differences.

Deep learning techniques represent a good alternative to cope with the drawbacks of hand-crafted approaches. The existing solutions taking advantage of CNN can be categorized under two

distinct groups: the two-stage techniques (which essentially follows the philosophy of the traditional approaches) and the direct pose regression. The approaches which fall within this first category attempt to improve the image retrieval stage (also known as place recognition) to be more robust to the aforementioned challenges. Typically, these techniques focus on extracting a compact and discriminant image representation as a feature vector. Therefore, a queried image can be retrieved in a large-scale dataset of pictures by comparing their feature vectors. Usually, this retrieval stage is speed up via various strategies such as dimension reduction [10], effective nearest-neighbor search, or other machine learning-based solutions [11].

One representative example of deep place localization technique is NetVLAD [10] where an end-to-end network inspired by the original VLAD descriptor aggregation is proposed. To provide enough data to train the network, the authors propose to take advantage of the Google Street View Time Machine to gather pictures of similar places under different viewpoints, occlusions, and illuminations. The drawback of such data mining technique is the large number of outliers contained in the dataset; therefore an appropriate weakly supervised loss is used to robustly train the network. This large-scale picture retrieval strategy demonstrates high reliability and robustness but does not allow to estimate the 3D pose of the camera by itself. For this purpose, an additional CNN-based [12] or traditional registration technique is required.

The recent survey paper proposed by Piasco et al. [11] contains additional information on these techniques and their variations.

To solve the 3D camera localization problem in a single step, multiple solutions have been developed. On this matter, one of the pioneering work is PoseNet [12], which proposes a straightforward but effective strategy to regress the 6DOF camera pose using an end-to-end convolutional network. For training, PoseNet takes a set of images of a target scene labeled with their respective rotation and translation (a standard off-the-shelf network is sufficient to achieve this task). After training, the 3D pose of

a queried image can be predicted through a single feed-forward. One benefit of such a technique is the possibility to automatically generate labeled data through standard Structure-from-Motion techniques. To perform the supervised training, the objective function to be minimized is the Euclidean distance between the ground-truth and the predicted translation vectors, as well as a quaternion distance for the orientation. This single stage CNN-based implementation has multiple advantages; PoseNet achieves real-time performances (a feed-forward typically requires less than 10ms) and is robust to challenging scenarios (i.e., motion blur, occlusion). Despite the numerous advantages offered by this technique, PoseNet does not ensure an accurate pose estimation when put in comparison against classical absolute camera pose estimation methods. Finally, direct CNN-based absolute pose regression lacks versatility since updating the map requires a full retraining of the network. For a comprehensive description of PoseNet, its limitations and its variants, we recommend reading [11, 13].

The current status of cameras' pose estimation using deep learning architectures is mitigated. While visual localization greatly benefits from deep neural networks – thanks to its ability to capture features invariant to illumination and viewpoint – direct absolute pose localization techniques are not yet able to reach the level of accuracy provided by traditional methods [13]. New research directions inspired by conventional structure-based approaches [14] emerge as potential alternatives to direct pose regression.

Deep Stereo Matching

Dense stereo matching is a central component for many vision-based applications such as obstacle detection, metric scale navigation, and large-scale 3D reconstruction. Traditional approaches solve the dense stereo matching as a multi-stage optimization problem based on handcrafted features. The large quantity of calibrated stereo dataset has strongly contributed to the popularization of deep learning based

stereo matching which rapidly demonstrated their superiority in extracting and comparing discriminant features.

The first approach employing deep learning [15] is a patch-based matching technique between the left and right image via a standard epipolar line search strategy. To perform this task, a Siamese structure is used to extract features from the left and right candidate patches and compute their matching score as the inner product of the two embeddings. Despite its architectural simplicity, this approach outperforms most existing conventional stereo-matching techniques; however, its practicability remains limited by its high computational cost. This method paved the way toward faster and more accurate techniques [16]; however, a final refinement from traditional approaches remains needed to reduce the noise of the final depth estimation.

Despite the improvement of patch-based matching, these techniques remain relatively inelegant and inefficient (slow and require extra refinement), to cope with these problems, DispNet [17] proposes a different approach where the disparity is directly estimated through an encoder-decoder network with skip connections. This network inputs the concatenated stereo image pair and is trained in a supervised manner using a large-scale annotated dataset. This end-to-end solution combines multiple advantages, such as a significant speed improvement and a competitive accuracy against patch-based matching approaches. The idea behind DispNet has been further improved in [18] by cascading two encoder-decoder structures. This network consists of two main parts: DispFullNet (a DispNet which outputs high-resolution disparity map with extra up-convolution modules to preserve fine details) followed by DispResNet which refines the output of the first disparity estimation by minimizing its residual error at multiple scales. This two-stage network improves the results of the initial DispNet even further.

More recently, a new generation of approaches inspired by traditional cost-volume aggregation strategies has shown high performances. The first attempt in this direction is GC-Net [19] which

proposes to build a cost volume by concatenating deep features extracted from both stereo images. This cost volume is processed with a multi-scale 3D encoder-decoder type to produce a regularized cost-volume. The final disparity map is computed from this volume using a differential *soft argmin* function. A plethora of cost-volume-based techniques have since been developed; these approaches are currently leading most stereo benchmarks.

D

Deep Multi-view Stereo

The previous 3D vision approaches introduced aim to estimate either the relative (visual odometry) or absolute pose (visual localization) of the cameras. On the other hand, Multi-View Stereo (MVS) consists in the pixel-wise 3D reconstruction of the scene given a set of unstructured images along with their respective intrinsic and extrinsic parameters. MVS algorithms output various types of scene representations such as: point cloud, depth map, or mesh [20]. In this short introduction, we will particularly focus our attention on depth maps' estimation from multiple views since it is the most commonly adapted strategy using deep learning networks. To some extent, multi-view stereo can be seen as a generalization of stereo disparity estimation to a larger set of images. If these two problems boil down to the dense correspondence estimation across images, MVS does not impose any restrictions in terms of viewpoints nor in the size of the input image set. Assuming that the projections of an arbitrary 3D point in the calibrated views share a common photometric profile, MVS can be described as a constrained optimization problem where the depth is estimated such that the photometric consistency is maximized across images. This photometric consistency is traditionally computed via patch-based similarity measures (such as Sum of Squared Differences, Normalized Cross Correlation, or Census) between images using plane-sweeping, epipolar scanning, or local patches propagation [20]. Usually, the resulting photo-consistency can

be modeled as a cost-volume or a set of depth maps. Given this photo-consistency data, the final output (e.g., 3D point cloud or a depth map) is obtained via a succession of filtering stages to reduce the noisy measurements and to enforce the visibility constraints as well as the spatial consistency of the 3D structure. The interested reader can refer to [20] for a deeper understanding of conventional MVS techniques.

Traditional approaches demonstrate particularly satisfying results under favorable conditions, such as well-textured environments, Lambertian surfaces, and large overlap between views. However, they usually do not encapsulate useful cues like semantic, shadow, or lighting information. If some attempts to incorporate such information in the traditional MVS pipeline demonstrated improved performance, their integration remains complex. Conversely, deep learning strategies are known for their abilities to automatically capture such features during the training process. This versatility gives an indisputable advantage to perform various tasks including patch matching [15] or single image depth estimation [21].

As an illustration, the early approaches for CNN-based image matching have been initially developed to solve the dense disparity estimation problem from a pair of rectified stereo images [15]. Alongside the development of calibrated stereo disparity estimation, various approaches designed for unconstrained two-view depth estimation in an end-to-end manner have been explored. A representative example is DeMoN [1] which solves the pose and structure problem jointly. To this end, the proposed architecture alternatively refines the optical flow and the depth/pose couple via a succession of encoder-decoder networks. If these techniques are generic (solving together the structure and the motion) and computationally effective, they are limited to only two views while MVS – by definition – can process an arbitrary number of images. In the past years, numerous works have been proposed to solve this particular case. Specifically, recent techniques inspired by the plane-sweeping strategy have shown competitive results. As

a first approach, DeepMVS [22] proposes to emulate the plane-sweeping technique through deep neural networks. Considering a reference image, a plane swept patch volume is pre-computed for each neighbor views of the scene. Each plane swept patch volume is processed individually by a neural network to compute their initial cost-volume through a deep patch matching technique. Thereafter, these initial cost volumes are refined individually through an encoder-decoder structure performing an intra-volume feature aggregation by incorporating the reference image VGG features during the decoding stage. This process gives a set of cost volumes which can be combined to perform the final depth estimation. In order to accumulate an arbitrary number of cost volumes, the authors propose to use an element-wise max pooling function to compute the output depth map. While DeepMVS demonstrates effective results, the approach is not strictly speaking an end-to-end solution since it requires a final refinement stage of the depth map via a conventional Conditional Random Field technique. To fill this gap, DPSNet [7] and MVSNet [23] propose to mimic closely the standard MVS pipeline (Cost volume computation, cost aggregation, and depth estimation) through an end-to-end trainable network. First, a deep features plane sweep volume for each pair of reference/neighbor images is computed. The resulting volumes are thereafter processed individually via 3D convolutions to provide a set of 3D cost volumes which can be fused together by simple averaging (allowing to incorporate from 2 to n images). Given the reference image features, the final cost volume is refined using a deep cost aggregation to regularize the noisy estimations. Finally, the depth map is computed using a *softmax* operation and a weighted sum of each predicted label to emulate the Winner-Takes-All methodology. These approaches have demonstrated faster and more accurate results than previous traditional and deep learning based approaches. They also generalized well to the various number of images and are even competitive against techniques specifically designed to handle two images such as [1, 15].

Overall, the recent research in deep learning based MVS led to very efficient methods which are drastically outperforming conventional techniques. However, further research is needed to improve their scalability to a large set of images.

Single Image Depth Estimation

While traditional techniques usually estimate depth information from a set of multiple images (i.e., Visual Odometry, Structure-from-Motion, Multi-view Stereo), deep learning provides the ability to estimate this information from a single viewpoint. Due to the lack of geometric information (camera parameters, prior on the structure of the scene, etc.), this problem is inherently ill-posed; however, deep neural network-based methods have the ability to automatically learn a certain number of useful cues. Among these cues, we can refer to the shading, texture gradient, linear perspective, and the relative size between objects in the image.

The first approach dedicated to solve this particular problem using deep learning is [21], which proposes a coarse-to-fine estimation of the depth map. The proposed network is composed of two main parts. Its first component is a coarse depth prediction relying on an encoder and a fully connected network to produce a rough and low-resolution estimate of the depth. This initial estimation is refined through a fully convolutional network estimating a larger and more detailed depth map. To train this model in a supervised manner, a large-scale RGB-D dataset is utilized to minimize the pixel-wise depth (scale-invariant) mean squared error between the prediction and the ground-truth. If this naive approach provides a rather accurate approximation of the depth from a single image, many cues are not explicitly included during the estimation process.

To improve the reliability and scalability of the technique, Chen et al. [24] propose to guide the depth map estimation with human annotated relative depth. To prepare the dataset, human annotators are asked to label the relative depth between two random points for each image in the dataset. From this data, the single image

depth network is trained such that it respects the ordinal relations between pairs of points. This technique increases significantly the versatility of the network to generalize to many scenarios such as indoor and outdoor scenes.

Despite the flexibility provided by deep ordinal networks [24] which allow learning single image depth without RGB-D datasets, this estimation remains very data dependent and require large-scale and accurately labeled datasets to ensure the transferability of these techniques. MegaDepth [25] proposes a novel dataset from multi-view Internet photo collections, where the 3D reconstruction from a standard structure-from-motion approach is refined and enhanced with semantic segmentation. Training existing networks with MegaDepth leads to significant improvements in term of accuracy and generalization.

To reduce the data dependency, other methods propose fully unsupervised single image depth estimation. For instance, in [4], the authors propose to learn depth prediction from video sequences by enforcing photo-consistency constraints with surrounding views.

Open Problems

Over the past years, the 3D vision field has significantly benefited from deep learning techniques. In particular, the tasks relying on dense features matching such as stereo disparity estimation or multi-view stereo have shown significant improvements in terms of robustness and accuracy when compared with handcrafted techniques. Additionally, these approaches generalize well to various environments, illuminations, and camera's configurations, making their deployment to practical/industrial applications realistic.

Other tasks, such as visual localization have also gained significant efficiency in performing large scale image retrieval under strong appearance changes. Visual localization is inherently more data dependent than image matching; therefore very large datasets are needed to train a neural network to extract discriminant and robust features. To alleviate these problems, multiple

solutions including online data mining and semi-supervised learning have been proposed. Thanks to this progress, recent deep learning techniques perform significantly better than their conventional counterparts.

If deep learning have undeniably improved the accuracy of traditional techniques for the aforementioned tasks, a performance gap remains for the problems related to camera pose estimation (absolute or relative). Indeed, for these particular cases, deep learning tends to be less efficient than conventional approaches. This can be understood by the limited quantity of labeled data and the complexity of the task for deep learning architectures. This phenomenon has recently been highlighted in [13] which demonstrates that the mechanism behind the absolute camera pose estimation using deep learning is actually closer to visual localization than continuous pose estimation.

Concerning the visual odometry problem using deep learning, most existing approaches have focused on successive images pose estimation without explicitly enforcing temporal or spatial consistency between a larger number of views. Therefore, the drift reported by deep learning techniques is usually higher than conventional SLAM approaches. Moreover, very few works propose a clear demonstration of their transferability. Therefore, these approaches lack of maturity and further research is needed before a potential popularization of these methods for practical applications.

Definition

Deep style transfer is an optimization technique, which is characterized by its use of deep neural networks (deep learning), used to manipulate digital images, or videos, to adopt the appearance or visual style of another image. As shown in Fig. 1, given a content image I , a style reference image S (such as an artwork by a famous painter), the output stylized image O will blend texture details from S and the local structure of I , to look like the content image, but “painted” in the style of the style image S .

Background

Style transfer is an example of image stylization, a problem studied for over two decades within the field of non-photorealistic rendering (NPR) [1,2], which often aims to make an image appear to be created by artists. These traditional NPR algorithms are in most cases designed for a certain type of styles (e.g., water colors, or brush strokes, or stipples) and may fail to generate arbitrary styles.

There exists an alternative path toward handling the task of style transfer, via generalization of texture synthesis algorithms – a representative work called “image analogy” [3], which learns the transformation between a training pair of images, a photo and an artwork depicting that photo, and reproduces a new image through texture synthesis. It is generalized to handle different kinds of styles. The drawback of learning image stylization based on low-level features is that it is still limited to compose a complex interplay between the content and style of an image as well as human beings. Thus far there is no artificial system with similar capabilities.

Deep Style Transfer, Fig. 1 Style transfer is to migrate the style/texture from the right style image to the left content image

Recently, visual perception such as object and face recognition with near-human performance was demonstrated by deep learning. As the pioneer work of *deep style transfer*, an artificial system [4] based on a deep neural network is proposed to create artistic images of high perceptual quality. It is able to produce arbitrary styles in general, beyond the capability of traditional texture synthesis, or NPR algorithms. This system [4] uses neural representations to *decompose* content and style from images and *recombine* them into a new image by using an optimization algorithm. As the objective of optimization, the stylized image is expected to have similar high-level feature responses (from the late convolution layer) as the content image while being as similar as the style image in correlation matrices (Gram matrices) of feature responses (from early to middle layers).

However, this method [4] is unable to yield plausible results for photorealistic styles, as mentioned in [5]. The key reason is that Gram matrices only measure global statistics of textures (or style patterns) and perform poorly in constraining their spatial layout. In other words, they fail to establish spatial correspondences between the content image and the style image explicitly. Thus, it is still challenging to make such a stylization, with an accurate transfer in local semantic regions, such as mapping style face to real face, as shown in Fig. 3.

Inspired by texture synthesis approaches, Li et al. [5] replace pixel-wise Gram matrices with patch-wise Markov Random Field models. For each target feature patch, their method will match it to the best matching style patch. Another representative work is “deep image analogy” [6],

which transfers visual attributes (such as color, lighting, texture, and style) across semantically related images. It adapts the notion of “image analogy” [3] to a deep feature space for finding semantically meaningful dense correspondences between two input images. This method is widely applicable for a variety of transfer tasks such as content-specific stylization, style to photo, and style to style. At some time, if an object is found in one image but not the other, it is hard to find proper matching between image pair [5, 6]. To address this issue, a hybrid approach proposed in [7] unifies global methods (e.g., [4]) and local methods (e.g., [5, 6]) into one framework. For regions that can find correct matching, it allows the local semantic-level transfer. Otherwise, it will degenerate to global style transfer.

These works [4–6] have shown that high-quality images can be generated by a time-consuming optimization procedure, which imposes a big limitation in real applications. To address this issue, more and more methods start to directly learn a feed-forward network to approximate the above optimization procedure and make the runtime more efficient. According to the numbers of styles generated by the network, these fast solutions can be categorized as *Per-Style-Per-Model* methods, *Multi-style-Per-Model* methods, and *Arbitrary-Style-Per-Model* methods.

Per-Style-Per-Model methods train a feed-forward network for one specific style. During the training, numerous content images are used to train the network which shares the same objective function to [4]. There are two representative works (i.e., [8, 9]), and their differences are mainly network architectures: auto-encoder with

a series of residual blocks used in [8] and multi-scale pyramid network used in [9]. Besides, Li et al. [10] consider a Markovian generative adversarial network to approximate another optimization-based method [5].

Multiple-Style-Per-Model methods [11–13] allow multiple styles being learnt in a single network. It shows more advantages over *Per-Style-Per-Model* methods, such as reducing model size greatly in producing various stylization results, supporting fast incremental training of new styles, fusing different style effects together naturally. There are two representative works [11, 12]. Dumoulin et al. [11] find that the scaling and shifting parameters in the instance normalization layer [14] can respond to a different style. Based on the observation, they only learn scaling and shifting parameters of the instance normalization layer for each style while keeping other layers unchanged. “Stylebank” proposed by [12] explicitly represents one style with one set of filter banks. For each style, the network shares the same encoder and decoder parts but learns a set of different convolutional kernels in the intermediate layer between the encoder and the decoder. An interesting finding is that the learnt filter banks might capture the representative textons of the style images.

Arbitrary-Style-Per-Model methods [15–17] aim to transfer arbitrary visual styles to content images using a single network. Either *Per-Style-Per-Model* or *Multiple-Style-Per-Model* is mainly limited by inability of generalizing to unseen styles. In contrast, *Arbitrary-Style-Per-Model* tackles these limitations without the requirement of training on pre-defined styles. The key idea is that a series of feature transforms (e.g., scaling and shifting [16], or whitening and coloring [17]) are embedded in an image reconstruction network. These transforms reflect a direct matching of feature covariance of the content image to a given style image, which shares similar spirits with the optimization of Gram matrix based cost in neural style transfer [4]. A more straightforward way is that each content feature patch is replaced by the most similar style feature patch [15] in the embedding space, which shares similar spirits

with “deep image analogy” [6]. In the end, a new decoder will be trained with a large number of style images to decode the transformed or recomposing content features.

The extension of deep style transfer from image to video, even to stereoscopic image and video, is very appealing. Directly applying image-based algorithms to each frame/view independently will produce very flickering results. Ruder et al. [18] address the flickering problem in the optimization-based method by using optical flow to constrain both the initialization and loss function during the stylization of next frame. It produces temporally coherent stylization results but is a very time-consuming optimization procedure. To speed up, Chen et al. [19] design an unfolded recurrent neural network. The underlying motivation is that the previous stylization result should be propagated to the next frame, if motion estimation is reliable; otherwise, the current frame should adopt new stylization result. The final result will be a composition of propagated result and new result based on a mask which measures the confidence of motion estimation. Chen et al. resort to feature-level propagation and composition to make the results robust to errors from flow estimation and image composition. A similar idea is also utilized to stereoscopic image and video style transfer [20].

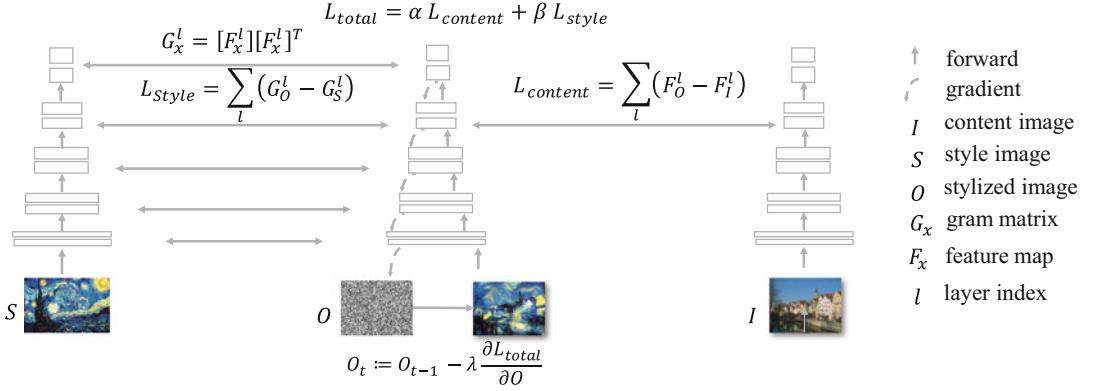

D

Theory

Optimization-Based Methods

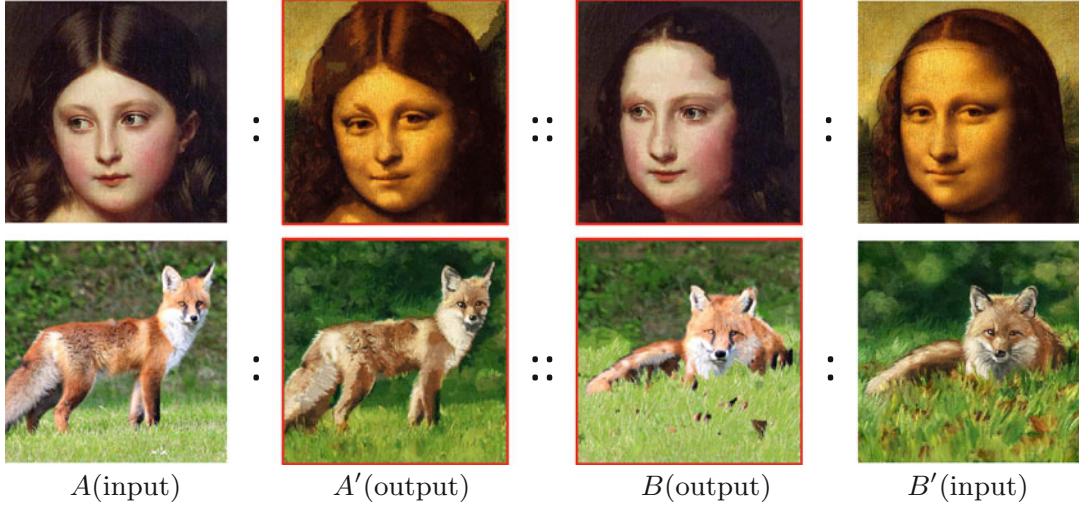

The pioneer work of deep style transfer [4] modeled the stylization procedure as feature decomposition and reconstruction. Given an image I , modern CNNs decompose it into hierarchical feature representations $\{F^1(I), \dots, F^n(I)\}$. Gatys et al. observe that the reconstruction from feature responses in higher layers (e.g., $F^n(I)$) maintains the high-level content in terms of objects and the reconstruction from the Gram matrices of feature responses reproduces the exact styles or textures.

Therefore, as shown in Figure 2, the stylization procedure can be modeled as an optimization problem: i.e., search a target image O which

Deep Style Transfer, Fig. 2 The neural style transfer algorithm proposed by [4]. It decomposes an image into feature maps using a pre-trained CNN and represents the content and style of an image with its feature and the

Gram matrices of features respectively. By optimization, the target image should have similar feature response as the content image and similar Gram matrices as the style image

Deep Style Transfer, Fig. 3 Two sample transfer results given by [6]

has similar feature response as the content image I (maintaining the structure) and similar Gram matrices of feature response as the style image S (maintaining the style). Thus, Gatys et al. define an objective function consisting of two terms:

$$\begin{aligned} L_{total}(O, I, S) &= \alpha L_{content}(O, I) \\ &\quad + \beta L_{style}(O, S), \end{aligned} \quad (1)$$

where α and β are the trade-off weights to control the final stylization extent. $L_{content}$ is the content loss that measures the mean square distance

between the content representation of the target stylized image O and the content image I .

$$L_{content}(O, I) = \sum_{l \in \{l_c\}} \|F^l(O) - F^l(I)\|^2, \quad (2)$$

where $\{l_c\}$ denotes the set of layers used for content representation and $F^l(x)$ is the feature maps of layer l .

Similarly, the style loss L_{style} is also defined as the sum of mean square distance between the Gram matrices (i.e., global correlations between filter responses of different channels) between the

target image O and the style image S of different layers $\{l_s\}$.

$$L_{\text{style}}(O, S) = \sum_{l \in \{l_s\}} \|G(F^l(O)) - G(F^l(S))\|^2. \quad (3)$$

Here, the Gram matrix $G^l(F)$ represents the style information of an input image and is defined as:

$$G^l(F) = F^l(F^l)^T, \quad (4)$$

where $F^l \in \mathcal{R}^{N_l \times HW}$ is the feature maps of layer l but is reshaped from $N_l \times H \times W$ to $N_l \times HW$. N_l is the channel number of layer l , and H, W are the width and height of feature maps, respectively. In this sense, Gram matrix neglects the spatial information and is a global statistics.

In the implementation [4], the pre-trained VGG network is used as the feature extractor F . ‘CONV4_2’ layer is used for content representation $\{l_c\}$ and ‘CONV1_1, CONV2_1, CONV3_1, CONV4_1, CONV5_1’ are used for style representation $\{l_s\}$. To obtain the optimal solution O , a gradient descent-based optimization procedure is used in [4] to minimize the objective function in Equation (1). An example produced by [4] is shown in Fig. 1.

This method can produce more impressive stylization results than traditional texture transfer, since a CNN is effective in decomposing content and style from images. However, since Gram matrix is too weak in local constraint, it often generates stylization results with texture that is randomly distributed. An alternative way is patch-based style transfer by combining a Markov Random Field (MRF) and a CNN [5]. It replaces the global style loss in Equation (1) with the MRF-based loss function to capture more local texture details. Specifically, let $\Phi(F(x))$ denote the list of all local patches extracted from $F(x)$; the new MRF-based style loss is defined as:

$$L'_{\text{style}}(O, S) = \sum_{l \in \{l_s\}} \sum_{i=1}^m \|\Phi_i(F^l(O)) - \Phi_{NN(i)}(F^l(S))\|^2. \quad (5)$$

Here m is the total patch number extracted from $F^l(O)$. For each patch $\Phi_i(F^l(O))$, the best matching style patch $\Phi_i(F^l(S))$ is found by using the normalized cross-correlation distance:

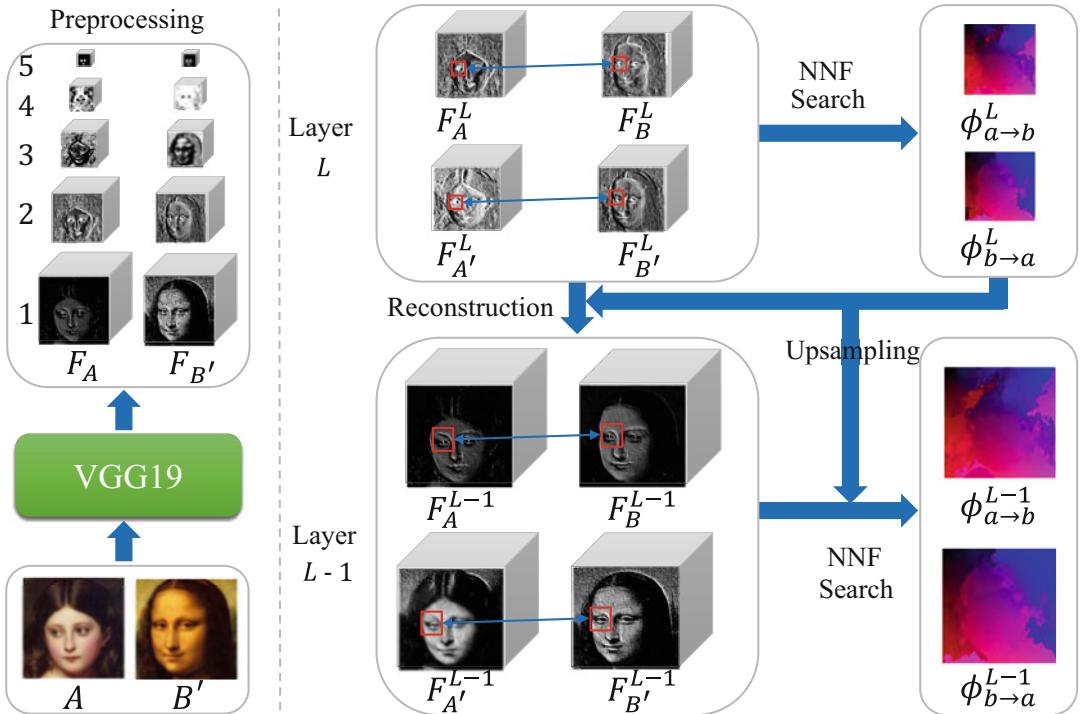

$$NN(i) = \arg \min_{j=1, \dots, m_s} \frac{\Phi_i(F^l(O)) \times \Phi_j(F^l(S))}{\|\Phi_i(F^l(O))\| \times \|\Phi_j(F^l(S))\|}. \quad (6)$$

D

This sets a data term to optimize pixel values of the output image. It does not explicitly establish the correspondence between two images.

In contrast, Liao et al. [6] transfer style in a more structure-preserving manner by using semantic-based dense correspondences. Figure 4 shows the system pipeline. Given an input image pair A and B' , they formulate style transfer as a problem of image analogies [3]: $A : A' :: B : B'$, where A' and B are unknown latent images. This analogy implies two constraints: 1) A and A' (also B and B') correspond at the same spatial position; and 2) A and B (also A' and B') are similar in appearance (style). In this way, the difficult mapping problem from A and B' is separated into one *in-place mapping* from A to A' and one *similar-appearance mapping* from A' to B' . The mapping from B' to A is achieved in the same way with the help of B .

Based on this formulation, they firstly compute deep features of A and B' through pre-trained CNN and initialize feature maps of two latent images A'/B at the coarsest CNN layer. Then, at each layer, a forward Nearest Neighbor Field (NNF) and an inverse NNF establish correspondences between feature maps of A and B as well as between feature maps of A' and B' . The extracted NNFs together with feature maps are used to reconstruct features of latent images A'/B at the next CNN layer. The NNFs obtained at the current layer are further upsampled to the next layer as their initialization. These three steps are repeated at each layer, updating correspondences from coarse to fine. For style transfer, A, B' can be set as the content and style image, respectively. Two example results are given in Fig. 3.

Deep Style Transfer, Fig. 4 The system pipeline of deep image analogy [6]. Thanks to the courtesy of Liao et al., this figure is directly borrowed from [6]

Feed-Forward Based Methods

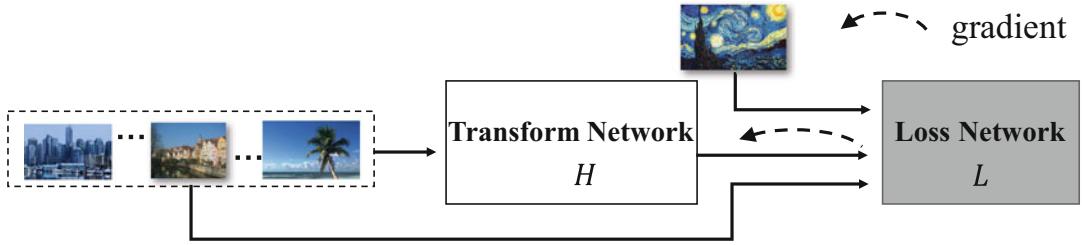

Optimization-based methods help understand the working principle of deep style transfer, but their computational cost is quite high, which makes it difficult for real applications, especially on mobile devices with limited computation resource. To speed up the optimization-based methods, *Per-Style-Per-Model* methods [8, 9] train a transform network \mathcal{H} to approximate the above optimization procedure. As shown in Fig. 5, the feature extracting network in Equation (1) is used as the loss network \mathcal{L} (by default, a VGG network pre-trained on the image classification task). At each training step, the stylized outputs of \mathcal{H} together with the corresponding content images and the specific style image (only one) will be fed into \mathcal{L} to calculate the loss defined in

Equation (1). Thanks to the differentiability of \mathcal{L} , its gradient can be back-propagated into \mathcal{H} to guide its learning. By training with a large number of content images, the transformer \mathcal{H} can learn the generality to stylize different images.

Multi-style-Per-Model methods [11, 12] further extend the capability of the network \mathcal{H} to learn multiple styles simultaneously. On one hand, Dumoulin et al. [11] replace the instance normalization layer in the network \mathcal{H} with a new conditional instance normalization (CIN) layer:

$$\text{CIN}(F(I), s) = \gamma^s * \left(\frac{F(I) - \mu(F(I))}{\sigma(F(I))} \right) + \beta^s, \quad (7)$$

which will learn a linear transformation that aligns the mean $\mu(\cdot)$ and the standard variance

Deep Style Transfer, Fig. 5 The feed-forward based style transfer algorithm, which uses a transform network \mathcal{H} to learn the optimization procedure in [4]. The learning

of \mathcal{H} is guided by the gradient back-propagated from the loss network L which has the same objective formulation as [4]

D

$\sigma(\cdot)$ of content image features $F(I)$ to the style-specific scaling parameter γ^s and shifting parameter β^s , respectively. Here, $\{\gamma^s, \beta^s\}$, ($s \in \mathcal{S}$) represents one of different styles and can be learnt by feeding different style images S to the loss network \mathcal{L} . Other layers of \mathcal{H} are shared for all style images.

On the other hand, Chen et al. [12] represent each style s , ($s \in \mathcal{S}$) with one specific filter bank kernel K_s . Its network consists of an encoder \mathcal{E} and a decoder \mathcal{D} . Given the input content image I , \mathcal{E} will first encode it into feature map $\mathcal{E}(I)$. To transfer a specific style s , $\mathcal{E}(I)$ will be convolved with its corresponding kernel K_s then decoded by \mathcal{D} to get the final stylization result O_s , i.e.,

$$O_s = \mathcal{D}(K_s \otimes \mathcal{E}(I)). \quad (8)$$

To fully decouple style and content information, they further constrain that, without applying any style kernel, the auto-encoder should reconstruct the original content image I :

$$\mathcal{D}(\mathcal{E}(I)) \longrightarrow I. \quad (9)$$

In this way, it guarantees that all the style information is only represented by its style kernel K_s but not absorbed into the encoder \mathcal{E} and decoder \mathcal{D} .

For *Arbitrary-Style-Per-Model* methods, their underlying idea is almost the same, i.e., transform the content feature as the same statistics as the style feature, for example, [16], which extends

the work [11]. Specifically, they first feed the content image I and the style image S into a pre-trained VGG network; then they use the adaptive instance normalization (AdaIN) layer to directly align the mean/standard deviation of the content feature $F(I)$ with those of style feature $F(S)$:

$$\begin{aligned} \text{AdaIN}(F(I), S) &= \sigma(F(S)) \\ &\times \left(\frac{F(I) - \mu(F(I))}{\sigma(F(I))} \right) \\ &+ \mu(F(S)). \end{aligned} \quad (10)$$

Next, a decoder network \mathcal{D} is trained with a large number of style images and content images to decode the transformed feature $\text{AdaIN}(F(I), S)$ into the final stylization result: $O = \mathcal{D}(\text{AdaIN}(F(I), S))$.

Open Problems

One may argue that to really achieve flexible style transfer, we need to produce representations that can totally disentangle visual styles and visual content. This is along the line of representation learning. We have made some limited progress with deep learning. With such disentangled representation of style and content, we may be able to further answer the following open questions:

- What is the characterization of the manifold of all existing visual styles?

- While sampling from such a style manifold is granted, are we able to extrapolate totally new styles based on understanding of this style manifold?
- Could the content representation from such a disentanglement facilitate better visual recognition, as it is invariant to styles?
- Are we able to decipher the aesthetics of all painting styles with such disentangled representation?
- Will research along this line eventually create truly creative AI system for arts?

We hope continued research thrusts along this would make arts more accessible to all people in the world.

Definition

Defocus blur is a loss of sharpness that occurs due to integrating light over the area of an aperture when the source of the area being captured is not on the image focal plane, i.e., the area is “out of focus.” The amount of blur that is visible in an image is a function of the lens aperture, the object and focal depth, and the camera pixel (or grain) size.

Background

Image blur can be described by a point spread function (PSF). A PSF models how an imaging system captures a single point in the world – it literally describes how a point “spreads” across an image. An entire image is then made up of a sum of the individual images of every scene point, where each point’s image is affected by the PSF associated with that point. For an image to be “in focus” means that one ideally does not want any image blur at a particular depth of the scene. Thus the PSF should be minimal, i.e., a delta function, where each scene point should correspond only to one image point. In

practice, PSFs can take on a range of shapes and sizes depending on the properties of an imaging system. When the PSF is large relative to the camera pixel or film grain size, an image with defocus blur is captured.

The fundamental cause of defocus blur is that real cameras capture images by integrating the light over a fixed opening in the lens, known as an “aperture” which has a non-zero area. Defocus blur is a function of aperture size and the relative position between camera and objects in the imaged scene. For very small apertures or “pinhole”-sized apertures, the blur or PSF and can be insignificant relative to the pixel size of the camera. However, in light-limited situations or when a particular photographic affect is desired, such as shallow depth of field in a portrait photo, larger apertures are used. With a large aperture, the “depth of field” is shallow, and the PSF for objects off the focal plane is larger. The amount of blur is depth dependent: it depends on the focal length of the lens and the focal depth, and it grows with distance from the focal plane, as illustrated in Fig. 1.

Theory

Image blur is described by a point spread function (PSF). The PSF models how an imaging system captures a single point in the world.

The most commonly used model for blur is a linear model, where the blurred image b is represented as a convolution of a kernel k , plus noise:

$$b = i \otimes k + n, \quad (1)$$

where \otimes is the convolution operation and $n \sim \mathcal{N}(0, \sigma^2)$ represents an additive Gaussian noise model. In this model, the blur is assumed to be constant over the entire image, i.e., spatially invariant; however, that is often not true in practice [1,2]. If there is depth variation in the scene, the blur will change with that depth. Similarly, in many lenses the shape of the blur changes across the image plane, as illustrated in Fig. 1. In both

Defocus Blur, Fig. 1 With defocus blur, the amount of blur is depth dependent; it depends on the focal length of the lens and the focal depth, and it grows with distance from the focal plane. An example of defocus blur is shown

of these cases, one can think of the blur kernel as being a function of image position, i.e., $k(x, y)$.

To model spatially varying blur, the spatially invariant kernel and convolution in Equation 1 can be replaced by a sparse re-sampling matrix that models the spatially variant blur, and the convolution process is now a matrix-vector product:

$$\mathbf{b} = \mathbf{A}\mathbf{i} + \mathbf{i}. \quad (2)$$

Each column of \mathbf{A} is the unraveled kernel for the pixel represented by that column. Thus the blurred response at a pixel in the observed image is computed as a weighted sum, as governed by \mathbf{A} , of the latent sharp image \mathbf{i} formed into a column-vector.

Representation: There are several common assumptions made on the form of a defocus blur kernel:

- The PSF is positive, i.e., all values in the kernel are non-negative
- The PSF is energy conserving, i.e., $\sum_i k_i = 1$
- The PSF is symmetric – radially or along some Cartesian axis
- The PSF has a known parametric form

The assumptions are listed in order from least to most restrictive. Positivity is a strong constraint and the least restrictive in that it does not eliminate any truly valid kernels, i.e., no true blur kernel can have negative values as blurring is a purely additive process. Another way of thinking

in the middle (From Joshi et al. [12]), and spatially varying defocus kernels (From Joshi et al. [12]) are shown on the right

of this is that there is no “negative” light. Similarly the second constraint is not very restrictive in that blurring is generally not considered to remove light, just spread it; thus, blur kernels should be energy conserving. Thus the assumptions of positivity and energy conservation are ones that can be used by virtually all PSF models. In practice, whether a particular model uses them depends on the nature of the other assumptions.

The second two assumptions are much more restrictive. Symmetry is typically used when one wants to generalize a 2D PSF from some 1D cross section [3]. Assuming a parametric form is also very restrictive as it assumes the entire shape of the blur kernel can be modeled by a low parameter mathematical model.

Defocus blur has two commonly used parametric models. A circular disk or “pillbox” function [4]:

$$k(x, y) = \begin{cases} 0 & \sqrt{x^2 + y^2} > r \\ \frac{1}{\pi r^2} & \sqrt{x^2 + y^2} \leq r \end{cases} \quad (3)$$

and a circularly symmetric 2D Gaussian [5]:

$$k(x, y) = C \exp \left(-\frac{x^2 + y^2}{2\sigma^2} \right), \quad (4)$$

where C is a normalization constant. In both cases, a single parameter determines the PSF – r for the pillbox and σ for the 2D Gaussian.

Application

Often defocus blur is used for artistic effect in photography, as a way to highlight the subject of a photograph. Estimation and removal of defocus blur constitutes an extensively researched area [4,6–9]. Estimated blur kernels are typically used for improving image quality by reducing blur using image deblurring and deconvolution methods [1,10–12]. Models of defocus blur are also used in depth estimation methods such as depth from defocus [11,13,14]. Recently, machine learning approaches have been used to estimate, characterize, and remove defocus blur [15–18].

► Polarized Light in Computer Vision

Definition

Image dehazing (or dehazing, for short) is a process to visually improve the visibility of images or videos degraded by haze or dust particles. Defogging is a similar process yet focusing on fog, which, unlike haze, is caused by water particles. Both dehazing and defogging are part of algorithms to enhance visibility in bad weather caused by light being scattered and absorbed by atmospheric particles. Since haze/fog can be present in day or night, dehazing/defogging algorithms have been developed to handle these two conditions.

Background

Poor visibility in outdoor scenes generates significant problems for many applications of computer vision. Most automatic systems for surveillance, intelligent vehicles, object recognition, etc. assume the input images have clear visibility. Unfortunately, this assumption does not always hold, particularly in bad weather. Therefore, improving the degraded visibility is practically important.

In outdoor scenes, poor visibility is caused by the substantial presence of various atmospheric particles that have significant density in the participating medium (creating haze, fog, mist, smoke, dust, etc.). Light from the atmosphere and light reflected from objects are absorbed and scattered by those particles, causing the visibility of a scene to be degraded. Physically, fog is a cloud of water droplets near the ground level, reducing the horizontal visibility to less than 1 km [1]. Unlike fog, haze is not water droplets. It is composed of dry particles (of dust or salt) so small that they cannot be seen individually with the naked eye, but the aggregate reduces horizontal visibility and gives the atmosphere an opalescent appearance (a bluish or yellowish veil) [1]. In hazy scenes, the horizontal visibility on the ground level is greater than 1 km but less than 5 km [2].

Besides fog and haze, there is also mist. In terms of visibility, mist is similar to haze (the horizontal visibility on the ground level is greater than 1 km but less than 5 km); however the particle type is the same as those of fog, which is water droplets. With respect to the opalescent appearance, mist can be discriminated from haze, since it gives a grayish cast to the sky [1].

Theory

In the field of optics and atmospheric sciences, there are a number of scattering models depending on the size of the particles and the complexity of the formulas. Most of them are derived from radiative transform (a physical phenomenon of energy transfer in the form of electromagnetic radiation, which is affected by absorption, emission and scattering processes) [3]. However, most of these models are too complex to be applied to computer vision algorithms (at least when this article is written). Hence, an approximated optical model for both haze and fog is more commonly used in computer vision (e.g., [4, 5]), which is based on Lambert-Beer law [6] and Koschmieder's equation [7]:

$$\mathbf{I}(x) = \mathbf{D}(x) + \mathbf{A}(x). \quad (1)$$

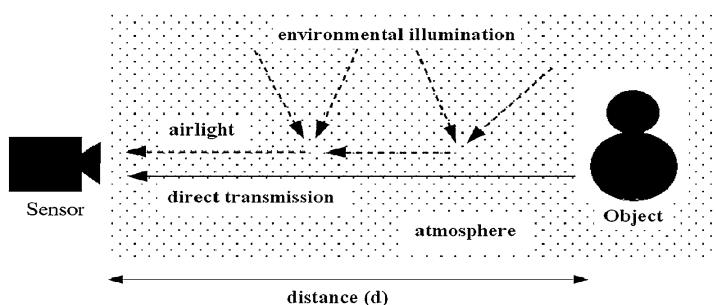

The first term is the direct attenuation (\mathbf{D}), and the second term is the airlight (\mathbf{A}):

$$\mathbf{D}(x) = \mathbf{L}_1(x)\rho(x)e^{-\beta d(x)} \quad (2)$$

$$\mathbf{A}(x) = \mathbf{L}_2(x)(1 - e^{-\beta d(x)}). \quad (3)$$

\mathbf{I} is the image intensity. x is the 2D spatial location. ρ is the reflectance of an object appeared in the image. \mathbf{L}_1 is the atmospheric light arriving at the objects. \mathbf{L}_2 is the atmospheric light that comes to the medium and is reflected to the camera without arriving at the objects. Further assumption is that $\mathbf{L}_1 = \mathbf{L}_2$, and both of them represent intensity of infinitely distant light sources and thus are assumed to be globally constant. β is the atmospheric attenuation coefficient. d is the distance between an object in the image and

Dehazing and Defogging, Fig. 1 The pictorial description of the optical model

D

the camera. β in the equation is assumed to be constant for different wavelengths. This assumption is common in many methods dealing with particles that the size is larger compared with the wavelength of light [8], such as, fog, haze, aerosol, etc. Moreover, β is constant for different spatial locations in the input image [5, 9]. Note that, \mathbf{I} , \mathbf{L}_1 , \mathbf{L}_2 , ρ in the equation are color vector (rgb), while the remaining variables are scalar.

$\mathbf{D}(x)$ in Eq. (2) is principally based on the Lambert-Beer law [6] for transparent objects, which states that light travels through a material will be absorbed exponentially. Equation (1) is basically Koschmieder's equation [7] that takes into account only a single scattering in the direction to the camera. Consequently, it likely fails to capture the effects of highly scattering media. Figure 1 shows the pictorial description of the model.

In terms of degree of polarization (DOP), airlight \mathbf{A} is partially polarized. Hence, two polarization directions of \mathbf{A} can be obtained using a polarizing filter attached to the camera, namely, parallel and perpendicular polarization direction with respect to the plane of incident [10–12].

Problem Definition

Based on Eq.(1), the problem can be generally described as follow: Given an image or a sequence of images whose intensity represented by $\mathbf{I}(x)$, estimate $\mathbf{R}(x)$ for every pixel, where $\mathbf{R}(x) = \mathbf{L}_1\rho(x)$, is the scene radiance had there not been particles along the line of sight.

Possible Assumptions and Solutions

For a single image, the problem described above is ill-posed. In the literature, a few approaches trying to tackle the problem have been proposed. The first approach is based on polarizing filters (e.g., [11, 12]). The main idea of this approach is to exploit two or more images of the same scene obtained by rotating a polarizing filter attached to the camera. Having at least two different intensity values of each pixel of the scene, [12] transforms the problem into a form solvable using ICA. The main assumption is that the scene is static while the filter rotates.

Another approach is based on multiple images of a scene taken in different weather conditions, i.e., with different properties of the participating medium (e.g., [4, 5]). By deriving two equations from Eq.(1), which represent the two input images, [5] can obtain the absolute values of airlight by assuming the presence of a totally dark object in the scene. Different approaches proposed by Tan and Oakley [13], Narasimhan and Nayar [9], Hautiere et al. [14], and Kopf et al. [15] are based on a single image, yet they require geometric information about the input scene.

This requirement might be impractical, and thus methods use in a single image and rely on image priors are introduced [16, 17]. Following these methods, many methods (e.g., [18–20]) are proposed. All the methods assume that β in Eq.(1) is constant across the light spectrum, which is a reasonable assumption [8]. Figure 2 shows the result of using the method of [16], which basically estimates the airlight, $\mathbf{A}(x)$, by maximizing local contrast.

Dehazing and Defogging, Fig. 2 Left: an image plagued by fog. Right: the result of enhancing visibility using the method introduced in Tan [16]

More comprehensive survey on the developments can be found in this paper [21], which discusses dehazing/defogging methods published up to 2016. A deep learning based dehazing method was introduced in [22]; and since then, many methods based on deep learning are proposed (see [23] for more comprehensive discussion). Most of these methods are designed to deal with daytime dehazing/defogging. As for the nighttime dehazing/defogging, the problem is more complex, due the presence of glow, low-light regions, noise, and also multiple light colors due to man-made light sources. Several methods have been proposed to tackle the problem of nighttime dehazing/defogging, e.g., [24–26].

Open Problems

Despite the rapid development in the recent years, the problem of dense haze or fog is still problematic. Given an image with considerably dense haze/fog, we do not know whether it is possible to extract the background scene behind the haze/fog. In other words, if the haze/fog is so thick, there are no methods to determine

whether there is information (or extractable information) of the background in the input image. This problem becomes more complex for nighttime haze/fog images.

Definition

Denoising is the process of recovering a reference signal that has been corrupted by noise. In computer vision, the reference signal is typically assumed to be the undistorted image of an object or scene, and noise is introduced as a result of the imaging process. The amount and type of noise changes from application to application. An example of a typical noisy image and the result of performing image denoising on it are shown in Fig. 1.

Background

Noise is an unavoidable consequence of the imaging process. Sources of noise include measurement and quantization errors introduced during signal acquisition and processing, thermal noise from the sensor and electronics in digital imaging systems, photographic grain in the case of film, and the physical nature of light itself.

The importance of denoising stems from the fact that noise in the input image can adversely affect the result of all subsequent visual processing. The value of image-dependent quantities

Denoising, Fig. 1 Left original, noisy MRI scan. Right result after denoising

such as brightness gradients, the accuracy in the localization of image features, the presence or absence of object boundaries, and even the subjective perceptual properties of the image are all affected to some degree by noise. Applications such as medical imaging, astronomy, low-light or high-speed photography, and synthetic aperture radar (SAR) imaging are typically characterized by larger amounts of noise relative to the reference signal.

Depending on the application, preprocessing the input with a denoising algorithm can improve the results obtained from further stages of visual processing. However, the denoising method should be selected with care since the denoising process is imperfect and will invariably destroy part of the information contained in the reference signal.

Theory

For a grayscale image, the perceived image brightness can be approximated by [1]

$$I = f(L + n_s + n_c) + n_q, \quad (1)$$

where I is the observed brightness value, $f(\cdot)$ is the sensor response function, L is the image

irradiance, n_s represents the noise contribution from brightness-dependent sources, n_c represents a constant noise factor, and n_q is the quantization noise.

Estimating all the quantities in this model is too complex a problem if only I is known, so in practice the simplified relationship $I = I_r + N$ is used instead where I is the observed image brightness, I_r is reference image that the denoising process must estimate, and N is the noise component. Since there is only one known value (the observed brightness) and two unknowns, the problem is under-constrained.

Additional external constraints must be placed on the properties of I_r and N so that a solution can be computed. Typically N is assumed to be i.i.d. noise, and most denoising methods assume a zero mean Gaussian distribution with fixed standard deviation. Depending on the constraints placed on the properties of I_r , we can group denoising methods into a handful of major classes.

Classes of Denoising Algorithms

The first class of image denoising methods is based on averaging the value of pixels within small image neighborhoods under the assumption that the brightness away from image edges should be uniform. These algorithms perform

anisotropic smoothing, so called because it has strong tendency to smooth uniform-looking regions in the image while preserving strong brightness discontinuities [2]. The original anisotropic smoothing algorithm [3], the bilateral filter [4], methods based on minimizing total variation [5], and the stochastic denoising algorithm [6] are all examples of denoising methods based on maximizing brightness uniformity across homogeneous regions.

A second class of algorithms is based on the analysis of image statistics. The underlying principle is that the statistical properties of natural images can be modelled and that given the model, denoising can be carried out by examining the statistics of a noisy image and transforming the image so that its statistics match those of learned model [7]. Common models include distributions of filter responses and pooled statistics for collections of image patches. Algorithms such as Gaussian scale mixtures [8], fields of experts [9], the nonlocal means method [10], and the block matching algorithm [11] rely on exploiting the statistical regularities of images or small image patches.

A third class of image denoising methods specifically designed to remove salt and pepper noise is based on outlier detection. The process involves estimating a distribution of brightness values around image neighborhoods and using this distribution to identify and remove outliers. The median filter [12] is an example of this class of denoising algorithms.

Regardless of the method, the goal of denoising is to remove as much of the noise as possible while preserving the information contained in the reference signal. For this reason, denoising algorithms are often evaluated using peak signal to noise ratio (pSNR) or the structured image similarity index (SSIM) [13] on images for which the noise-free reference is known.

Application

Denoising can be a useful preprocessing step for images from domains such as medical imaging, astronomy, or synthetic aperture radar. It is

also applicable to digital photography under low illumination conditions and to the restoration of archival footage and photographs. Image editing and image processing programs typically include denoising modules.

Experimental Results

D

The quality of the results produced by different algorithms changes from image to image and across different domains. But recent benchmarks [14] indicate that the block matching algorithm achieves better performance overall on natural images with different amounts of Gaussian noise.

Definition

Dense reconstruction aims on determining the complete 3D geometry of a static environment solely from a set of provided images.

Background

Correspondences between images depicting a static scene cannot only be established for a small set of visually salient regions but can be also extended to the entire image domain (i.e., to all pixels). Under the assumption of a static environment (or equivalently, a rigidly moving scene captured by a static camera), corresponding points in images together with

known camera calibration induce a 3D point. Thus, a dense set of correspondences implies a densely sampled surface in 3D. Establishing per-pixel correspondences between only two (or any small number of) narrow-baseline images is usually referred as computational stereo. *Dense reconstruction* addresses the more general problem of obtaining the full 3D geometry from a larger collection of images. In contrast to computational stereo, the returned surfaces are not 2.5D depth maps (as in stereo) but can possess arbitrary topology.

Theory

Determining the dense 3D geometry of a static scene from images can be achieved via direct or via indirect approaches:

- Direct approaches estimate the dense 3D geometry by using all available images simultaneously.
- Indirect methods estimate partial 3D models from a subset of (usually narrow-baseline) images (e.g., via computational stereo) and subsequently merge the partial models into a globally consistent geometry.

Direct Methods

Direct methods estimate the likelihood of the 3D surface being at a particular position via computation of a *photo-consistency score* incorporating all given images. Typically the 3D region of interest $\Omega \subseteq \mathbb{R}^3$ is discretized as a voxel space, and photo-consistency is computed with respect to the voxels. Since accurate visibility is not yet known, the photo-consistency score must be robust against potential occlusions. Approximate visibility of a surface patch in the images can be determined e.g., by view frustum and backface culling, and when a coarse estimate of the 3D geometry (e.g., the corresponding visual hull) is available. By traversing the voxel space in a

conservative order with respect to visibility and computing photo-consistency by only using certainly unoccluded images, one obtains the *space carving* method [1]. Sufficiently photo-inconsistent voxels are declared as empty and influence the visibility of not-yet-visited voxels in the images. Under certain assumptions, the set of occupied voxels (which is called the photo hull) contains the true 3D geometry. For objects with little texture, the space carving results are not satisfactory, and spatial smoothness assumptions need to be added. The volumetric graph cut approach [2] can be interpreted as regularized space carving. Since the state of a voxel (empty or occupied) is determined by a global optimization method, a robust photo-consistency score for each voxel is computed using static and approximate visibility information.

The knowledge of sparsely sampled surfaces, e.g., by triangulating correspondences between interest points, can be used to discretize Ω more adaptively by a general tetrahedral mesh. In such a representation, it is possible to employ a higher-resolution discretization where the true surface is expected [3, 4].

The task of determining the 3D geometry consistent with all given images can be formulated as mesh evolution approach, which is inspired, e.g., by deformable contour approaches used in image segmentation. The evolution of the mesh is guided by external forces based on the photo-consistency and optionally on silhouette data and internal forces regularizing the mesh [5, 6]. One drawback of such methods is that the obtained result may strongly depend on the initial mesh and only local minima of the underlying energy are usually reached.

Indirect Approaches

This set of methods first computes a collection of depth maps from a suitable narrow-baseline subset of images and fuses these depth images into a consistent 3D model. Since knowing the exact visibility of 3D locations in the images is not required for photo-consistency computation in a small baseline setting, these methods do

not need a coarse geometry to estimate potential occlusions. Furthermore, sophisticated computational stereo methods are available to generate high-quality depth maps ultimately yielding photo-realistic reconstructions. On the other hand, indirect methods do not utilize the available image data to the full extent, since the original images are usually not considered in the depth map fusion step.

Merging multiple depth maps can be identified as a particular instance of surface fitting from unorganized point data (e.g., [7, 8]), but it is clearly beneficial to exploit the specific structure in the input data. The mathematical formulations employed for depth map fusion can be tracked back to the problem of merging partial range scans obtained by an active sensor device, e.g., laser data or from structured light. Early approaches use an explicit polygonal representation [9], but more current methods are usually based on implicit volumetric surface representations capable of handling surfaces with arbitrary genus. It is a common aspect of all volumetric approaches that they return watertight meshes, i.e., surfaces may be hallucinated in occluded regions. In general, depth map fusion using a volumetric representation can be formalized as determining a minimizer $u : \Omega \rightarrow \{-1, 1\}$ of a functional E ,

$$E(u) = \phi(u; \{d_i\}) + \psi(u),$$

where $\Omega \subset \mathbb{R}^3$ is the region of interest (usually a 3D bounding box), $\phi(u; \{d_i\})$ is a compatibility (data fidelity) function measuring the agreement of the solution u with the set of input depth maps $\{d_i\}$, and $\psi(\cdot)$ denotes the spatial regularization of u . The interpretation of u is that $u(x) = 1$ if the 3D location x is occupied (solid) and $u(x) = -1$ if x corresponds to empty space. Often u is allowed to attain fraction values, e.g., $u : \Omega \rightarrow [-1, 1]$. In the following, let $D_i : \Omega \rightarrow \mathbb{R}$ be the signed distance transform induced by the depth map d_i , and $F : \Omega \rightarrow \mathbb{R}^3$ is a 3D vector field with $F(x)$ corresponding to a (smoothed) surface normal induced by the sampled depth maps. $F(x) = \mathbf{0}$ if x is distant to any of the depth map surfaces. By appropriate choice of ϕ and ψ , one obtains

- *Volumetric range image integration* [10] (with $\phi(u; \{d_i\}) = \int_{\Omega} \Sigma_i (u(x) - D_i(x))^2 dx$ and $\psi \equiv 0$)
- *Poisson surface reconstruction* [11] (with $\phi(u) = \int \|F = \nabla u\|^2 dx$ and $\psi \equiv 0$)
- *Global shape fitting* [12] (with $\phi(u) = \int F^T \nabla u dx$ and $\psi(u) = \int \|\nabla u\| dx \doteq TV(u)$)
- *TV-L¹ depth map fusion* [13] (with $\phi(u; \{d_i\}) = \int_{\Omega} \Sigma_i |u(x) - D_i(x)| dx$ and $\psi(u) = TV(u)$)

The above mentioned methods use a uniformly sampled voxel space to discretize the domain Ω . Determining a minimizer u for these energies is relatively simple due to their intrinsic convexity and amounts, e.g., to per-voxel averaging [10] or solving a sparse linear system of equations [11]. The final triangular mesh can be extracted from the implicit volumetric representation as the zero-level set, e.g., via the marching cubes method [14].

Application

Dense reconstruction plays a fundamental role in fully automatic 3D content creation from image data. Its application ranges from 3D city modeling and cultural heritage preservation to obstacle avoidance in autonomous systems navigation and 3D face reconstruction for character animation. Dense reconstruction can achieve an accuracy comparable to actively measured geometry (using laser range scanners or structured light) by relying only on passive imaging sensors [15, 16]. Accurate dense scene geometry can be augmented with texture images or more general appearance properties enabling photo-realistic rendering of virtual 3D representations.

Definition

Depth distortion refers to the distortion on the recovered structure from motion or from stereo due to imprecision or errors in the cameras' intrinsic and extrinsic parameters.

Background

In structure from motion, when a camera's intrinsic parameters are imprecise or even erroneous, the estimated motion is not accurate, and the structure inferred from motion will be a distorted version of the true structure in the environment. In stereo, when the cameras' intrinsic and extrinsic parameters are imprecise or even erroneous, the reconstructed 3D scene will be a distorted version of the true scene in the environment.

Theory

As an example, Fig. 1 illustrates a case where the focal length is misestimated. The top view of two cameras is shown. The line segment BE is the true structure in the environment. It is projected to the images according to the true optical center O_1 and O_2 , respectively. However, if the estimation of the focal length is not accurate, the

reconstructed structure will be distorted. In the figure, the optical centers are estimated to be at O'_1 and O'_2 . Then, the reconstructed structure will be $B'E'$, which is clearly different from the true one BE .

In general, given N views of a scene, the 3D reconstruction of a point \mathbf{M} is a function of its image points $\{\mathbf{m}_1, \dots, \mathbf{m}_N\}$, the cameras' intrinsic parameters $\{\mathbf{c}_1, \dots, \mathbf{c}_N\}$, and the cameras' extrinsic parameters $\{\mathbf{p}_1, \dots, \mathbf{p}_N\}$. That is,

$$\mathbf{M} = f(\mathbf{m}_1, \dots, \mathbf{m}_N; \mathbf{c}_1, \dots, \mathbf{c}_N; \mathbf{p}_1, \dots, \mathbf{p}_N). \quad (1)$$

If a parameter, say \mathbf{c}_1 , is misestimated by $\Delta\mathbf{c}_1$, i.e., $\mathbf{c}'_1 = \mathbf{c}_1 + \Delta\mathbf{c}_1$, then the reconstructed 3D point will be

$$\begin{aligned} \mathbf{M}' = f(\mathbf{m}_1, \dots, \mathbf{m}_N; \mathbf{c}_1 \\ + \Delta\mathbf{c}_1, \dots, \mathbf{c}_N; \mathbf{p}_1, \dots, \mathbf{p}_N), \end{aligned} \quad (2)$$

which is a distorted version of \mathbf{M} and is different from \mathbf{M} .

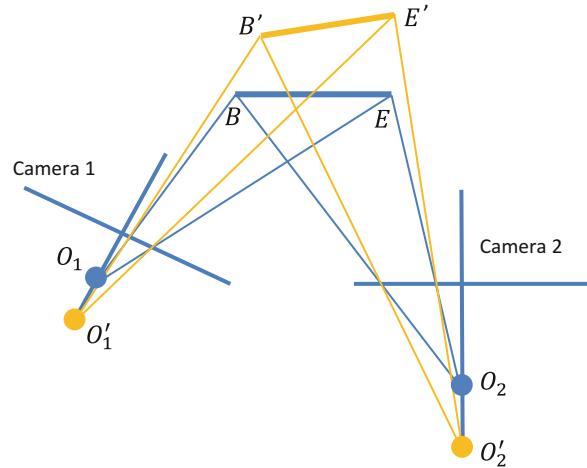

If the error in the parameter is small, we can use Taylor expansion and ignore the high-order terms. The first-order approximation of the error in 3D reconstruction due to $\Delta\mathbf{c}_1$ will be

$$\begin{aligned} \mathbf{M}' - \mathbf{M} = \frac{\partial}{\partial \mathbf{c}_1} \left(f(\mathbf{m}_1, \dots, \mathbf{m}_N; \mathbf{c}_1 \right. \\ \left. + \Delta\mathbf{c}_1, \dots, \mathbf{c}_N; \mathbf{p}_1, \dots, \mathbf{p}_N) \right) \quad (3) \\ \Delta\mathbf{c}_1 \equiv \mathbf{J}_{\mathbf{c}_1} \Delta\mathbf{c}_1, \end{aligned}$$

where $\mathbf{J}_{\mathbf{c}_1}$ is the Jacobian matrix of $f(\cdot)$ with respect to \mathbf{c}_1 . In practice, the exact error in the parameters is usually unknown. If the error can be modeled as a Gaussian, then the error in 3D reconstruction can also be approximated as a Gaussian. Let the error in \mathbf{c}'_1 , $\Delta\mathbf{c}_1$, be a Gaussian with mean 0 and covariance matrix $\sum_{\mathbf{c}_1}$, then the covariance matrix of the 3D reconstruction \mathbf{M}' is given by

Depth Distortion, Fig. 1

Illustration of depth distortion due to imprecise focal length

$$\sum_M = \mathbf{J}_{c_1} \sum_{c_1} \mathbf{J}_{c_1}^T. \quad (4)$$

The reader is referred to [1–3] for details.

The impact of the error in a camera's different intrinsic parameters on 3D reconstruction is not necessarily the same in magnitude. For example, the error in the coordinates of the principal point has little effect in 3D reconstruction [4, 5]. Cheong and Peh [6] provides a more detailed discussion on depth distortion due to calibration uncertainty.

Definition

Depth estimation describes the process of measuring or estimating distances from sensor data, typically in a 2D array of depth range data. The sensors may be either optical camera configu-

rations (monocular, stereo, or multiview stereo camera rigs), active projector-camera configurations, or active range cameras.

Background

Depth estimation is one of the fundamental computer vision tasks, as it involves the inverse problem of reconstructing the three-dimensional scene structure from two-dimensional projections. Given a 2D image of a 3D scene, the goal of depth estimation is to recover, for every image pixel, the distance from the camera center to the nearest 3D scene point along the pixel's viewing direction. The resulting 2D array of distance values is called the depth map, which is aligned with the camera coordinate system. The challenge of depth estimation is to recover, with sufficient accuracy, the depth map from the given image. Depth estimation can be accomplished in three principal ways: by triangulation from different viewpoints, by coaxial methods along the camera viewing direction, or by a learning system, which learns the mapping from the image to the depth map from data. For the first two cases, estimation methods may be either passive, based on image data alone, or active, with additional sensor control or scene illumination as supporting data. Binocular stereo, for example, is representative for a passive triangulation method, while laser interferometry is a typical active coaxial method.

As the depth map is organized in a regular 2D image grid and contains the depth value for each pixel, it is sometimes also called 2.5D model. The depth map is not a full 3D shape representation, as it contains depth to the nearest visible 3D scene elements only and does not handle regions that are occluded from the camera's viewpoint. Extensions to layered depth images (LDI) exist that can handle multiple depth values for occluded scene elements [20], but LDIs are still restricted to the camera viewpoint and do not handle full 3D data. Full 3D surface estimation from arbi-

trary viewpoints is the topic of 3D modeling of surfaces and volumetric 3D reconstruction methods, which can be obtained by merging multiple 2.5D depth maps or by tomographic methods that actively scan a volume with multiple projections and reconstruct the 3D volume surface density. For tomographic methods, which are common in 3D medical and material science volume analysis, and for 3D modeling, refer to the related concepts. A good overview and bibliography on all related concepts to depth estimation can be found in [21].

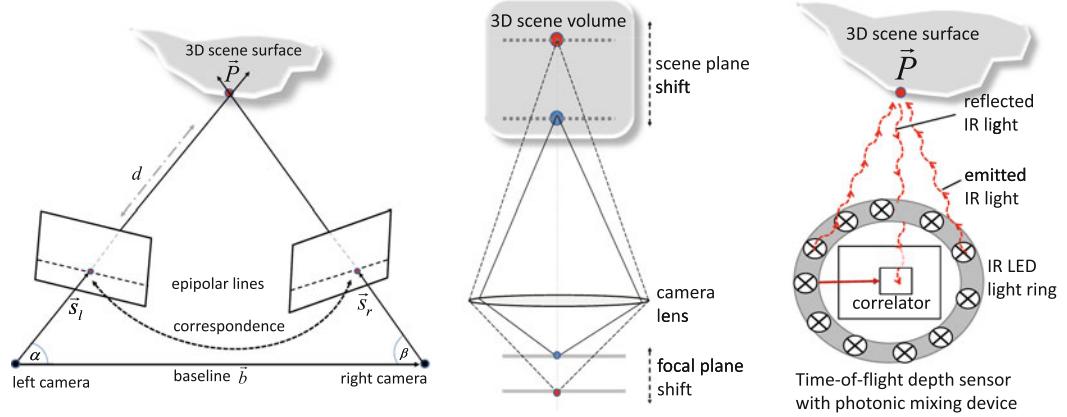

D

Theory

Triangulation

Triangulation is the most common approach for depth estimation. At least two images from different viewpoints observe the same 3D scene, and a 3D scene point is triangulated from the observed 2D projections of the scene point by ray intersection of the viewing rays; see Fig. 1 (left). The depth d is the length of the viewing ray from camera center to ray intersection. It can be computed easily from the triangulation triangle, given the length between the camera centers (baseline b) and the two angles α and β between the viewing rays and the baseline. This requires that the cameras are calibrated w.r.t. each other in a calibrated stereo rig configuration and that the corresponding 2D projections of the observed 3D scene point can be related to each other. The latter causes most of the problems in depth estimation, because the 2D search of corresponding projection pairs in the 2D images is difficult.

The correspondence problem can be simplified to a one-dimensional search when the relative orientation between the cameras, the epipolar geometry, is utilized [10]. The spatial triangulation plane or epipolar plane, which is constructed by the camera baseline b and the viewing ray s_I of one camera, intersects the image plane of the other camera in a line, the epipolar line. Hence the correspondence search is confined to

Depth Estimation, Fig. 1 Depth estimation principles. Left: depth estimation by stereo triangulation of corresponding projections. Center: active time-of-flight depth

estimation by phase shift correlation. Right: coaxial depth estimation by focal plane shift

this line and called disparity estimation. Disparity estimation is further simplified if the epipolar line corresponds to horizontal image scan lines. This is the case in standard stereo geometry where both cameras are aligned in identical orientation and shifted in horizontal scan line direction only. Stereo cameras with convergent configurations can be rectified to a virtual alignment by a rectifying homography or with other, more general transformations [16]. A generalization to rectification is the plane sweep, where the images of multiple calibrated cameras are compared by projecting onto a common 3D reference plane. Shifting the plane throughout the depth volume allows multi-camera depth estimation [3].

Passive Correspondence Analysis

Passive correspondence estimation relies on image data alone and requires that the image contains sufficient intensity variations to obtain a unique correspondence match. Correspondences are found by evaluating a cost function of the local intensity data along the search range. There exist a large variety of cost functions and evaluation schemes, ranging from data-driven evaluation of local cost function minimization [9], over semiglobal optimization along epipolar lines [11], to global optimization

schemes including smoothness constraints [2]. A good source for algorithms and benchmarking is the Middlebury database and their evaluation test scenario [18] and more recently the KITTI database for stereo and optical flow [7].

Active Correspondence Analysis

The main drawback of image-based correspondence analysis is the dependency on sufficient intensity variation in the images. One way out is to replace one of the cameras with an active video projector and to project unique patterns, which are easily identified by the other cameras, into the scene. There exist a variety of approaches. Coded light projectors project a time series of deterministic codes for unique correspondence, or a statistically distributed pattern is projected for optimal correspondence search. The patterns might be projected either in visible or in near-infrared light range. Stripe projection systems generate stripes of spectrally colored light [1], or even single laser light stripes are used for easy identification in industrial depth inspection systems. One very successful variant of an active depth triangulation system is the Kinect 1 (a trademark of Microsoft) sensor device that couples an infrared pattern projector and corresponding infrared camera for fast depth estimation with a visual color camera

for simultaneous color and depth capture. Such systems deliver reliable dense depth maps for many scenes but are restricted in depth range to a few meters. Depth estimation in the longer range may be obtained by triangulating laser scanning devices that scan the scene with a rotating mirror laser reflected into the sensing camera.

Coaxial Depth Estimation

One drawback of the triangulation method is that the scene is observed from different viewpoints, and hence occlusion might occur at object boundaries. If the baseline between the cameras is small, then fewer occlusion boundaries occur, but the depth measurement is not very accurate due to the small triangulation angle. If, on the other hand, a large baseline is chosen, then the triangulation may be accurate but the correspondence problem is more difficult due to the changing perspective. Coaxial methods do not suffer from such problems, as they measure depth from one viewpoint only. Active coaxial depth estimation has its foundations in classical interferometry systems. A coherent laser beam is sent out, reflected back at the 3D scene point, and received at the sensor. The distance the light wave has traveled causes a phase shift between emitted and returning light and hence interference. Due to the short wavelength of light, this principle is very accurate but covers only a very small unambiguous depth range. Recently, a novel class of depth sensors has emerged that either exploits the traveling time of a very short light impulse to measure the time of flight directly or that modulates an infrared LED light source with a periodic signal amplitude and measures the signal phase shift by correlation between outgoing and reflected light. The correlation sensor is a 2D image array of photonic correlation mixers that allows to directly estimate depth in a range of meters, depending on the modulation frequency; see Fig. 1 (center). Typical depth ranges are up to 10 m. Such time-of-flight range cameras [19] are active coaxial depth estimation devices that in principle may deliver dense and accurate depth maps in real time and can be used for depth estimation of dynamic time-varying scenes [12].

One very popular device has been the Kinect 2.0 (a trademark of Microsoft) that has been discontinued but very recently been resurrected in 2019 as cloud-connected Azure Kinect DK in connection with the Microsoft HoloLens 2 device.

Another option to estimate depth from a coaxial view is to change camera parameters and to relate the observed image changes to depth. This principle is observed by depth from focus algorithms. A series of images with different focal settings and aperture is recorded, and depth is computed from image sharpness variations [15]. This principle has been applied very successfully in depth-of-field microscopy, where a 3D volume of semitransparent objects like biological cells is scanned with shifting focal planes and very narrow depth-of-field settings; see Fig. 1 (right). Thus, a 3D stack of slices is obtained for 3D analysis, very much like 3D tomography.

D

Learned Depth Estimation

Machine learning techniques use data examples to infer the underlying structure and pattern of the processed data as a mathematical function. After the training on a huge amount of examples, the algorithms learn to generalize and can be evaluated on new inputs. Similar to semantic segmentation, where each pixel is assigned a class label, machine learning methods are trained to estimate the depth value of each pixel of an arbitrary monocular input image. In contrast to semantic segmentation, however, the difficulty in depth estimation lies in the inherent ambiguity. Since the projection of the 3D scene onto the 2D image has irretrievably discarded the depth information, theoretically an infinite number of 3D scenes can be considered as the origin of the projection. To resolve this ambiguity, the used techniques need to evaluate the global context of the entire image content in addition to local image information to determine the depth values. Solutions have been proposed with Markov random fields [17], neural networks [4, 13], or a combination of both [14].

In classical supervised learning based on huge data sets of monocular images and the

corresponding depth maps [7], the error functions have to be selected carefully to take also the scaling ambiguity into account. For example, the relation between different points in the image can be evaluated instead of the absolute distance [4]. Alternatively, the error function is based on a spacing-increasing discretization, and the optimizer executes an ordinal regression [5]. In order to exploit the advantages of the existing even larger data sets of stereo images without depth maps, unsupervised approaches are also used. For example, the disparity estimation of individual image positions can be learned from existing stereo image pairs. By warping the second stereo image from the disparities into the first image, visualization errors can be measured and used as a loss function [6, 8]. The disparity map can then be transformed into a depth map via triangulation. This new field of learned depth estimation shows very promising results and huge potential for monocular depth conversion, but care must be taken that sufficient numbers of training images including depth are available.

Definition

The process of descattering refers to enhancing images acquired in scattering media.

Background

Imaging in scattering media poses special concerns for computer vision methods. Examples for such media include haze or bad weather, water, blood, and body tissue. Light propagating in such media is scattered and attenuated. When imaging, some light from the source is scattered back from the medium toward the camera, before ever reaching the object. This light is an additive radiance component in the image that veils the object. In air, this additive component is often termed *airlight*, and in water and tissue, it is termed *veiling-light* or *backscatter* (this term will be used further on). The backscatter hampers visibility by reducing contrast and signal-to-noise ratio (SNR) in the images [1]. The backscatter increases the measured radiance, which increases the photon noise, without increasing the signal value. Thus, there are methods that aim to *descatter* the image, i.e., reduce the effects of scattering. This sometimes has the effect of extending the visibility range.

Correcting for backscatter in a single image is inherently ill-posed. When observing a single pixel, it is impossible to know what percentage of its intensity is reflected from the object and how much is contributed by the backscatter. Moreover, the backscatter value in a pixel is an accumulation of light scattered by the medium between the object and the camera. Thus, the accumulated backscatter increases with the object distance, which generally changes spatially in the image. This is a nonuniform effect which complicates recovery. However, the coupling of backscatter and the 3D structure of the scene also provides an opportunity since recovering either the backscatter or the distance can imply the other. After removal of the estimated backscatter, some methods also try to compensate for light attenuation. Reference [2] provides elaborate physical theory of scattering media. The reader is referred to the “Dehazing and Defogging” entry in this encyclopedia and to [3] for vision in the atmosphere and to [4, 5] for imaging under artificial illumination.

Descattering, Fig. 1 (a) Setup for descattering by polarized artificial illumination [5]. (b) Setup for the descattering by structured illumination [19]. (c) Result from single

underwater image descattering [10]. Raw image, descattered image, and range map (*left to right*). (Reproduced with permission from the authors)

Methods

Because of the ill-posed nature of the problem, some descattering methods use auxiliary information or specialized hardware. Alternatively, single image methods use image priors or constraints or use deep neural networks.

A known range map was used in [6]. In [7], the extreme values of the scene range are used, together with user indication of an airlight area in the image. Instead of range information, Ref. [7] relies on user indication of an area in the image that is not affected by the medium. In [3], the authors use images of the same scene under different weather conditions.

Single-image descattering methods rely on either smoothness constraints [8, 9] and different image priors [10, 11] (example in Fig. 1a) or use deep neural networks. Some of them first estimate the optical properties of the medium [12]. The reader is referred to [13, 14] for very comprehensive reviews of the growing body of research on single-image descattering. So far,

single-image methods have been demonstrated on images acquired under natural ambient illumination.

In highly scattering media, natural illumination has a limited range. Thus, several types of specialized hardware and instrumentation have been deployed. Time gating [15] exploits the fact that the light from the object arrives to the sensor in a different time than the scattered light, as they travel different optical path lengths. By opening the shutter for a very short period of time, the light reflected off an object can be separated from the scattered light. This requires strong laser illumination and a gated (streak) camera, with high temporal resolution [16]. The time of arrival of the object reflectance also reveals its distance. Recent developments in single-photon avalanche diode (SPAD) detectors show promising results with this respect [17].

Rather than scanning the time of flight, various methods perform spatial scanning. Laser line scan methods use a highly collimated laser source that scans the scene. The laser source is imaged

by a synchronized narrow field of view. Such systems have been shown to be very efficient, with a range of up to 6 attenuation lengths [18]. Structured light [19–22] methods capture a wide field of view with various illumination patterns. Figure 1b shows an example for a structured light setup. To overcome ambient illumination [23], synchronize the sensor's rolling shutter with the illumination such that they adhere to the epipolar constraint.

Another approach modulates light by polarization. It has been shown that high degrees of polarization can be observed in backscatter. Therefore, polarization discrimination has been used to reject scattered light in images taken in haze, underwater, and also through the skin. The light can be polarized naturally by scattering [24, 25] or be actively polarized [5, 26]. Figure 1c illustrates a setup of active polarized illumination. Some works assume the light reflected from the object is less polarized than the backscatter. Others assume the light from the object (often metal ones) is more polarized. When polarizing the light source, linear polarization or circular polarization can be chosen to optimize the backscatter degree of polarization in the specific medium.

Often, acoustic waves are less scattered than light in a medium and therefore can penetrate much deeper into the scattering media. However, sonic and ultrasonic images have less resolution than optical images and suffer from speckles. In photoacoustic microscopy, a pulsed laser beam is focused into biological tissue. The laser pulse creates sudden thermal expansion, generating ultrasonic waves, which are then detected to form an image. In this method, the light has to travel only half of the optical path while enabling high resolution [27].

Fluorescence is emission of light following excitation by light of a different wavelength. This phenomenon is used in microscopy to optically separate (using appropriate filters) the desired signal from scattered light that has the illuminant color [28].

The process of optical scattering is time reversible. Thus, in [29], the authors have shown that they can back propagate the scattering by a phase conjugate mirror.

Synonyms

Concept languages; Terminological logics

Definition

Description logics (DLs) is a family of logic-based knowledge representation formalisms for characterizing object classes and relationships between them.

Background

DLs have been developed to provide well-founded tools for knowledge representation and reasoning. Modern systems offer expressive concept languages with highly optimized reasoners, for example, for concept subsumption, instance classification or consistency checks. DLs have gained additional importance due to OWL-DL, the standardized DL for the Semantic Web. Mature software tools exist to support the development of OWL-DL knowledge bases, notably the editor Protégé.

Theory

Knowledge representation in DLs is based on unary predicates called concepts (or concept terms), binary predicates called roles (or role terms), and so-called individuals. A concept is interpreted in a set-theoretical semantics as a set of elements from a domain of discourse (also called universe), a role is interpreted as a set of pairs of elements from the domain, and an individual denotes a particular element of the domain. The elements in the second position of a role pair are called role fillers. Functional roles which map each first argument into at most one role filler are called features.

To construct a knowledge base, one has to fix a set of concept names, a set of role names, and a set of individuals. Names can be used to build complex concept and role terms. This is accomplished with the help of operators whose meaning is precisely defined in terms of the set-theoretical semantics.

Important concept operators supported by DLs include:

- Concept union, intersection, and negation
- Existential qualification, cardinality restriction
- Role axioms (e.g., reflexivity, disjointness, transitivity, inverse roles)

Definitions of concepts and roles and their relationships to each other form the TBox (terminological box), assertions about individuals in terms of unary and binary relationships form the ABox (assertional box). Typically, the TBox contains taxonomical hierarchies as background knowledge for a domain of discourse, while the ABox describes concrete facts. Modern DLs are designed to be decidable, i.e., to allow sound and complete reasoning processes. This limits their expressivity to a subset of first-order logic (FOL). The computational complexity of DL reasoning services has been shown to depend critically on the expressivity of the language.

Concrete domain predicates offer an interesting way to integrate quantitative data from low-level signal processing with symbolic high-level interpretations. Several DL systems allow predicates over natural and real numbers for concept definitions involving numerical restrictions.

One of the first Computer Vision applications developed with knowledge representation using a DL-like formalism was VEIL [1] which employed Loom for deductive reasoning in high-level image interpretation. Loom is a very expressive experimental system, but different from modern DLs, Loom's deductive procedures are not rigorously complete. The usefulness of DLs for Computer Vision applications is still being explored. In principle, DLs may offer a well-founded formalism for connecting vision to higher-level knowledge and may provide reasoning facilities for an artificial cognitive system. But there are also aspects which limit the usefulness for Computer Vision.

One problematic aspect is the limited expressivity of DLs which may prohibit intuitive concept formulations for symbolic scene interpretation. For example, in applications such as activity monitoring or situation recognition, it is desirable to define compositional hierarchies where concepts describe aggregates of constituents meeting certain constraints. Unfortunately, constraints cannot be expressed except in simple cases, and powerful constraint reasoners are not provided by DL systems.

Another problematic aspect is the limited support for the scene interpretation process which can be provided by the deductive reasoning services of DLs. Scene interpretation is known to be basically equivalent to abduction or logical model construction; hence none of the usual DL reasoning services is immediately applicable.

It has been shown, however, that DLs can be extended or combined with other systems in useful ways. An interesting extension is by a rule system. While the unrestricted use of rules may jeopardize decidability, their employment for ABox reasoning (as “DL-safe rules”) can be supported without losing the advantages of a DL system.

In [2] rules are used to model the abduction process for multimedia interpretation, for example, to provide deep annotations for multimedia web pages. ADL TBox represents background knowledge, and a DL ABox represents a low-level description of a multimedia document. The rules describe which higher-level hypotheses can be entertained to explain the low-level facts.

In [3] an OWL ontology of activity concepts, extended by SWRL rules (SWRL is the Semantic Web Rule Language proposed for OWL), is used as the DL kernel of a system for activity recognition. The concept definitions of the ontology are translated into compositional hierarchies representing hypothetical activities and into rules and constraints in JAVA and JESS (the JAVA Expert System Shell). Using rule engines in parallel, the interpretation system tries to instantiate activity hypotheses based on scene observations, this way generating scene descriptions at higher compositional levels.

Application

Applications areas of DL systems include:

- Semantic Web (e.g., logic-based information retrieval)
- Electronic Business (e.g., reasoning about service descriptions)
- Medicine, Bioinformatics (e.g., representing and managing biomedical ontologies)
- Process Engineering (e.g., formal representation of chemical processes)
- Software Engineering (e.g., representing the semantics of UML class diagrams)
- High-level Computer Vision (e.g., defining high-level concepts for scene interpretation)
- Cognitive Robotics (e.g., for representing an activity ontology)

Open Problems

The scalability of DL reasoning services is still a challenge, and new optimization techniques are developed to deal with large knowledge bases. Practical experiences, in particular with OWL-DL, have also revealed the need for more expressivity. SWRL (Semantic Web Rule Language) and its successor RIF (Rule Interchange Format) provide extensions in terms of rule expressions similar to Datalog. Computer Vision applications are mainly restricted to symbolic interpretation processes; DL system support for powerful interfaces to quantitative descriptions has yet to be developed.

Dichromatic Reflection Model

Shoji Tominaga

Department of Computer Science, Norwegian University of Science and Technology, Gjøvik, Norway

Nagano University, Ueda, Nagano, Japan

Definition

The dichromatic reflection model is a model that describes light reflected from an object's surface as a linear combination of two components. These components are the body (diffuse) reflection and the interface (specular) reflection.

Background

Reflection models are used for image analysis and object recognition in computer vision, as well as image rendering in computer graphics. Shafer proposed the dichromatic reflection model for inhomogeneous dielectric materials [13]. The first body reflection component provides the characteristic object color, and the second interface reflection component has the same spectral composition as illumination. Thus, according to the dichromatic reflection model, all color values on a uniform object surface are described as a linear combination of two color vectors: the illumination color vector and the body color vector. Tominaga and Wandell proposed a method

for testing the adequacy of the model. They show that under all illumination and viewing geometries, the spectral reflectance function is described as the weighted sum of two functions of the constant interface reflectance and the body reflectance [19]. This model is called the standard dichromatic reflection model of Type I. Moreover, Tominaga extended this model to describe surface-spectral reflectances of a variety of materials [15].

Theory

Standard Dichromatic Reflection Model

Model for Inhomogeneous Dielectrics (Type I)

The radiance of light reflected from an object's surface, $Y(\theta, \lambda)$, is a function of the wavelength λ and the geometric parameters θ where λ ranges over a visible wavelength and θ includes the illumination direction angle, the viewing angle, and the phase angle. The dichromatic reflection model for an inhomogeneous dielectric object describes the reflected light as the sum of interface and body reflections, as shown in the following formula:

$$Y(\theta, \lambda) = c_I(\theta)L_I(\lambda) + c_B(\theta)L_B(\lambda) \quad (1)$$

where the terms $L_I(\lambda)$ and $L_B(\lambda)$ are the spectral power distributions of the interface and body reflection components, respectively. These components are unchanged as the geometric angles vary, and then the weights $c_I(\theta)$ and $c_B(\theta)$ are the geometric scale factors. Let $S_I(\lambda)$ and $S_B(\lambda)$ be the surface-spectral reflectances for the two components, and let $E(\lambda)$ be the spectral power distribution of the incident light to the surface. So we derive

$$Y(\theta, \lambda) = c_I(\theta)S_I(\lambda)E(\lambda) + c_B(\theta)S_B(\lambda)E(\lambda) \quad (2)$$

The total reflectance is defined by dividing the color signal $Y(\theta, \lambda)$ by $E(\lambda)$ as

$$S(\theta, \lambda) = c_I(\theta)S_I(\lambda) + c_B(\theta)S_B(\lambda) \quad (3)$$

The standard dichromatic reflection model incorporates the Neutral Interface Reflection (or Constant Interface Reflection) assumption [9], which means that the interface reflection component $S_I(\lambda)$ is constant and can be eliminated from Eq. (3). This is shown as follows:

$$S(\theta, \lambda) = c_I(\theta) + c_B(\theta)S_B(\lambda) \quad (4)$$

The Neutral Interface Reflection assumption is applied to most materials, such as plastics and paints, because the interface reflection follows Fresnel's law [1] where the index of refraction is approximately constant for oil and water across the visible spectrum. For such surfaces, the specular reflection appears to have the same color as the illumination.

Extended Dichromatic Reflection Models

Model for Cloth (Type II)

There are many kinds of cloth materials such as silk, wool, rayon, polyester satin, cotton, velveteen, and velour. It is observed that the cotton and velveteen include little specular reflection from the surfaces, while the silk, wool, satin, and velour include gloss on the cloth surfaces, which show dichromatic reflection. The satin, however, is not described in Type I, because surface reflectance for such a material is dichromatic; but the specular reflection at the interface includes no illumination color. Therefore, the surface-spectral reflectance function is described as the generalized dichromatic reflection model of Type II seen below

$$S(\theta, \lambda) = c_I(\theta)S_I(\lambda) + c_B(\theta)S_B(\lambda) \quad (5)$$

where the interface reflectance component is not necessarily constant on wavelength.

Model for Metal (Type III)

Metals have quite different reflection properties from dielectric materials, because they only have interface reflection. If the surface is shiny and stainless, body reflection of the reflected light is negligibly small. So a sharp specular highlight is observed only at the viewing angle of the mirror direction. This type of reflection follows Fresnel's law, and the surface-spectral reflectance function depends on the incidence angle of illumination. It is pointed out that the surface-spectral reflectances of some metals are described by two interface reflection components, one of which is the constant spectral reflectance [15]. Therefore, the dichromatic reflection model of Type III is defined (*for approximating the surface-spectral reflectance function of a metal*) as

$$S(\theta, \lambda) = c_{I1}(\theta) S_I(\lambda) + c_{I2}(\theta) \quad (6)$$

The right-hand side in Eq. (6) represents two interface reflection components. The first component corresponds to the specular reflection at the normal incidence, which produces the major object color of a metallic surface. The second component is constant on wavelength, which corresponds to the grazing reflection at the horizontal incidence where the spectral reflectance is whitened.

Application

The dichromatic reflection models are useful in a variety of image processing, such as color image understanding [6, 7, 10], object identification and segmentation [5, 14, 18, 20], highlight and gloss detection [8], and color constancy and illuminant estimation [3, 17]. Most reflection models in computer graphics are based on the standard dichromatic reflection model [2, 4, 11, 12, 16].

Definition

Differential geometry studies spatial entities in local (infinitesimal) neighborhoods. This approach enables one to exploit the power of (multi-)linear algebra. Geometrical entities are differential invariants, the generic example being the curvature of planar curves. The number of relevant differential invariants increases in more complicated settings like – in this entry – that of surfaces in three-dimensional Euclidean space.

Background

The differential geometry of surfaces in three-dimensional Euclidean space is often called “classical differential geometry” as its history goes back to the founding fathers of infinitesimal

calculus, Newton and Leibnitz. There exists a huge literature, although novel additions are still forthcoming. This entry reviews the basics. There is ample literature for those needing to delve deeper.

Theory

D

Surfaces are smooth, two-parameter manifolds immersed into Euclidean three-space \mathbb{E}^3 . One requires that all partial derivatives are defined, and one often requires some form of “genericity.” For instance, many of the constructions discussed here will be undefined for planar surfaces, or spheres, and so forth.

There are many ways to represent surfaces, many of them useful in particular contexts. Perhaps the most commonly useful representation is by means of a parameterization $\mathbf{x}(u, v)$, where $\mathbf{x} \in \mathbb{E}^3$ and $\{u, v\} \in \mathbb{R}^2$. That is to say, the surface is treated as a two-parameter manifold immersed in Euclidean three-space. This representation is used here.

Unlike the case of space curves, there is no obvious way to introduce a parameterization akin to “arc length parameterization,” as this would limit the discussion to “developable surfaces,” surfaces that are metrically (“can be rolled out into”) planes. Most surfaces are intrinsically curved though; the sphere is an example. Thus the parameterization is assumed to be general, although regular, that is to say, the parameter curves are supposed to mesh like the weave and weft of a cloth.

One objective is to describe surfaces purely in terms of their “shape,” disregarding their spatial attitude and location. This is akin to the “natural equations” of space curves, which are fully characterized by their curvature and torsion. The case of surfaces is more complicated because one cannot simply characterize them by their curvatures, but needs certain additional constraints. Unlike curves, not anything goes (see below).

The Metrical Description of Surfaces

One naturally attaches a moving frame to a surface, much like the Frenet frame in the case of

curves. For a surface one has two tangents, \mathbf{x}_u and \mathbf{x}_v , and in \mathbf{E}^3 this immediately gives rise to a third vector $\mathbf{x}_u \times \mathbf{x}_v$, thus yielding a complete frame (see Figs. 1 and 2). The third vector is usually normalized as $\mathbf{n}(u, v)$, the surface normal. It is orthogonal to the tangent plane spanned by the two tangents. The metric of the tangent plane is conventionally expressed in terms of the First Principal Form

$$\mathbf{I}(du, dv) = d\mathbf{x} \cdot d\mathbf{x} = Edu^2 + 2Fdudv + Gdv^2, \quad (1)$$

where

$$E(u, v) = \mathbf{x}_u \cdot \mathbf{x}_u, \quad (2)$$

$$F(u, v) = \mathbf{x}_u \cdot \mathbf{x}_v, \quad (3)$$

$$G(u, v) = \mathbf{x}_v \cdot \mathbf{x}_v. \quad (4)$$

Because the First Principal Form is positive definite, one necessarily has $E > 0$, $G > 0$, and $EG - F^2 > 0$. Knowing $\mathbf{I}(u, v)$ allows one to calculate the lengths of curves on the surface, the surface area of patches of the surface, angles between directions on the surface, and so forth. Specifically, the area element is

$$dA(u, v) = \sqrt{EG - F^2} du dv = \|\mathbf{x}_u \times \mathbf{x}_v\| du dv. \quad (5)$$

The First Principal Form is independent of the representation, that is to say $\mathbf{I}(u, v) = \mathbf{I}'(u', v')$, although the coefficients E , F , and G are not.

The curvature of the surface has to do with the second-order derivatives \mathbf{x}_{uu} , \mathbf{x}_{uv} , and \mathbf{x}_{vv} . One

conventionally introduces the Second Fundamental Form

$$\begin{aligned} \mathbf{II}(du, dv) &= -d\mathbf{x} \cdot d\mathbf{n} = d^2\mathbf{x} \cdot \mathbf{n} \\ &= Ldu^2 + 2M du dv + N dv^2, \end{aligned} \quad (6)$$

where

$$L(u, v) = -\frac{1}{2} (\mathbf{x}_u \cdot \mathbf{n}_v + \mathbf{x}_v \cdot \mathbf{n}_u) = \mathbf{x}_{uv} \cdot \mathbf{n}, \quad (7)$$

$$M(u, v) = -\frac{1}{2} (\mathbf{x}_u \cdot \mathbf{n}_v + \mathbf{x}_v \cdot \mathbf{n}_u) = \mathbf{x}_{uv} \cdot \mathbf{n}, \quad (8)$$

$$N(u, v) = -\mathbf{x}_v \cdot \mathbf{n}_v = \mathbf{x}_{vv} \cdot \mathbf{n}. \quad (9)$$

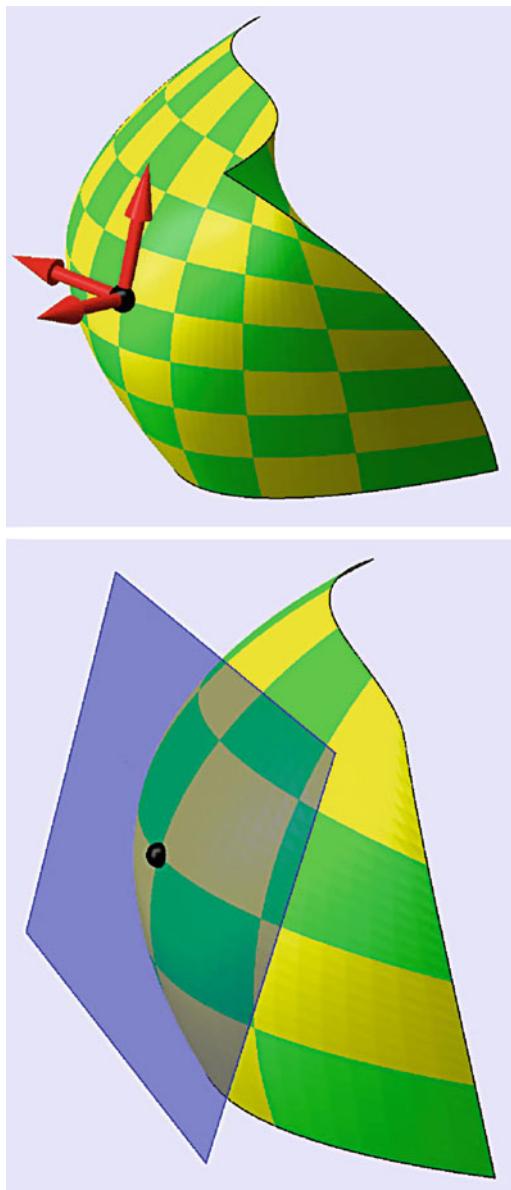

The Second Principal Form, like the First Principal Form, is independent of the representation, that is, $\mathbf{II}(u, v) = \mathbf{II}'(u', v')$, if the normal has the same direction (otherwise \mathbf{II} changes sign), although the coefficients L , M , and N are not.

The Second Principal Form describes the shape of the surface in the sense that the distance of the point $\mathbf{x}(u + du, v + dv)$ to the tangent plane at $\mathbf{x}(u, v)$ is (to the second order in $\{du, dv\}$) equal to $\frac{1}{2}\mathbf{II}_{u,v}(du, dv)$, the surface $\frac{1}{2}\mathbf{II}_{u,v}(du, dv)$ being the osculating paraboloid at $\{u, v\}$.

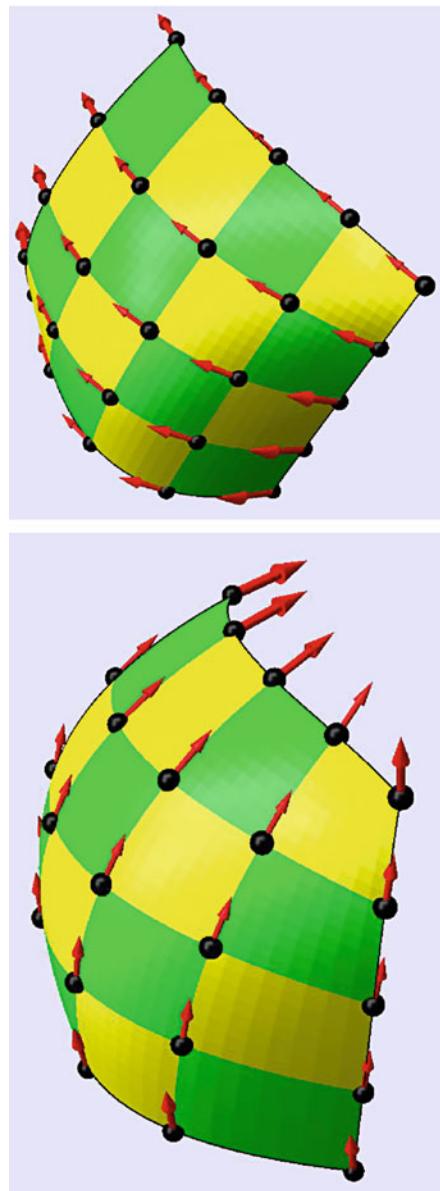

It is convenient to introduce Dupin's indicatrix (Figs. 3, 4, and 5)

$$\mathbf{II}_{u,v}(du, dv) = \pm \varepsilon^2, \quad (10)$$

with $\varepsilon \ll 1$, which, generically, is an ellipse or hyperbola. One thinks of the indicatrix as the outline of the wound that is inflicted if you take a chip off the surface with a flat knife. If the indicatrix is an ellipse, the surface is called elliptic; if it is a hyperbola, it is called hyperbolic at that point. In case $LN - M^2 = 0$, one has the degenerate parabolic case.

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space, Fig. 1 At left, the tangent plane at a point of a smooth surface. At right, a frame composed of the two tangents along the parameter directions and the unit surface normal. The tangent vectors span the tangent plane

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space, Fig. 2 The two fields of surface tangents x_u and x_v

There are various ways to conceive of the curvature of surfaces. One common way is to consider the curvatures of its normal sections (Fig. 6) that are the curves of intersection with planes that contain the normal direction. The normal curvature depends on the direction $du : dv$, the normal curvature being given by

$$\begin{aligned} k_n(du, dv) &= \frac{\text{II}(du, dv)}{\text{I}(du, dv)} \\ &= \frac{Ldu^2 + 2Mdudv + Ndv^2}{Edu^2 + 2Fdudv + Gdv^2}. \end{aligned} \quad (11)$$

The principal curvature varies between two extreme values, the *principal curvatures* $\kappa_{1,2}$. The principal curvatures are the solutions of the quadratic equation

$$k^2 - 2Hk + K = 0, \quad (12)$$

where

$$H = \frac{EN + GL - 2FM}{2(EG - F^2)} = \frac{1}{2}(k_1 + k_2), \quad (13)$$

$$K = k_1 k_2 = \frac{LN - M^2}{EG - F^2}. \quad (14)$$

The differential invariant $H(u, v)$ is known as the mean curvature, and the invariant $K(u, v)$ as the Gaussian curvature. One easily shows that points with $K > 0$ are elliptic and points with $K < 0$ hyperbolic. For points with $K = 0$, one or both of the principal curvatures vanish. In the latter case, one has planar points (the osculating paraboloid being degenerated to a plane); in the former case, a cylindrical point (the osculating paraboloid being degenerated to a cylinder).

The “mean curvature” is not just the mean of the principal directions. One can easily show that the mean of the normal curvatures of arbitrary mutually perpendicular normal sections also equals the mean curvature.

Another way to understand the Gaussian curvature is through the relation

$$K = \frac{\mathbf{n}_u \times \mathbf{n}_v \, du dv}{\mathbf{x}_u \times \mathbf{x}_v \, du dv} = \frac{d\Omega}{dA}, \quad (15)$$

where $d\Omega$ is the solid angle subtended by the bushel of normals inside the patch of area dA . This is the direct analogon of the definition of the curvature of curves as the rate of change of direction with respect to arc length. One often introduces the Third Principal Form $\text{III} = d\mathbf{n} \cdot d\mathbf{n}$ through the relation

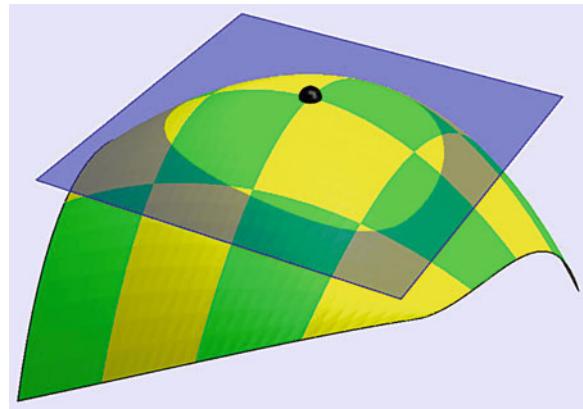

$$\text{III} - 2H \text{ II} + K \text{ I} = 0. \quad (16)$$

Notice that III equals the First Principal Form of the unit sphere. The mapping of the surface $\mathbf{x}(u, v)$ on the unit sphere $\mathbf{n}(u, v)$ is known as the Gauss map, or spherical image. Its area magnification is the Gaussian curvature, and the magnification in an arbitrary direction is the normal curvature in that direction. The Gauss map is a very convenient tool in a great many applications (Figs. 7, 8, 9, 10 and 11).

The directions $du : dv$ of the principal sections are evidently special; they are known as the principal directions of curvature (see Fig. 12). One easily shows them to be mutually orthogonal. Curves for which the tangents coincide with directions of principal curvature are lines of curvature. A patch of the surface free of umbilical points (points where Dupin’s indicatrix is a circle, thus where the principal directions are undefined) can be covered with a mesh of two mutually orthogonal families of lines of curvature. For such a parameterization, one has $F = M = 0$, a most “natural” representation of the surface for many purposes. In that case, the principal curvatures are $\kappa_1 = L/E$, $\kappa_2 = N/G$. An intuitive, because geometrical, characterization of the principal directions is $d\mathbf{n} \times d\mathbf{x} = 0$. In such a case, one has $d\mathbf{n} = -k\mathbf{dx}$, the formula of Rodriguez. On the Gaussian sphere, conjugate directions map on mutually orthogonal directions. Euler’s theorem $k_n = k_1 \cos^2 \varphi + k_2 \sin^2 \varphi$

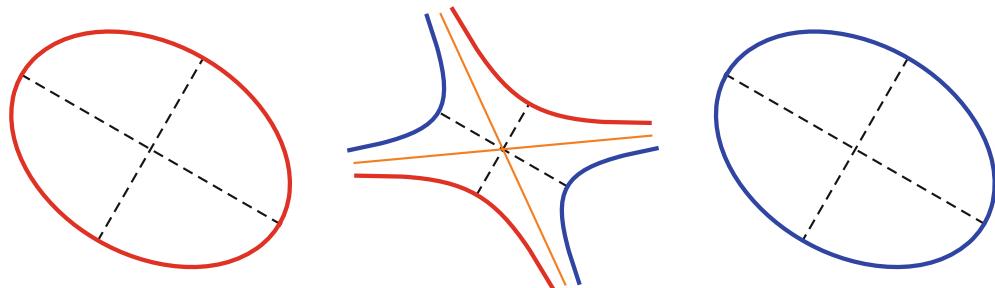

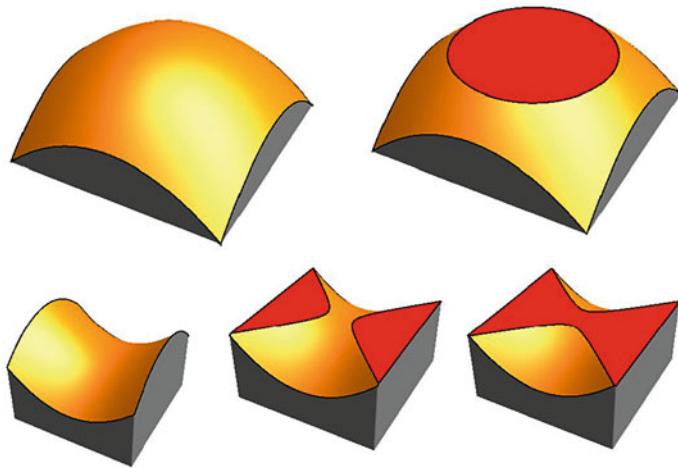

**Differential Geometry
of Surfaces
in Three-Dimensional
Euclidean Space, Fig. 3**

Dupin's indicatrix can be understood as the shape of the “wound” inflicted to a surface by a cut parallel to the tangent plane. Such curves may have arbitrary shapes, but generically one obtains the cases shown in Fig. 5 for infinitesimally small wounds

**Differential Geometry
of Surfaces
in Three-Dimensional
Euclidean Space, Fig. 4**

Dupin's indicatrix (the “wound”) in the case of an elliptic (*top*) and a hyperbolic (*bottom*) surface point. In the case of the elliptic point, the indicatrix has only one branch; in the case of the hyperbolic point it has two

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space, Fig. 5 Dupin's indicatrices for convex and concave elliptic, and for a hyperbolic

surface point. The principal directions are dashed, the asymptotic directions drawn in yellow. The red and blue curves represent the two branches of the indicatrix

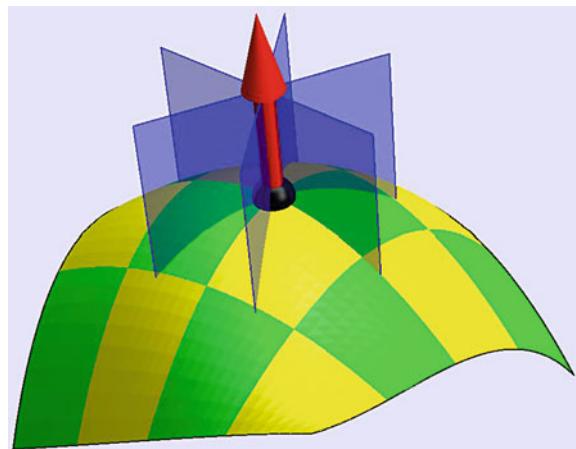

φ relates the normal curvature in the direction ϕ with respect to the first principal direction to the principal curvatures. Notice that it trivially applies to umbilical and planar points too.

In the case of a hyperbolic point, the principal curvatures are of opposite sign and, by Euler's

theorem, there apparently exist directions for which the normal curvature vanishes. These directions are given by $\text{II}(du, dv) = 0$, and are known as asymptotic directions. At generic hyperbolic points, there exist apparently two, mutually transverse, asymptotic directions. They

The field of surface normals. The Gauss map, or spherical image, is obtained by moving all normals to the origin. Hence, one obtains a map from the surface to the unit sphere

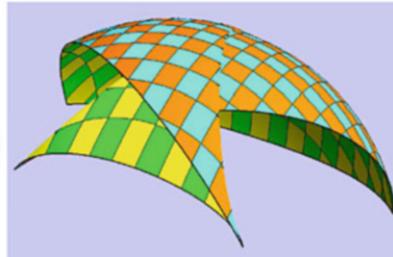

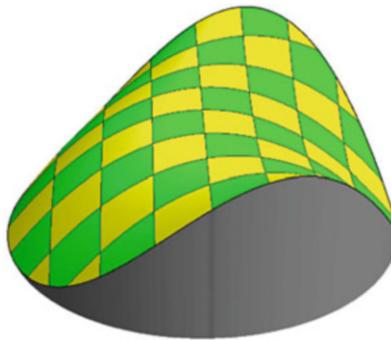

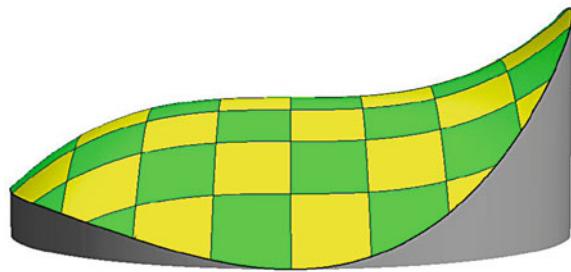

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space, Fig. 8 At left, the so-called “shoe surface” $\{u, v, u^3/3 - v^2/2\}$; at right, its spherical image. Notice the fold in the spherical image.

The fold is image of the parabolic curve $u = 0$. The points with parameters $\{\pm u, v\}$ have parallel normals and thus map on the same point of the unit sphere

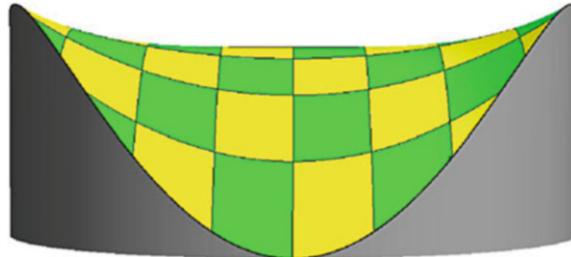

**Differential Geometry
of Surfaces
in Three-Dimensional
Euclidean Space, Fig. 9**

As seen from a tangent to the parabolic curve, the outline of the shoe surface has an inflection. This is generic

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space, Fig. 10 At left, the “Menn’s surface” $\{u, v, au^4 + u^2v - v^2\}$; at right, its

spherical image. Here the Gaussian image has a cusp; in the neighborhood of the cusp point, one has triples of parallel normals at distinct points of the surface

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space, Fig. 11 At the cusp of Menn’s surface, the surface is very flat; from this

viewpoint, the curvature of the outline is zero. Such points are generically isolated points on parabolic curves

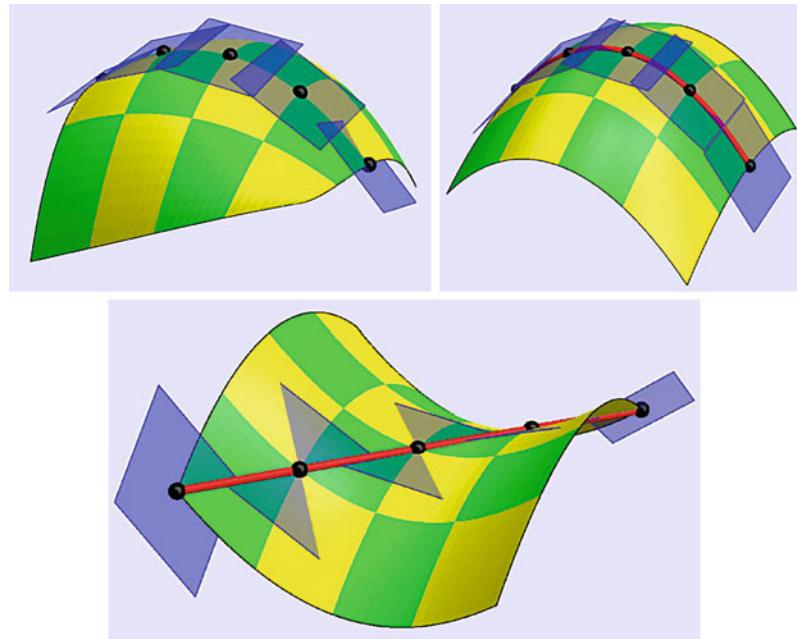

are bisected by the principal directions. A curve whose tangents are asymptotic directions is known as an asymptotic curve. In the neighborhood of a hyperbolic point, one may cover the surface with a mesh of two mutually transverse families of asymptotic lines. In such a case, one has $\text{II}(du, dv) = M du dv$. The curvature vector \mathbf{k} of an asymptotic curve is perpendicular to the normal; typically the osculating plane is tangent to the surface. In such cases, the torsion

satisfies $\tau^2 + K = 0$, the formula of Beltrami–Enneper (Fig. 13).

Directions $du: dv$ and $\delta u: \delta v$ are called mutually conjugate in case one has $d\mathbf{x} \cdot d\mathbf{n} = d\mathbf{x} \cdot \delta \mathbf{n} = 0$. This condition can also be written in the form $Ldu\delta u + M(d\delta u + \delta udv) + Ndv\delta v = 0$, which formally looks like a scalar product. At a generic point, each direction has a conjugate mate. The directions of principal curvature are mutually conjugate, whereas the asymptotic directions

D

are self-conjugate. The conjugate directions are important in computer vision because they relate the occluding contour to the viewing direction.

Like in the case of curves, one would like to attach a “moving frame” to the surface (Fig. 14). Classically, one has the Gauss equations

$$\beta_1^2 = \frac{LF - ME}{EG - F^2} \quad (20)$$

$$\beta_2^1 = \frac{NF - MG}{EG - F^2} \quad (21)$$

$$\begin{pmatrix} \mathbf{x}_{uu} \\ \mathbf{x}_{uv} \\ \mathbf{x}_{vv} \end{pmatrix} = \begin{pmatrix} \Gamma_{11}^1 & \Gamma_{11}^2 & L \\ \Gamma_{12}^1 & \Gamma_{12}^2 & M \\ \Gamma_{22}^1 & \Gamma_{22}^2 & N \end{pmatrix} \begin{pmatrix} \mathbf{x}_u \\ \mathbf{x}_v \\ \mathbf{n} \end{pmatrix}, \quad (17)$$

$$\beta_2^2 = \frac{MF - NE}{EG - F^2}. \quad (22)$$

and the Weingarten equations

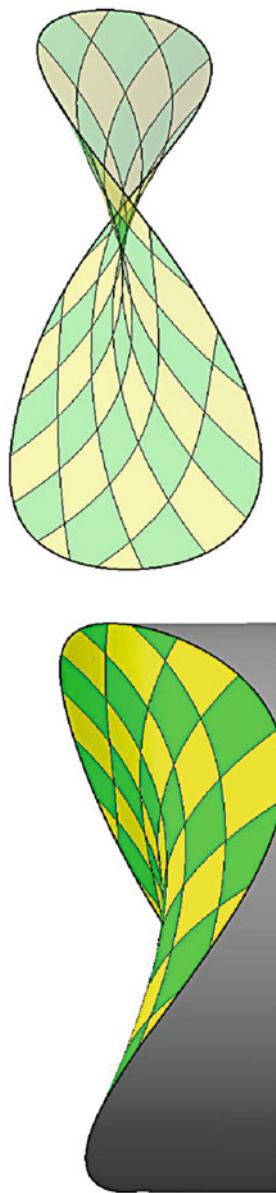

$$\begin{pmatrix} \mathbf{n}_u \\ \mathbf{n}_v \end{pmatrix} = \begin{pmatrix} \beta_1^1 & \beta_1^2 \\ \beta_2^1 & \beta_2^2 \end{pmatrix} \begin{pmatrix} \mathbf{x}_u \\ \mathbf{x}_v \end{pmatrix}, \quad (18)$$

where the Γ_{ij}^k are the Christoffel symbols of the second kind, and

$$\beta_1^1 = \frac{MF - LG}{EG - F^2} \quad (19)$$

The Christoffel symbols of the second kind depend on the coefficients of the First Principal Form and their derivatives. One has

$$\begin{aligned} \Gamma_{11}^1 &= \frac{GE_u - 2FF_u + FE_v}{2(EG - F^2)} & \Gamma_{12}^1 &= \frac{GE_v - FG_u}{2(EG - F^2)} \\ \Gamma_{22}^1 &= \frac{2GF_v - GG_u - FG_v}{2(EG - F^2)} & \Gamma_{11}^2 &= \frac{2EF_v - EE_v + FE_u}{2(EG - F^2)} \\ \Gamma_{11}^2 &= \frac{2EF_v - EE_v + FE_u}{2(EG - F^2)} & \Gamma_{12}^2 &= \frac{EG_u - FE_v}{2(EG - F^2)} \\ \Gamma_{22}^2 &= \frac{EG_v - 2FF_v + FG_u}{2(EG - F^2)}. \end{aligned} \quad (23)$$

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space,
Fig. 13 At *left*, a view of a hyperbolic surface. Notice the singular outline; this is generic for a view along an asymptotic direction. At *right*, a partially transparent

hyperbolic surface which allows one to judge the singularity of the outline more easily.
It is a cusp. In the opaque view, only one branch of the cusp is visible at any time

From the Gauss equations, the geometrical interpretation of the Christoffel symbols of the second kind is obvious: the symbol Γ_{ij}^k is the k -component ($k = u, v$) of the rate of change of the tangent \mathbf{x}_i ($i = u, v$) when transported over \mathbf{x}_j ($j = u, v$). Although the notation Γ_{ij}^k might suggest that the geometrical object Γ is a tensorial quantity, this is really not the case; its transformational properties are different.

In analogy with the case of space curves, one might guess that the “natural equations” of a surface are simply the coefficients of the First and Second Principal Forms as a function of $\{u, v\}$. However, this is not the case, the reason being the equality of mixed partial derivatives (i.e., $(\mathbf{x}_u)_v = (\mathbf{x}_u)_v$). One has to impose the additional constraints (“compatibility equations”),

$$L_v - M_u = L\Gamma_{12}^1 + M\left(\Gamma_{12}^2 - \Gamma_{11}^1\right) - N\Gamma_{11}^2, \quad (24)$$

$$M_v - N_u = L\Gamma_{22}^1 + M\left(\Gamma_{22}^2 - \Gamma_{12}^1\right) - N\Gamma_{12}^2, \quad (25)$$

the Codazzi–Mainardi equations, and

$$\begin{aligned} LN - M^2 &= F_{uv} - \frac{1}{2}E_{vv} - \frac{1}{2}G_{uu} + \\ &+ \frac{1}{EG - F^2} \left(\det \begin{vmatrix} 0 & F_v - \frac{1}{2}G_u & \frac{1}{2}G_v \\ \frac{1}{2}E_u & E & F \\ F_u - \frac{1}{2}E_v & F & G \end{vmatrix} \right. \\ &\left. - \det \begin{vmatrix} 0 & \frac{1}{2}E_v & \frac{1}{2}G_u \\ \frac{1}{2}E_v & E & F \\ \frac{1}{2}G_u & F & G \end{vmatrix} \right), \end{aligned} \quad (26)$$

which, by changing $LN - M^2$ into $K(EG - F^2)$, is known as Gauss’ Theorema Egregium. It expresses the Gaussian curvature in terms of the metric and its first-order derivatives, a major result of classical differential geometry. Now we have the result that I and II, satisfying the compatibility equations, and with $E, G, EG - F^2 > 0$, determine the surface up to Euclidean movements.

With special parameterizations, these formulas may simplify greatly. For instance, in terms

of a parameterization with lines of curvature, the Codazzi–Mainardi equations can be written as

$$\frac{\partial k_1}{\partial v} = \frac{1}{2} \frac{E_v}{E} (k_2 - k_1), \quad \frac{\partial k_2}{\partial u} = \frac{1}{2} \frac{G_v}{G} (k_1 - k_2). \quad (27)$$

An important special case in many applications is the description of the surface as a Monge patch $x\mathbf{e}_x + y\mathbf{e}_y + z(x, y)\mathbf{e}_z$, where $\mathbf{e}_{x, y, z}$ are an orthonormal Cartesian basis of \mathbb{E}^3 . One can conventionally write $p = z_x$, $q = z_y$ for the first- and $r = z_{xx}$, $s = z_{xy}$, $t = z_{yy}$ for the second-order partial derivatives of the “height function” $z(x, y)$. Then the tangents are $\mathbf{t}_x = \mathbf{e}_x + p\mathbf{e}_z$ and $\mathbf{t}_y = \mathbf{e}_y + q\mathbf{e}_z$, the normal $\mathbf{n} = (-p\mathbf{e}_x - q\mathbf{e}_y + \mathbf{e}_z)/\sqrt{g}$, where $g = 1 + p^2 + q^2$ is the squared area element $EG - F^2$. The First Fundamental Form is

$$\begin{aligned} I(dx, dy) &= (1 + p^2) dx^2 + 2pq dx dy \\ &+ (1 + q^2) dy^2, \end{aligned} \quad (28)$$

the Second Principal Form

$$II(dx, dy) = \frac{r dx^2 + 2s dx dy + t dy^2}{\sqrt{g}}, \quad (29)$$

whereas the Christoffel symbols become

$$\begin{aligned} \Gamma_{11}^1 &= \frac{pr}{g}, \quad \Gamma_{12}^1 = \frac{ps}{g}, \quad \Gamma_{22}^1 = \frac{pt}{g}, \\ \Gamma_{11}^2 &= \frac{qr}{g}, \quad \Gamma_{12}^2 = \frac{qs}{g}, \quad \Gamma_{22}^2 = \frac{qt}{g}, \end{aligned} \quad (30)$$

and the coefficients of the Weingarten equations

$$\begin{aligned} \beta_1^1 &= \frac{spq - rq^2 - r}{g^{3/2}}, \quad \beta_2^1 = \frac{tpq - sq^2 - s}{g^{3/2}}, \\ \beta_1^2 &= \frac{rpq - sp^2 - s}{g^{3/2}}, \quad \beta_2^2 = \frac{sqp - tp^2 - t}{g^{3/2}}. \end{aligned} \quad (31)$$

Expression for many types of surface representations (e.g., implicit form of the type $F(x, y, z) = 0$) or special forms (e.g., surfaces of revolution) are readily found in the literature.

Of course, one often has to deal with data that are not in some convenient analytical form.

Differential Geometry of Surfaces in Three-Dimensional Euclidean Space, Fig. 14

The “moving frame” of a surface. The rotations and deformations of the frame as it moves over the surface are described by the equations of Gauss and Weingarten

This calls for methods of numerical analysis and computational geometry.

Open Problems

In this section, we described the classical differential theory of surfaces. Many settings in computer vision and image processing do not involve a Euclidean structure though. Cases include affine and projective spaces, as well as (especially important in image processing) “isotropic differential geometry” in “graph spaces.” In such cases, one needs to substitute the appropriate differential geometry. Examples abound where authors failed to take this into account and used expressions from Euclidean differential geometry inappropriately. The reader should beware.

Definition

Invariants are entities that do not change under the action of a transformation group, e.g., projective invariants are unchanged under

projective transformations. One can distinguish between differential and algebraic invariants. Algebraic invariants involve algebraic forms such as points, lines, conics, etc., while differential invariants involve general differentiable curves and surfaces.

Background

This entry concentrates on differential invariants of curves, mostly in the plane. Also touched on are differential invariants of space curves and surfaces and of fields such as optic flow and shading.

Projective differential and algebraic invariants, well developed in the mathematical literature, were both introduced into computer vision in [1] in order to eliminate the search for the correct viewpoint when trying to recognize an object. Compared to algebraic invariants, the advantages of differential invariants are as follows: (i) Differential invariants can describe any arbitrary curve visible in the image. Algebraic curves in images are quite limited. While ellipses are common as projections of round objects, other algebraic curves are rare. (ii) Algebraic invariants require whole curves to be visible and are thus susceptible to occlusions. Differential invariants can be extracted from any visible parts of the curve. The disadvantage is that the differential invariants are harder to extract from the image reliably.

Wilczynski's method [2–4] was the first to obtain closed-form formulas for projective invariants of curves and surfaces. While interesting mathematically, it has proved difficult to implement in vision because of the high order of derivatives involved.

Cartan's “moving frame” method [5] is easily applied to transformations that have a natural arc length, such as Euclidean or unimodular affine transformations (i.e., area preserving, with $|T| = 1$). In the latter case, one can obtain the affine arc length and affine curvature. However it is hard to apply it to transformations (such as projectivities) which do not admit a natural arc-length parameter.

The determinants method [6] takes advantage of the invariant properties of determinants under linear transformations and is also very useful for algebraic invariants. Here it is used to obtain the affine arc length and curvature more simply than in Cartan's method.

All the above methods depend on the availability of derivatives of the curve $\mathbf{x}(t)$ w.r.t. the parameter t . These can be hard to extract reliably. The canonical method [7, 8] dispenses with both the derivatives and the curve parameter. The parameter is not really a part of the geometry of the curve; it is an artifact introduced for convenience. It turns out that while no method can reduce the number of descriptors that one needs to extract, the canonical method provides descriptors that are more robust and easier to extract. In a nutshell, an auxiliary implicit curve (i.e., a function $f(x, y)$ without a parameter) is fitted around a point of the data curve. Then the coordinate system is transformed to a canonical, or standard system, in which this auxiliary curve has a standard simple form. All quantities in this system are invariant.

Another important issue is the connection between 2-D images and 3-D objects. It has long been known that (in general) the projection from a 3-D shape to a single 2-D image does not have invariants. There is simply not enough information in a 2-D image to make up for the missing depth information by purely geometric means. The invariants described above are 2-D to 2-D (or n -D to n -D). However, there are useful invariant *constraints* between invariants of 3-D curves and those of their 2-D projections [9]. These can identify a shape with the help of information from known models.

As differential invariants often involve derivatives, a method is described for obtaining accurate derivatives [10]. The common methods yield incorrect results even in the analytic noiseless case. This systematic error is analyzed and corrected. This method has wider applicability than to invariants.

Theory

It is useful in projective geometry to replace the normal Cartesian coordinates (x, y) of a point in the plane by a triplet

$$\mathbf{x} = (x_1, x_2, x_3)^t = \lambda(x, y, 1)^t \quad (1)$$

with an arbitrary factor λ . The t denotes the transpose. To these one adds points with $x_3 = 0$ which have no corresponding Cartesian coordinates but can be thought of as the points at infinity. The point $(0,0,0)$ is excluded from the space. The homogeneous coordinates are also convenient in the affine subgroup of the projective transformation group. In this case one sets $\lambda = 1$ and $x_3 = 1$.

In these coordinates a projective transformation (projectivity) can be written as a linear transformation of \mathbf{x} to $\tilde{\mathbf{x}}$:

$$\tilde{\mathbf{x}} = \lambda(\mathbf{x})T\mathbf{x} \quad (2)$$

with T being a constant 3×3 matrix. The factor λ can change arbitrarily from one point to another.

A shape can be described in different ways by various shape descriptors s_k . A curve can be expressed parametrically as $\mathbf{x}(t)$, in which case the descriptors are usually derivatives with respect to t . It can also be expressed implicitly as a function $f(\mathbf{x}, s_k) = 0$, with the descriptors s_k being constant coefficients, e.g., of a conic. They transform to \tilde{s}_k .

A *relative invariant* I of weight w is defined as a function of the shape descriptors s_k that transforms as

$$I(\tilde{s}_k) = J^{-w} I(s_k) \quad (3)$$

J is the Jacobian of the transformation. There are in general different weights for different J s: J of the coordinate transformation is the determinant $|T|$, and there is also J of a parameter change, that is, $d\tilde{t}/dt$. A change can also result from multiplication of s_k homogeneously by a factor λ . This is of importance in projective homogeneous coordinates. In this case the invariant can change as

$$I(\lambda s_k) = \lambda^d I(s_k) \quad (4)$$

with d being the *degree* of the invariant.

An invariant of weights and degree zero is *absolute*.

The Jacobians and λ can vary from one point to another, namely, they depend on \mathbf{x}, t , but they do not depend on the descriptors s_k of the shape itself.

General Properties

Among the general properties of interest here are whether there is a set of invariants that are necessary and sufficient to describe a shape. For differential invariants the completeness theorem holds ([5], p. 144):

Theorem 1 *All differential invariants of a (transitive) transformation group in the plane are functions of the two lowest-order invariants and their derivatives.*

This is equivalent to saying that the original curve can be reconstructed from the two lowest-order independent invariants that exist at each point, up to the relevant transformation. This is because these invariants contain all the information about the curve except for a group transformation.

This completeness makes it possible to create an invariant “signature” of a curve. For example, in the Euclidean case, all invariants can be derived from the curvature and the arc length (Euclidean invariants) at each point, $\kappa(\tau)$. Thus, one can use the signature, namely, the plot of the curvature vs. the arc length, to recognize the curve up to a Euclidean transformation. Similar quantities can be derived in the affine case as described later. In the projective case, there is no natural arc length or curvature, but there are still two independent invariants at each curve point that can be plotted against each other. Since this signature is invariant to the viewpoint, the curve can be recognized without a search for the correct viewpoint. This is done without having to find the point correspondence along the curve, a common and difficult problem.

Another general property is that the more general the transformation is, the more descriptors one needs to extract from the image to find invariants. The general projectivity in the plane has eight coefficients that need to be eliminated, so to obtain two invariants, one needs to extract from the image at least ten descriptors per point. The affine subgroup has only six coefficients to eliminate and the Euclidean has three. Thus more general invariants lead to using higher-order derivatives or higher-order implicit curves.

A 1-D Projective Differential Invariant

First it is worth mentioning a well-known one-dimensional differential invariant, namely, the Schwarzian derivative [6]. Consider a particle moving along a straight line, with its position at a time t measured by a (nonhomogeneous) coordinate $x(t)$. The Schwarzian derivative S_x is defined as

$$S_x \equiv \left(\frac{x''(t)}{x'(t)} \right)' - \frac{1}{2} \left(\frac{x''(t)}{x'(t)} \right)^2 \quad (5)$$

and it is invariant under projective transformations of the line, given by $\tilde{x} = (ax + b)/(cx + d)$, with arbitrary a, b, c, d , as can be verified directly.

Furthermore, the differential equation

$$S_x = g(t) \quad (6)$$

(where $g(t)$ is given) determines the function $x(t)$ up to 1-D projectivity. The Schwarzian derivative is not invariant to change of the parameter t , except by a 1-D projectivity similar to that of x .

It is interesting that this invariant can be obtained as an infinitesimal limit of the well-known 1-D cross ratio.

Wilczynski's Method

This method finds invariants of the projective transformation (2) in stages. First it finds invariants to the linear part T of the transformation, and from those it derives invariants to λ and then to change in the curve parameter t .

Given a plane curve $\mathbf{x}(t)$, invariants to T can be obtained by solving the linear algebraic system of equations

$$\mathbf{x}''' + 3p_1\mathbf{x}'' + 3p_2\mathbf{x}' + p_3\mathbf{x} = 0 \quad (7)$$

for the three unknowns p_1, p_2, p_3 at point t . It is easy to show, by multiplying the equation through by T , that these solutions p_i are invariant to T . (In fact, p_i are expressible as determinants which fit the determinants method.) However, they are not invariant to change in the arbitrary factor $\lambda(\mathbf{x}(t))$ nor to change in the curve parameter t . From these p_i one constructs the “semi-invariants”:

$$P_2 = p_2 - p_1^2 - p_1' \quad (8)$$

$$P_3 = p_3 - 3p_1p_2 + 2p_1^3 - p_1'' \quad (9)$$

These remain unchanged under multiplication of the coordinates by a factor $\lambda(\mathbf{x})$, but not under change of the parameter t .

The full invariants are

$$\Theta_3 = P_3 - \frac{3}{2}P_2' \quad (10)$$

$$\Theta_8 = 6\Theta_3\Theta_3'' - 7(\Theta_3')^2 - 27P_2\Theta_3^2 \quad (11)$$

Under change of the parameter t , they transform as $\tilde{\Theta}_w = (d\tilde{t}/dt)^{-w}\Theta_w$, and thus w is the weight (Eq. (3)). The subscript corresponds to the weight w .

Θ_3 is the only linear invariant and $\sqrt[3]{\Theta_3}$ can be called the projective arc length. All other invariants can be derived from Θ_3, Θ_8 and their derivatives. This is a special case of the completeness Theorem 1. The original curve can be derived from these up to a projectivity. The above two invariants can thus be called a *complete* set of independent invariants.

These two invariants still contain the unknown weights, which vary from point to point. To eliminate them the method uses the invariant $\Theta_{12} = 3\Theta_3\Theta_8' - 8\Theta_3'\Theta_8$. This leads to the two absolute invariants [1]:

$$I_1 = \frac{\Theta_3^8}{\Theta_8^3}, \quad I_2 = \frac{\Theta_3^4}{\Theta_{12}} \quad (12)$$

These can be plotted against each other in an invariant plane with coordinates I_1, I_2 . This yields an invariant signature curve identifying the original curve up to a projectivity.

Since these invariants contain the eighth derivative, they are not very practical. The semi-invariant P_2 above contains the fourth derivative only. The other, P_3 , contains the fifth but it can be replaced by

$$P_3^* = P_3 - P'_2 \quad (13)$$

which again contain only fourth derivatives.

One can clearly see the burden that the curve parameter imposes on the method. The semi-invariants P_2, P_3^* are invariant to the projectivity and contain only fourth derivatives. It is the requirement of invariance to the change of parameter t that pushes the number of derivatives needed to eight. Thus, if the parameter can be eliminated, there will be fewer local quantities needed, and the robustness of the invariance will increase.

The Canonical Method

As was seen above, the need to eliminate the parameter t pushes the order of derivatives needed from four to eight. The canonical method [7, 8, 11] does not have a parameter in the first place. It can be applied quite generally but here the application to projectivities is described.

The basic idea is to transform the given coordinate system to a “canonical,” or standard system, which is determined only by the shape itself. Since this canonical system is independent of the original system, it is invariant. All quantities defined in it are thus invariant.

An important simple example is the Euclidean invariants. To find an invariant at a given point \mathbf{x}_1 on a curve, one attaches a circle at that point so that the tangent (first derivative) of the circle coincides with that of the curve at \mathbf{x}_1 (Fig. 1). Also, the radius of the circle is set so that second derivatives of the circle and the curve are equal at \mathbf{x}_1 . Thus one obtains three so-called points of contact between the given curve and the circle at \mathbf{x}_1 that are infinitesimally close and linearly independent.

The next step is to move \mathbf{x}_1 to the origin and rotate the curve so that its tangent coincides with the x -axis. Now \mathbf{x}_1 and the derivative dy/dx vanish there (Fig. 1). By this one has exhausted all the Euclidean transformations (translations and rotation) and arrived at a “canonical” Euclidean coordinate system. In this system all quantities are Euclidean invariants as they cannot be changed by any further Euclidean transformation. In particular, the distance from \mathbf{x}_1 to the center of the circle (which now lies on the y -axes) is invariant. This is the radius of curvature which is thus proved invariant.

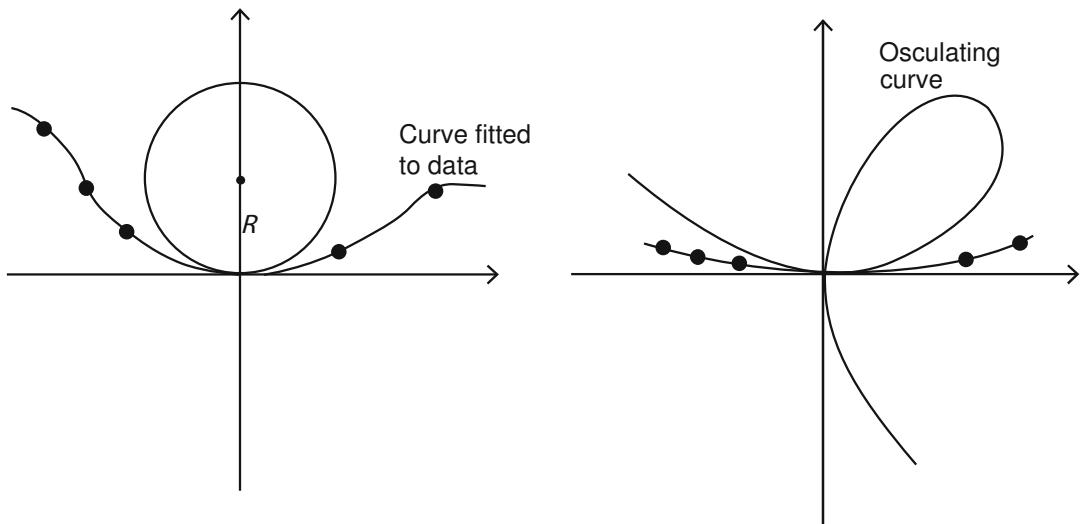

Although derivatives were mentioned, there is no need to actually find them. Instead one can fit a circle, $(x - x_0)^2 + (y - y_0) = R^2$, to the curve around point \mathbf{x}_1 . The coefficients of this circle, R, x_0, y_0 , can be found without derivatives or a curve parameter. In principle one needs only three data points to fit a circle, but in practice one wants a wider window around \mathbf{x}_1 . It is convenient to fit a conic in this window. A conic can be expressed as a matrix of coefficients A , satisfying $\mathbf{x}^t A \mathbf{x} = 0$. This is easier to fit because the conic is linear in its coefficients A . One can then find the appropriate circle from this conic algebraically. After moving to the canonical system, the new conic coefficients \tilde{A} are all invariants.

This method can be generalized to the projective case. Instead of the circle, one uses a more general “osculating curve” with more points of contact with the given curve at \mathbf{x}_1 . To eliminate the eight projective coefficients, one needs an osculating curve with at least eight contact points. A suitable choice for projectivities is the “nodal cubic” [7] (Fig. 1). After moving to a Euclidean canonical system, this can be expressed as

$$f_{osc} = c_0 x^3 + c_1 y^3 + c_2 xy^2 + c_3 x^2 y + c_4 y^2 + xy = 0 \quad (14)$$

This curve intersects itself at the origin so it has two tangents there, one lying along the x -axis. The other tangent is called the “projective normal” [4].

The image curve is given as data pixels so one needs to fit a differentiable curve to it. Instead of fitting a conic A around \mathbf{x}_1 as before, one fits a higher-order form such as a cubic or a quartic

Differential Invariants, Fig. 1 Osculating curves: circle (left) and folium (leaf) of Descartes (right)

$f(\mathbf{x}) = 0$. In principle, a cubic f will do, having nine coefficients plus the point's position on the curve. In practice, however, it was found [11] that a wide window is necessary for robustness to noise, and this requires a higher-order curve such as a quartic

$$f(x, y) = a_0 + a_1x + \dots + a_{14}y^4 = 0 \quad (15)$$

(Not all its coefficients need be independent.)

After finding f above by fitting to the data, one finds the osculating nodal cubic (14) from it algebraically. The goal is now to transform the coordinates so that this nodal cubic (14) takes on the simple coefficient-free form

$$x^3 + y^3 - 3xy = 0 \quad (16)$$

known as a *folium of Descartes*, Fig. 1, using projective transformations.

One obtains it, in a nutshell, as follows. Three of the eight projectivity parameters were already eliminated by moving to a Euclidean canonical frame, namely, moving the origin to \mathbf{x}_1 and rotating so that the x -axis is tangent to the curve there. Thus one already has the x -axis of the canonical system. The canonical y -axis is now chosen as the other tangent of the nodal cubic, the projective normal. One now skews the system so that this

projective normal becomes perpendicular to the x -axis. This will eliminate the term with c_4 in the nodal cubic (14). Next, the coefficients c_0, c_1 are eliminated by scalings in the x and y directions. One obtains

$$\tilde{x}^3 + \tilde{y}^3 + \tilde{c}_2\tilde{x}\tilde{y}^2 + \tilde{c}_3\tilde{x}^2\tilde{y} + \tilde{x}\tilde{y} = 0 \quad (17)$$

The coefficients in this system, \tilde{c}_2 and \tilde{c}_3 , are *differential affine invariants* because one has reached an affine canonical system – all possible affine transformations (translations, rotation, skewing, scalings) have been used to eliminate all the possible affine transformation coefficients. The remaining coefficients cannot be changed by any further affine transformation so they are affine invariants.

A projective canonical system is obtained by eliminating the last two coefficients \tilde{c}_2, \tilde{c}_3 using the remaining projective transformations of tilt and slant, obtaining the folium of Descartes (16). One then transforms the original fitted curve f , Eq. (15), to this new system and obtains new coefficients \tilde{a}_i for it. Since this system is projectively invariant, these \tilde{a}_i are invariants. One can choose some suitable combinations of them as invariants I_1, I_2 .

In summary, the canonical method with implicit curves was used to eliminate the

high-order derivatives and the curve parameter. Further details can be found in [11].

The Method of Determinants

The method of determinants is the main tool for deriving invariants of algebraic forms. It can also be used to derive differential affine and Euclidean invariants.

This method takes advantage of the properties of determinants under linear transformations. Many geometric entities can be cast in the form of determinants of points in homogeneous coordinates. In 1-D, the distance between points x_1, x_2 is

$$D_{12} = x_1 - x_2 = \begin{vmatrix} x_1 & x_2 \\ 1 & 1 \end{vmatrix} \quad (18)$$

Similarly in 2-D, the area of a triangle can be written as

$$S_{123} = \frac{1}{2} \begin{vmatrix} x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \\ 1 & 1 & 1 \end{vmatrix} \quad (19)$$

In the projective case, the coordinates can be multiplied by arbitrary factors, e.g., $\mathbf{x}_i = \lambda_i(x_i, y_i, 1)^t$. Thus the projective transformation (2) transforms a determinant by multiplying it by $|T|$ and λ_i :

$$|\tilde{\mathbf{x}}_1, \tilde{\mathbf{x}}_2, \tilde{\mathbf{x}}_3| = \lambda_1 \lambda_2 \lambda_3 |T| |\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3| \quad (20)$$

Thus, a determinant of points in homogeneous coordinates is a *relative projective invariant* of weight 1 in $|T|$ and degree 1 in each λ_i . It is a relative affine invariant with $\lambda_i = 1$.

The above properties are used to find invariants of various algebraic forms. The main trick is to find ratios of various determinants (e.g., lengths, areas) in which all the factors λ_i as well as $|T|$ cancel out, so one gets absolute invariants. When ratios cannot do the trick, then “cross ratios,” or ratios of ratios, usually do. Beyond points, determinants of higher-order forms such as conics and cubics are also easily obtained, e.g., for two conics [6]. The duality of points and lines in the projective case makes it possible to interchange their roles in the determinants.

Explicit Differential Affine Invariants

In the canonical method, one obtains implicit (parameter-less) invariants. Here one obtains explicit differential affine invariants by using the determinants of the derivative vectors $\mathbf{x}', \mathbf{x}''$, etc. at point t . The affine case is simpler than the projective case. First, it is assumed that $\lambda = 1$ so λ does not have to be eliminated. Second, the third coordinate is now $x_3 = 1$, and it is involved only with translations. Since the derivatives eliminate any translation coefficients, it is sufficient now to deal with a 2-D nonhomogeneous coordinate transformation:

$$\tilde{\mathbf{x}} = \begin{pmatrix} \tilde{x} \\ \tilde{y} \end{pmatrix} = T \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} \quad (21)$$

For this transformation the 2-D determinant $|\mathbf{x}', \mathbf{x}''|$ is a relative invariant of weight 1 in $|T|$, analogous to Eq. (20). It can thus be used to define the *affine arc length* [5]:

$$\tau = \int_{t_0}^t |\mathbf{x}', \mathbf{x}''|^{1/3} dt \quad (22)$$

It is absolute w.r.t. \tilde{t}' but relative w.r.t. $|T|$. It will now be used as an invariant parameter for all the differentiation, denoting derivatives as, e.g., \mathbf{x}_τ . Although an arc length depends on a starting point t_0 , the derivatives with respect to it do not. Higher-order relative invariants can now be obtained as further determinants. One immediately obtains the *affine curvature*:

$$\kappa_{af} = |\mathbf{x}_{\tau\tau}, \mathbf{x}_{\tau\tau\tau}| \quad (23)$$

involving the fourth-order derivative w.r.t. t .

The affine curvature is constant along conics and only conics. It is related to the conic area, a relative invariant, $\pi \kappa_{af}^{3/2}$. Thus one can interpret the affine curvature geometrically as the area of a conic that osculates the curve at $\mathbf{x}(\tau)$.

For unimodular affine transformations, i.e., with $|T| = 1$, all these relative invariants become absolute. They have been obtained by Cartan in the moving frame method [5].

Explicit Differential Euclidean Invariants

In this case T is orthonormal, and one has a new invariant, namely, the differential arc length $\mathbf{x}'^t \cdot \mathbf{x}'$. This can be used to define the integral Euclidean arc length:

$$\tau = \int (\mathbf{x}'^t \cdot \mathbf{x}')^{1/2} dt \quad (24)$$

Using derivatives w.r.t. this parameter, one can define the *Euclidean curvature*

$$\kappa = |\mathbf{x}_\tau, \mathbf{x}_{\tau\tau}| = x_\tau y_{\tau\tau} - y_\tau x_{\tau\tau} \quad (25)$$

The Euclidean invariants are all absolute as $|T| = 1$.

Projection from 3-D to 2-D

The above invariants involve the transformation from 2-D to 2-D shapes. Similar invariants can be derived in n -D spaces. In vision one is more often interested in the projection from 3-D objects to 2-D images. It has been shown that there are no invariants to such transformations because one loses the depth dimension.

However it has been shown [9, 12] that there exist invariant *constraints*, i.e., quantities in the image that constrain the 3-D corresponding invariants to a subspace of their full invariant space. In particular, for given five 2-D image points, the corresponding 3-D invariants are constrained to lines in a 3-D invariant space. These constraints were obtained by analyzing the projection properties of determinants. Similar methods have been used to obtain constraints in the differential case for the projection of 3-D curves to 2-D [9].

Such constraints are very useful in combination with given 3-D models of the objects. These models provide additional constraints that, together with the invariant constraints, identify an object uniquely. This was applied in [12] to images of vehicles.

Related Invariants

Euclidean and affine differential invariants of space curves and surfaces are the subject of differential geometry, e.g., [5]. Projective differential invariants of surfaces are derived in [3]. Semi-differential invariants, combining

differential and algebraic invariants, reduce the number of derivatives at the price of adding points or lines with unknown correspondence. They are described in [8, 13, 14]. Invariants of field flows are described in [15] and are applied to shape from shading in [16]. The evolution of invariants in scale space is studied in [13, 15]. Invariant differentiation, based on constructing invariants of mesh points along curves, is studied in [17, 18].

D

Accurate Differentiation

Many of the methods described above depend on obtaining derivatives of the image data. Given the noise and digitization errors in the image, derivatives can be quite inaccurate, especially at high orders. It is shown below that the current differentiation methods are inaccurate even for a first-order derivative in noiseless data. It is shown how to obtain accurate derivatives of any order in the noiseless case and how to mitigate the effect of the noise. Details are in [10].

To overcome the noise, it is common to convolve the image with a smoothing filter S such as a Gaussian. For a differentiable S , it is easy to show, using integration by parts, that the n -th derivative of the image data, $f^{(n)}$, smoothed by S , can be obtained as a convolution with the n -th derivative $S^{(n)}$ of the filter S :

$$f_s^{(n)} = S \otimes f^{(n)} = S^{(n)} \otimes f \quad (26)$$

where $f_s^{(n)}$ is the smoothed version of $f^{(n)}$. In practice it is common to use a version of the filter $S^{(n)}$ that is truncated on a finite interval, $S_{\text{trunc}}^{(n)}$. However this truncated filter is not differentiable at its ends so the above equation is not valid for it. This is more than a technicality. A quick check of the above equation with simple polynomial data, $f = x^k$, will immediately reveal that a truncated Gaussian filter yields erroneous derivatives even in this analytic, noiseless case. The error gets much worse for higher-order derivatives.

To solve the problem, the truncated filter can be replaced by a differentiable approximation of it such as a spline [10]. For the n -th derivative, one can use an n -th-order differentiable spline.

In practice, there is no need to really calculate the splines. It is well known that the n -th-order derivative of an n -th-order polynomial spline, defined on given $n + 1$ points, at the center of the spline, is nothing but the n -th-order *central difference* of the given points. (For an even number of points, this holds between the two central points). The first-order differencing can be applied as a filter $D = (-1, 1)$. Applying this filter n times yields the corrected filter for smoothed n -th-order differentiation [10]:

$$S^{[n]} = D \otimes D \otimes D \otimes \dots \otimes S = D^n \otimes S \quad (27)$$

This *difference-based* filter replaces the erroneous derivative-based filter $S_{\text{trunc}}^{(n)}$, and the invalid differentiation equation (26) is replaced by

$$f_s^{(n)} = D^n \otimes S \otimes f = S^{[n]} \otimes f \quad (28)$$

Unlike the old filter, this new filter yields accurate derivatives for polynomials up to order $n + 1$, namely, $f_s^{(n)} = f^{(n)}$, for the non-smoothing filter $S = \delta_{ij}$. For higher-order polynomials, the derivatives will be smoothed by the spline, but there will be no errors from filter truncation.

It is easy to show that the D^n are equal to the standard central difference filters, e.g.:

$$D = (-1, 1) \quad (29)$$

$$D^2 = (1, -2, 1) \quad (30)$$

$$D^3 = (-1, 3, -3, 1) \quad (31)$$

$$D^4 = (1, -4, 6, -4, 1) \quad (32)$$

For a pixel distance of h , the above filters are divided by h^n .

Regardless of the smoothing filter S , it was shown [10] that better noise suppression is obtained when it is applied over a larger window, namely, to more data points, because in a larger sample, random errors tend to cancel out.

Applications

Object Recognition by Contours

In [11] various objects are recognized by finding invariants of their contours. For each contour an invariant “signature” curve is obtained. This signature is unique to the contour up to the relevant transformation by Theorem 1.

In this case the contour is an implicit curve, $f(x, y) = 0$. The canonical method described above is appropriate for this case. Invariants are found at each point of the contour by fitting an implicit quartic curve to the contour data around that point and finding the invariants of this quartic at that point. Two invariants are then plotted against each other to obtain the invariant signature. As in the explicit case, one needs a wide window around each point to reduce noise, which requires a higher-order curve such as the quartic to better fit to the data, even though the analytic invariants only need a cubic curve. In [19], a similar approach was used to recognize logos, which usually comprise of well-defined curves. A hierarchical approach was used for feature extraction, page segmentation, and indexing.

Recognizing Surfaces

This application deals with surfaces that have been scanned and digitized in 3-D. The output of such scanning is often some curves on the surface rather than the surface range data. Therefore it is useful to recognize space curves in order to recognize the surface. In [20] differential invariants of space curves are used to recognize geometric primitives such as spheres, cylinders, cones, and tori. A 3-D version of the canonical method is used.

Definition

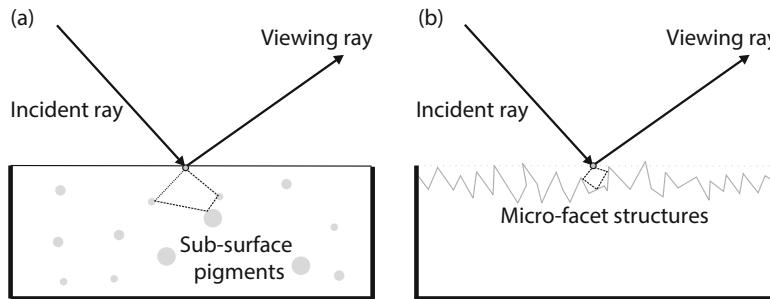

Diffuse reflection is a qualitative term to describe the relative, low-pass responses of different materials to incident illumination.

Background

Diffuse reflection can be described in relation to its opposite, specular (i.e., mirror) reflection. While an object with specular reflection allows direct measurement of the light that strikes the surface of the object, diffuse reflection destroys (i.e., “blurs”) the illumination information. Without scene priors, it is generally impossible to accurately recover the incident illumination on a diffuse scene from measured intensities, even if the surface geometry, viewing direction, and object BRDF are known. A large class of materials can be described by diffuse reflectance models which, although usually low parametric, are diverse in nature and do not follow any fixed analytic form.

Theory

Ramamoorthi et al. [1] have described the diffuse reflectance as containing lower frequencies in the

Diffuse Reflectance, Fig. 1 The two diagrams depict diffuse reflection for a scene point with a vertical surface normal. In (a), color pigments under a smooth, non-specular surface scatter the incident illumination back into

the viewing direction. In (b), reflection off microfacets can also cause diffuse reflection, even if the individual microfacets exhibit specular reflection

appropriate dual space. Generally, this implies that a low number of bases can fully describe the diffuse reflectance function, although the exact number depends on the analytic form of the reflectance function.

Diffuse reflectances from smooth non-specular surfaces are modeled as rays of light that penetrate into the surface of a material, reflecting off of and being absorbed by flakes of color pigments, as shown in Fig. 1a. Such a physical explanation describes the popular Lambertian model [2] and a variety of extensions such as through microfacets [3]. Rough specular surfaces can also exhibit diffuse reflection, and these can be accounted for through microfacet modeling [4] as shown in Fig. 1b.

Since diffuse reflection is a subjective term, many scene effects that exhibit the property of “blurring” the incident illumination are commonly termed as diffuse effects. These include global illumination effects in the scene such as sub-surface scattering and interreflections in skin and marble [5–7]. Strictly speaking, however, such effects are high parametric and global in nature and should not be incorrectly modeled as local, diffuse reflectance.

Computational Tractability

The main popularity of diffuse reflectance models is that they are low parametric and therefore have been used for inferring scene geo-

try (photometric stereo [8], shape from shading [9]). The high-frequency and global effects of the scene are modeled as noise in these approaches and usually ignored. Diffuse reflection has been shown as a good prior for scene recovery [10,11]. Psychophysical experiments have also confirmed that humans can accurately estimate scene and illumination properties [12], and much work has been done to replicate this for machine vision, tracing its roots back to retinex theory [13].

With scene priors, recent efforts have shown that inverse rendering is possible not only with diffuse reflectance but also with scenes exhibiting complex reflectances [14]. The strategy has been to focus on scenes where large amounts of data are available and learn deep priors that allow mapping between even single images and all scene properties, such as surface normals and material effects. These recent trends may force a redefinition of the relative term “diffuse” to mean reflectances for which priors exist, possibly from large amounts of data.

Definition

Diffusion filtering is a smoothing technique motivated by equilibration processes in physics that allows for structure-preserving smoothing.

Background

Many problems in computer vision require smoothing or spatial aggregation of information. The most basic problem is image denoising, where noise ought to be removed from an image while preserving its relevant structures. Diffusion filtering is one among several methodologies that are capable of removing noise without blurring and dislocating image edges. The strong relationships to other filters with similar capabilities, such as wavelet shrinkage, the bilateral filter, and variational regularization, have been shown in various papers [1–3].

Theory

Diffusion filtering is motivated by the concept of diffusion in physics. Diffusion leads to equilibration of concentrations, for instance, in fluids. It is by definition a mass preserving process. Mass can

move to locally change the concentration levels, but it cannot appear or disappear.

In diffusion, a concentration gradient ∇u creates a flux j as described by Fick's law:

$$j = -D \nabla u, \quad (1)$$

where D is a positive definite, symmetric diffusion matrix, which describes the magnitude and orientation preference of the flux. Combining Fick's law with the mass preservation property leads to the diffusion partial differential equation (PDE)

$$\frac{\partial u}{\partial t} = -\operatorname{div} j = \operatorname{div}(D \nabla u). \quad (2)$$

In image processing, we can interpret image intensities as concentrations and use the same diffusion PDE to smooth these image intensities. The initial condition is set by the input image

$$u(x, y, t = 0) = I(x, y). \quad (3)$$

For $t \rightarrow \infty$, diffusion yields the equilibrium state, i.e., a constant value image, where the value is the mean of the input image.

Depending on the choice of the diffusion matrix D , one can distinguish different cases:

- If D is the identity matrix, we obtain homogeneous diffusion, where mass is equally distributed in all directions with a magnitude that only depends on the gradient. The corresponding PDE is also known as the heat equation, and there exists an analytic solution, which corresponds to convolution with a Gaussian kernel with variance $\sigma^2 = 2t$.
- If D is a diagonal matrix with identical entries, it degenerates to a scalar g , often called diffusivity, and leads to isotropic diffusion. There is no orientation preference, but the magnitude of the flux may vary from point to point independent of the gradient. The diffusivity can be chosen as a decreasing function of the image gradient, for instance,

$$g(|\nabla I|) = \frac{1}{|\nabla I| + 1}, \quad (4)$$

which leads to a reduction of diffusion across edges and hence edge-preserving smoothing.

- In case of a general matrix D , the diffusion process is called anisotropic diffusion, as there is also a preference with regard to the orientation of smoothing. For instance, it is quite common to smooth along edges, but not across them. There is some confusion about terminology in the literature, as many papers, among them the original work on diffusion filtering by Perona and Malik [4], speak of anisotropic diffusion, although they use a scalar diffusivity rather than the full diffusion tensor.

Diffusion filters can further be separated into linear and nonlinear diffusion filters. In case of linear filters, the diffusion matrix D or diffusivity g does not depend on the smoothed image u but on some external quantity, usually the gradient of the input image I . This leads to PDEs that are linear in u . In case of nonlinear diffusion filters, the diffusion matrix or diffusivity depends on u and thus lead to nonlinear PDEs. Usually, nonlinear diffusion filters should be preferred as they take the enhanced image u into account when defining the areas where smoothing should be reduced, whereas linear diffusion relies on noisy measurements in the input image.

The diffusion PDEs can be solved numerically using iterative schemes. Most common is an explicit time discretization, which leads to the update equation

$$u^{k+1} = u^k + \tau \operatorname{div} (D(u^k) \nabla u^k), \quad (5)$$

where τ is a time step size, which must not be too large for the scheme to be stable. Details about discretization, stability, and many other properties of diffusion filters can be found in [5]. For fast implementations, it is also recommended to look into the works on AOS and FED schemes [6, 7].

D

Diffusion Filtering, Fig. 1 *Left:* noisy color image. *Right:* result after applying nonlinear isotropic diffusion

Application

Diffusion filters are mainly used for image denoising. The corresponding PDEs, however, can be found in numerous other computer vision applications, especially in the context of variational methods. The Euler-Lagrange equation of the regularizer in variational models leads to a diffusion PDE of the general form

$$\operatorname{div}(D\nabla u) = 0, \quad (6)$$

where u in this case is the modeled function that should minimize the variational energy. Very popular is the total variation regularizer [8]

$$\int |\nabla u| dx dy \quad (7)$$

the Euler-Lagrange equation of which is

$$\operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) = 0. \quad (8)$$

A (linear) diffusion process is implicitly also part of Laplacian eigenmaps and spectral clustering [9, 10].

Experiment

Diffusion processes can be easily extended to vector-valued images, such as color images. Figure 1 shows a noisy color image and the enhanced version after applying total variation flow

$$\frac{\partial u_k}{\partial t} = \operatorname{div}\left(\frac{\nabla u_k}{\sqrt{\sum_{l=1}^3 |\nabla u_l|^2}}\right). \quad (9)$$

Relation between objects and their digital images

Definition

Digitization is a mathematical model of converting continuous subsets of the plane or space (representing real objects) to digital sets in \mathbb{Z}^2 or \mathbb{Z}^3 or similar grids (representing segmented images of these objects). This definition can be generalized to any dimension $n > 3$: Digitization converts (transforms) continuous subsets of \mathbb{R}^n to digital sets in \mathbb{Z}^n or, equivalently, to functions from \mathbb{Z}^n to $\{0, 1\}$.

Background

A fundamental task of knowledge representation and processing is to infer properties of real objects or situations given their representations. In spatial knowledge representation and, in particular, in computer vision and medical imaging, real objects are represented in a pictorial way as finite and discrete sets of pixels or voxels. The discrete sets result in a quantization process, in which real objects are approximated by discrete sets. In computer vision, this process is called sampling or digitization and is naturally realized by technical devices like computer tomography scanners, CCD cameras, or document scanners. Digital images obtained by digitization are suitable to estimate the real object properties like volume and surface area. Therefore, a fundamental question addressed in spatial knowledge representation is: Which properties inferred from discrete representations of real objects correspond to properties of their originals, and under what conditions this is the case? While this problem is well-understood in the 2D case with respect to topology [1–5], it is not as simple in 3D, as shown in [6]. Only recently a first comprehensive answer to this question with respect to important topological and geometric properties of 3D objects has been presented in [7, 8].

Some recent works done for the general case are shown below. It is proven in [9] that although Gauss digitized boundaries of subsets of \mathbb{R}^n , for $n \geq 3$ may not be manifolds, non-manifoldness may only occur in places where the normal vector is almost aligned with some digitization axis, showing that although an object and its digitization are close in the Hausdorff sense through the projection map, they may not be homeomorphic. Nevertheless, in that entry, the authors prove the validity of the digital surface integral as a multigrid convergent integral estimator of subsets of \mathbb{R}^n , for $n \geq 3$, as long as the digital normal estimator is also multigrid convergent. In addition, [10] is a short survey on digital analytical geometry where the main idea is to analytically characterize digital sets to describe its continuous counterpart in \mathbb{R}^n , for $n \geq 3$ and related transform. This way, digital subsets of \mathbb{Z}^n are defined

by a list of inequalities and not by an enumeration of points in \mathbb{Z}^n . Finally, in [11], a modus operandi is proposed to model a digital subset of \mathbb{Z}^n as a cubical complex proving that the digital fundamental group of a digital subset of \mathbb{Z}^n is isomorphic to the fundamental group of its corresponding cubical complex, ensuring the topological correctness of the approach. Thus, properties of digital subsets of \mathbb{Z}^n can be computed on their corresponding cubical complexes using powerful algebraic-topological tools. Observe that this last approach "closes" a loop: starting from a continuous subset of \mathbb{R}^n , a digital subset of \mathbb{Z}^n is obtained and used to compute a cubical complex whose embedding in \mathbb{R}^n is again a continuous subset of \mathbb{R}^n .

The description of geometric and, in particular, topological features in discrete structures is based on graph theory, which is widely accepted in the computer science community. A graph is obtained when a neighborhood relation is introduced into a discrete set, e.g., a finite subset of \mathbb{Z}^2 or \mathbb{Z}^3 , where \mathbb{Z} denotes the integers. On the one hand, graph theory allows investigation into connectivity and separability of discrete sets (e.g., for a simple and natural definition of connectivity, see [12, 13]). On the other hand, a finite graph is an elementary structure that can be easily implemented on computers. Discrete representations are analyzed by algorithms based on graph theory, and the properties extracted are assumed to represent properties of the original objects. Since practical applications, for example, in image analysis, show that this is not always the case, it is necessary to relate properties of discrete representations to the corresponding properties of the originals. Since such relations can describe and justify the algorithms on discrete graphs, their characterization contributes directly to the computational investigation of algorithms on discrete structures. This computational investigation is an important part of the research in computer science and, in particular, in computer vision [14], where it can contribute to the development of more suitable and reliable algorithms for extracting the required shape properties from discrete representations.

It is clear that no discrete representation can exhibit all features of the real original. Thus one has to accept compromises. The compromise chosen depends on the specific application and on the questions which are typical for that application. Real objects and their spatial relations can be characterized using geometric features. Therefore, any useful discrete representation should model the geometry faithfully in order to avoid false conclusions. Topology deals with the invariance of fundamental geometric features like connectivity and separability. Topological properties play an important role, since they are the most primitive object features and human visual system seems to be well-adapted to cope with topological properties.

However, one does not have any direct access to spatial properties of real objects. Therefore, real objects are represented as bounded subsets of the Euclidean space \mathbb{R}^3 and their 2D views (projections) as bounded continuous subsets of the plane \mathbb{R}^2 . Hence, from the theoretical point of view of knowledge representation, the goal is to relate two different pictorial representations of objects in the real world: a discrete and a continuous representation.

Already two of the first entries in computer vision deal with the relation between the continuous object and its digital images obtained by modeling a digitization process. Pavlidis [1] and Serra [2] proved independently in 1982 that an r -regular continuous 2D set S (the definition follows below) and the continuous analog of the digital image of S have the same shape in a topological sense. Pavlidis used 2D square grids and Serra used 2D hexagonal sampling grids.

In 3D this problem is much more complicated. In 2005 it has been shown in [6] that the connectivity properties are preserved when digitizing a 3D r -regular object with a sufficiently dense sampling grid, but the preservation of connectivity is much weaker than topology. Stelldinger and Köthe [6] also found out that topology preservation can even not be guaranteed with sampling grids of arbitrary density if one uses the straightforward voxel reconstruction, since the surface of the continuous analog of the digital

image may not be a 2D manifold. The question on how to guarantee topology preservation during digitization in 3D remained unsolved until 2007.

The solution was provided in [7], where the same digitization model as Pavlidis and Serra is used, and also r -regular sets (but in \mathbb{R}^3) are used to model the continuous objects. As already shown in [6], the generalization of Pavlidis' straightforward reconstruction method to 3D fails since the reconstructed surface may not be a 2D manifold. For example, Fig. 1a, b shows a continuous object and its digital reconstruction whose surface is not a 2D manifold. However, it is possible to use several other reconstruction methods that all result in a 3D object with a 2D manifold surface. Moreover it is also shown in [7] that these reconstructions and the original continuous object are homeomorphic and their surfaces are close to each other.

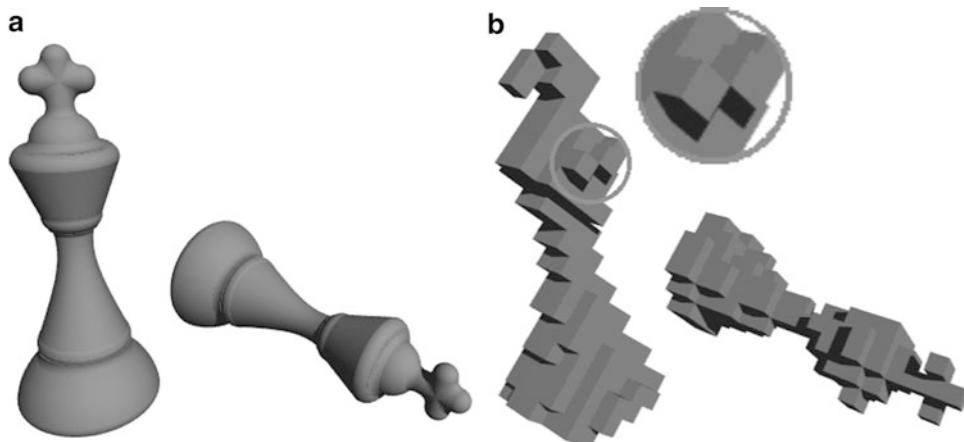

The first reconstruction method, majority interpolation, is a voxel-based representation on a grid with doubled resolution. It always leads to a well-composed set in the sense of [15], which implies that a lot of problems in 3D digital geometry become relatively simple.

The second method is the most simple one. It just uses balls with a certain radius instead of cubical voxels. When choosing an appropriate

radius, the topology of an r -regular object will not be destroyed during digitization.

The third method is a modification of the well-known marching cubes algorithm [16]. The original marching cubes algorithm does not always construct a topologically sound surface due to several ambiguous cases [17, 18]. As shown in [7] and [8], most of the ambiguous cases can not occur in the digitization of an r -regular object and that the only remaining ambiguous case always occurs in an unambiguous way, which can be dealt with by a slight modification of the original marching cubes algorithm. Thus the generated surface is not only topologically sound, but it also has exactly the same topology as the original object before digitization. Moreover it is shown that one can use trilinear interpolation and that one can even blend the trilinear patches smoothly into each other such that one gets smooth object surfaces with the correct topology. Each of these methods has its own advantages making the presented results applicable to many different image analysis algorithms.

In the general case, well-composed digital subsets of \mathbb{Z}^n do not present topological paradoxes. They also have very interesting properties and practical applications. Different "flavors" of well-composedness (WC) are present in the literature: WC based on equivalence of connectivities (EWC), digital WC (DWC), WC in the

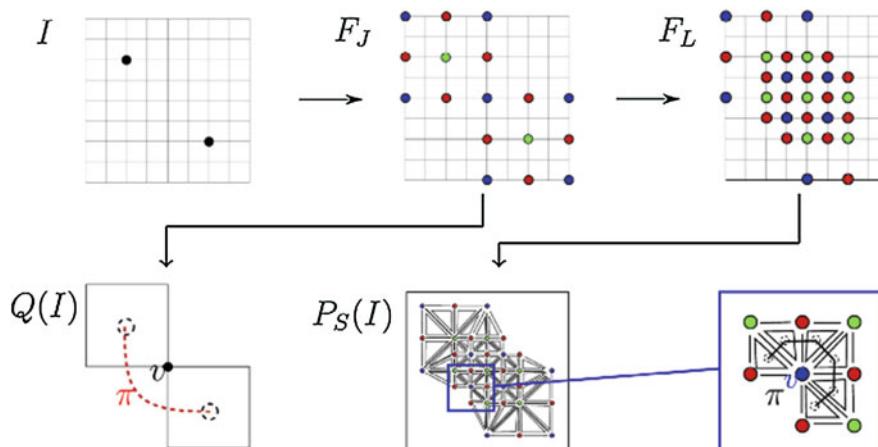

Digitization, Fig. 1 The digital reconstruction (b) of an r -regular object (a) may not be well-composed, i.e., its surface may not be a 2D manifold as can be seen in the magnification

Alexandrov sense (AWC), and WC in the continuous sense (CWC). All these definitions are equivalent in 2D. For the 3D case, we have DWC \Leftrightarrow AWC \Leftrightarrow CWC. For the nD case, $n \geq 3$, we have EWC \Leftarrow DWC. The rest of equivalences for the case $n > 3$ are open problems nowadays. The definition of well-composedness has also been extended to arbitrary grids and multivalued images (AGWC) (see [19]).

Methods for repairing digital subsets of \mathbb{Z}^n , for $n > 3$, to convert them in well-composed ones are a complicated open problem. A first step in this direction is done in [20] in which a combinatorial method is given for computing a simplicial complex homotopy equivalent to the cubical complex associated to a given digital subset of \mathbb{Z}^n . This simplicial complex is continuously well-composed for $n \leq 3$ and weakly well-composed for $n > 3$ in the sense that for any two n -simplices incident to a common vertex v , there always exists a face-connected path of n -simplices incident to v . A graphical diagram of the method is given in Fig. 2. Observe that cubical and simplicial complexes derived from that method are also stored as digital subsets of \mathbb{Z}^n , so that later calculations on the elements of the complex can be done efficiently.

Theory

The (Euclidean) *distance* between two points x and y in \mathbb{R}^n is denoted by $d(x, y)$, and the (Hausdorff) *distance between two subsets of \mathbb{R}^n* is the maximal distance between each point of one set and the nearest point of the other. Let $A \subset \mathbb{R}^n$ and $B \subset \mathbb{R}^m$ be sets. A function $f : A \rightarrow B$ is called *homeomorphism* if it is bijective, and both it and its inverse are continuous. If f is a homeomorphism, then A and B are *homeomorphic*. Let A and B be the two subsets of \mathbb{R}^n (particularly, $n = 2$ or 3). Then a homeomorphism $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ such that $f(A) = B$ and $d(x, f(x)) \leq r$, for all $x \in \mathbb{R}^n$, is called an *r-homeomorphism* of A to B , and A and B are *r-homeomorphic*. A *Jordan curve* is a set $J \subset \mathbb{R}^n$ which is homeomorphic to a circle. Let A be any subset of \mathbb{R}^n . The *complement* of A is denoted by A^c . All points in A are *foreground*, while the points in A^c are called *background*. The *open ball* in \mathbb{R}^n of radius r and center c is the set $\mathcal{B}_r(c) = \{x \in \mathbb{R}^n \mid d(x, c) < r\}$, and the *closed ball* in \mathbb{R}^n of radius r and center c is the set $\overline{\mathcal{B}}_r(c) = \{x \in \mathbb{R}^n \mid d(x, c) \leq r\}$. The *boundary* of A , denoted ∂A , consists of all points $x \in \mathbb{R}^n$

Digitization, Fig. 2 We start from $I = (\mathbb{Z}^n, F_I)$ being F_I a digital subset of \mathbb{Z}^n (in fact, $F_I \subset 4\mathbb{Z}^n$). The digital subset F_J of \mathbb{Z}^n encodes the cells of the associated cubical complex $Q(I)$ (blue is used for 0-cells, red for 1-cells, and green for 2-cells). Now, we “repair” F_J to obtain the digital subset F_L of \mathbb{Z}^n by “thickening” the critical points

of F_J . Then, we compute the simplicial complex $P_S(I)$ whose set of vertices is F_L , satisfying that there exists a face-connected path of n -simplices in $P_S(I)$ joining any two n -simplices incident to a common vertex in $P_S(I)$, that is, $P_S(I)$ is weakly well-composed (see [20])

with the property that if B is any open set of \mathbb{R}^n such that $x \in B$, then $B \cap A \neq \emptyset$ and $B \cap A^c \neq \emptyset$.

An open ball $\mathcal{B}_r^0(c)$ is *tangent* to ∂A at a point $x \in \partial A$ if $\partial A \cap \partial \mathcal{B}_r^0(c) = \{x\}$. An open ball $\mathcal{B}_r^0(c)$ is an *osculating open ball of radius r to ∂A at point $x \in \partial A$* if $\mathcal{B}_r^0(c)$ is tangent to ∂A at x and either $\mathcal{B}_r^0(c) \subseteq A^0$ or $\mathcal{B}_r^0(c) \subseteq (A^c)^0$, where A^0 is a maximal open subset of A , i.e., A without its boundary.

Definition 1 A set $A \subset \mathbb{R}^n$ is called *r -regular* if, for each point $x \in \partial A$, there exist two osculating open balls of radius r to ∂A at x such that one lies entirely in A and the other lies entirely in A^c . Examples illustrating 2D and 3D cases are shown in Fig. 3.

Note that the boundary of a 3D r -regular set is a 2D manifold surface. Any set S which is a translated and rotated version of the set $\frac{2r'}{\sqrt{3}}\mathbb{Z}^3$ is called a *cubic r' -grid* and its elements are called *sampling points*. Note that the distance $d(x, p)$ from each point $x \in \mathbb{R}^3$ to the nearest sampling point $s \in S$ is at most r' . The *voxel* $\mathcal{V}_S(s)$ of a sampling point $s \in S$ is its *Voronoi region* \mathbb{R}^3 : $\mathcal{V}_S(s) = \{x \in \mathbb{R}^3 \mid d(x, s) \leq d(x, q), \forall q \in S\}$, i.e., $\mathcal{V}_S(s)$ is the set of all points of \mathbb{R}^3 which are at least as close to s as to any other point in S . In particular, note that $\mathcal{V}_S(s)$ is a cube whose vertices lie on a sphere of radius r' and center s .

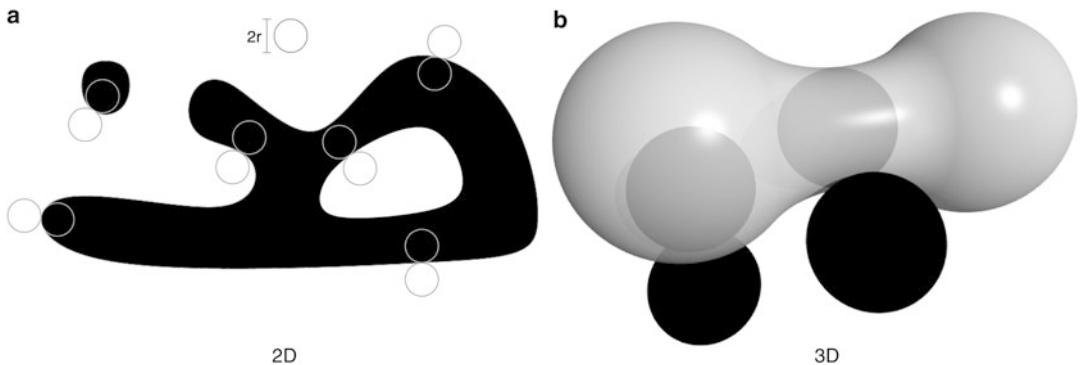

Definition 2 Let S be a cubic r' -grid, and let A be any subset of \mathbb{R}^3 . The union of all voxels

with sampling points lying in A is the *digital reconstruction of A with respect to S* , $\hat{A} = \bigcup_{s \in (S \cap A)} \mathcal{V}_S(s)$.

This method for reconstructing the object from the set of included sampling points is the 3D generalization of the 2D *Gauss digitization* (see [13]) which has been used by Gauss to compute the area of discs and which has also been used by [1] in his sampling theorem.

For any two points p and q of S , $\mathcal{V}_S(p) \cap \mathcal{V}_S(q)$ is either empty or a common vertex, edge, or face of both. If $\mathcal{V}_S(p) \cap \mathcal{V}_S(q)$ is a common face, edge, or vertex, then $\mathcal{V}_S(p)$ and $\mathcal{V}_S(q)$ are *face-adjacent*, *edge-adjacent*, or *vertex-adjacent*, respectively. Two voxels $\mathcal{V}_S(p)$ and $\mathcal{V}_S(q)$ of \hat{A} are *connected in \hat{A}* if there exists a sequence $\mathcal{V}_S(s_1), \dots, \mathcal{V}_S(s_k)$, with $k \in \mathbb{Z}$ and $k > 1$, such that $s_1 = p$, $s_k = q$, and $s_i \in A$ (or equivalently, $\mathcal{V}_S(s_i) \subset \hat{A}$), for each $i \in \{1, \dots, k\}$, and $\mathcal{V}_S(s_j)$ and $\mathcal{V}_S(s_{j+1})$ are face-adjacent, for each $j \in \{1, \dots, k-1\}$. A (connected) *component* of \hat{A} is a maximal set of connected voxels in \hat{A} .

Definition 3 Let S be a cubic r' -grid, and let T be any subset of S . Then $\bigcup_{t \in T} \mathcal{V}_S(t)$ is *well-composed* if $\partial(\bigcup_{t \in T} \mathcal{V}_S(t))$ is a surface in \mathbb{R}^3 or, equivalently, if for every point $x \in \partial(\bigcup_{t \in T} \mathcal{V}_S(t))$, there exists a positive number r such that the intersection of $\partial(\bigcup_{t \in T} \mathcal{V}_S(t))$ and $\mathcal{B}_r^0(x)$ is homeomorphic to the open unit disk in \mathbb{R}^2 , $\mathbb{D} = \{(x, y) \in \mathbb{R}^2 \mid x^2 + y^2 < 1\}$.

Digitization, Fig. 3 For each boundary point of a **2D/3D, r -regular** set exists an outside and an inside osculating open r -disc/ball

Well-composed digital reconstructions can be characterized by two local conditions depending only on voxels of points of S . Let s_1, \dots, s_4 be any four points of S such that $\bigcap_{i=1}^4 \mathcal{V}_S(s_i)$ is a common edge of $\mathcal{V}_S(s_1), \dots, \mathcal{V}_S(s_4)$. The set $\{\mathcal{V}_S(s_1), \dots, \mathcal{V}_S(s_4)\}$ is an instance of the *critical configuration (C1)* with respect to $\bigcup_{t \in T} \mathcal{V}_S(t)$ if two of these voxels are in $\bigcup_{t \in T} \mathcal{V}_S(t)$ and the other two are in $(\bigcup_{t \in T} \mathcal{V}_S(t))^c$ and the two voxels in $\bigcup_{t \in T} \mathcal{V}_S(t)$ (resp. $(\bigcup_{t \in T} \mathcal{V}_S(t))^c$) are edge-adjacent, as shown in Fig. 4a. Now, let s_1, \dots, s_8 be any eight points of S such that $\bigcap_{i=1}^8 \mathcal{V}_S(s_i)$ is a common vertex of $\mathcal{V}_S(s_1), \dots, \mathcal{V}_S(s_8)$. The set $\{\mathcal{V}_S(s_1), \dots, \mathcal{V}_S(s_4)\}$ is an instance of the *critical configuration (C2)* with respect to $\bigcup_{t \in T} \mathcal{V}_S(t)$ if two of these voxels are in $\bigcup_{t \in T} \mathcal{V}_S(t)$ (resp. $(\bigcup_{t \in T} \mathcal{V}_S(t))^c$) and the other six are in $(\bigcup_{t \in T} \mathcal{V}_S(t))^c$ (resp. $\bigcup_{t \in T} \mathcal{V}_S(t)$) and the two voxels in $\bigcup_{t \in T} \mathcal{V}_S(t)$ (resp. $(\bigcup_{t \in T} \mathcal{V}_S(t))^c$) are vertex-adjacent, as shown in Fig. 4b. The following theorem from [15] establishes an important equivalence between well-composedness and the (non)existence of critical configurations (C1) and (C2).

Theorem 1 ([15]) *Let S be a cubic $r0$ -grid and let T be any subset of S . Then, $\bigcup_{t \in T} \mathcal{V}_S(t)$ is well-composed if the set of voxels $\{\mathcal{V}(s) | s \in S\}$ does not contain any instance of the critical*

configuration (C1) nor any instance of the critical configuration (C2) with respect to $\bigcup_{t \in T} \mathcal{V}_S(t)$.

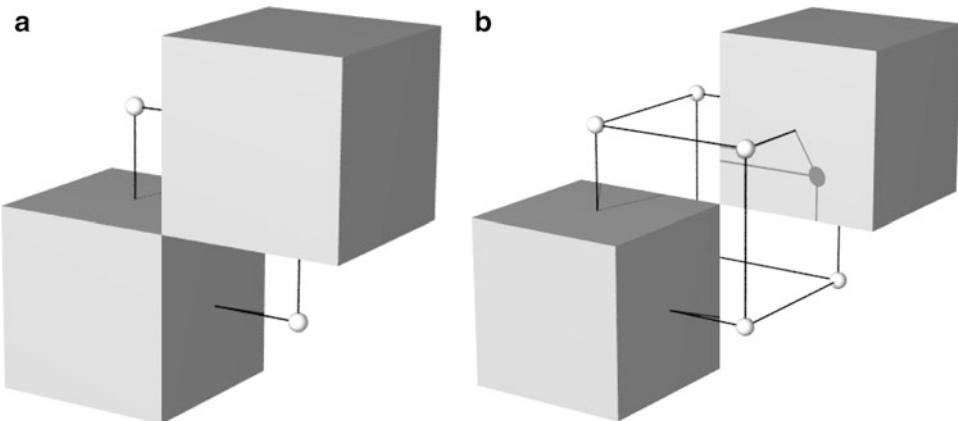

A simple consequence of the 2D digitization theorem by [1] is that the reconstruction of an r' -regular set is well-composed. The main difficulty of 3D digitization as compared to 2D lies in the fact that digital reconstruction \hat{A} of A with respect to S is not guaranteed to be well-composed. An example is provided in Fig. 5. Therefore, it is necessary to repair \hat{A} in order to ensure the topological equivalence between A and repaired \hat{A} . The first topology-preserving repairing method has been proposed in [7], where also the following theorem is proven. It is an interesting observation that it took 25 years to obtain this 3D theorem.

D

Theorem 2 ([7]) *If A is an r -regular object and S is a cubic r' -grid with $2r' < r$, then the result of the topology-preserving repairing method of the reconstruction \hat{A} is r -homeomorphic to A .*

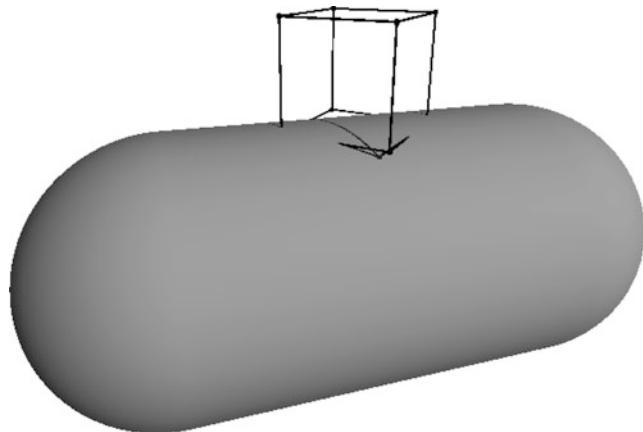

Application

A complete understanding of the loss of information due to the digitization process is fundamental for the justification of any computer vision application. If the relevant information is not

Digitization, Fig. 4 (a) Critical configuration (C1). (b) Critical configuration (C2). For the sake of clarity, only the voxels of foreground or background points are shown

Digitization, Fig. 5 The surface of an object only needs to have an arbitrarily small but nonzero curvature in order to make occurrences of the critical configuration (C1) possible in the digital reconstruction

contained in the digital image, there is no way to reconstruct it without using context knowledge. Thus, whenever one needs to have guarantees for the correct behavior of some computer vision algorithm, one has to be aware of what happens during digitization. This entry gives an exemplary insight to the topic, the related problems, and the way to solve them.

composed images own in \mathbb{Z}^n that reflect the continuous world is a promising line of research, such as the link between critical points and Morse theory [21] or topological persistence [22] and tree of shapes. A more exhaustive list can be consulted in [19, Section 10].

Open Problems

The analysis of the effect of digitization to the information being extractable from an image is a challenging research area. The newest results approximate real acquisition processes and thus give direct implications for many computer vision algorithms which rely on precise information of the structures being approximated by the digital image. However, in reality the digitization process is still more complicated than the models which are used for topological or geometric sampling theorems. The goal is to derive guarantees for digitization models approximating real digitization processes.

For the case $n \geq 3$, the equivalences between the different definitions of well-composedness (EWC, DWC, AWC, EWC, AGWC) is an open problem together with a general method for repairing non-well-composed digital sets in \mathbb{Z}^n . Besides, the study of which properties well-

Definition

Dimensionality reduction is the process of reducing the dimension of the vector space spanned by feature vectors (pattern vectors). Various kinds of reduction can be achieved by defining a map from the original space into a dimensionality-reduced space.

Background

The feature space, i.e., the vector space spanned by feature vectors (pattern vectors) defined on d -dimensional space, can be transformed into a vector space of lower-dimension $d' (< d)$ spanned by d' -dimensional feature vectors through linear or nonlinear transformation. This transformation allows feature vectors to be represented by lower-dimensional vectors, and various kinds of vector operations and statistical analysis, such as multivariate analysis, machine learning, clustering, and classification, become less expensive to perform. Moreover, it tackles the “curse of dimensionality,” the various problems created by dealing with data of high dimensionality.

Theory and Application

The most common linear approaches for dimensionality reduction are principal component analysis (PCA) and linear discriminant analysis (LDA). PCA, LDA, and related techniques have been used for pattern recognition and computer vision. It is generally considered that PCA offers reduction for information representation, while LDA offers reduction for classification (Fig. 1).

PCA finds principal axes so as to maximize the variance of the pattern vectors' distribution in a dimensionality-reduced space. It is theoretically identical to a discrete and finite case of Karhunen-Loeve transform. In PCA, d' principal axes are obtained as eigenvectors $\Phi_1, \dots, \Phi_{d'}$, which are eigenvectors corresponding to the d' largest eigenvalues of Σ , $\lambda_1, \dots, \lambda_{d'}$. Σ is the covariance matrix of feature vectors and is defined as

$$\Sigma = \frac{1}{n} \sum_{\mathbf{x}} (\mathbf{x} - \mathbf{m})(\mathbf{x} - \mathbf{m})^T \quad (1)$$

where \mathbf{x} are d -dimensional feature vectors, n is the number of feature vectors, and \mathbf{m} is the mean of feature vectors (i.e., $\mathbf{m} = \frac{1}{n} \sum \mathbf{x}$).

LDA realizes a linear transform into $(c - 1)$ -dimensional space so as to maximize the between-class distance, which is the distance between the pattern distribution of each class; c is the number of classes (categories). The bases of the transformed space are obtained as the eigenvectors of $\Sigma_W^{-1} \Sigma_B$, where Σ_W is within-class covariance matrix and Σ_B is the between-class covariance matrix. They are written as

$$\Sigma_W = \sum_{i=1}^c \left(\frac{1}{n} \sum_{\mathbf{x} \in \mathcal{X}_i} (\mathbf{x} - \mathbf{m}_i)(\mathbf{x} - \mathbf{m}_i)^T \right) \quad (2)$$

$$\Sigma_B = \sum_{i=1}^c \frac{n_i}{n} (\mathbf{m}_i - \mathbf{m})(\mathbf{m}_i - \mathbf{m})^T \quad (3)$$

where \mathbf{m}_i is the mean of the feature vectors that belong to i th class \mathcal{X}_i and \mathbf{m} represents the

total mean of all feature vectors. As the rank of matrix Σ_B is $(c - 1)$, the dimension of the space determined by LDA is not more than $(c - 1)$.

PCA- and LDA-based techniques such as class-featuring information compression (CLAFIC) [17] and learning subspace method (LSM) [10] have been studied and widely applied to various pattern recognition tasks like character recognition and phoneme classification. More recently, they have been applied to more complicated tasks, such as face recognition [2, 16] and 3D object recognition [9].

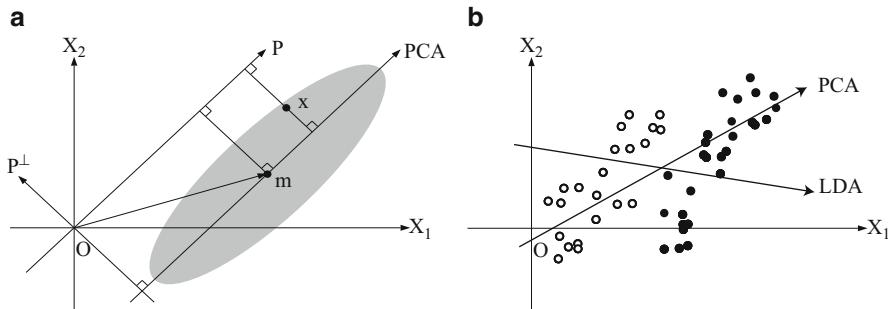

Multidimensional scaling (MDS) is another classic technique for reconstructing a subspace to represent pattern distribution. Given only the dissimilarities (distances) between any pairs of patterns (objects, samples), MDS outputs basis vectors that minimize the distance errors in the subspace spanned by the bases. Distance matrix \mathbf{D} , whose (i, j) element is the distance between \mathbf{x}_i and \mathbf{x}_j , is transformed by the Young-Householder transformation into matrix \mathbf{H} as follows:

$$\mathbf{H} = -\frac{1}{2} \mathbf{J}_n \mathbf{D} \mathbf{J}_n \quad (4)$$

$$\mathbf{J}_n = \mathbf{I}_n - \frac{1}{n} \mathbf{1}_n \quad (5)$$

where \mathbf{I}_n denotes an n -dimensional identity matrix and $\mathbf{1}_n$ denotes a square matrix, all of whose elements are 1. The principal axes minimizing the distance errors are obtained as the eigenvectors of matrix \mathbf{H} .

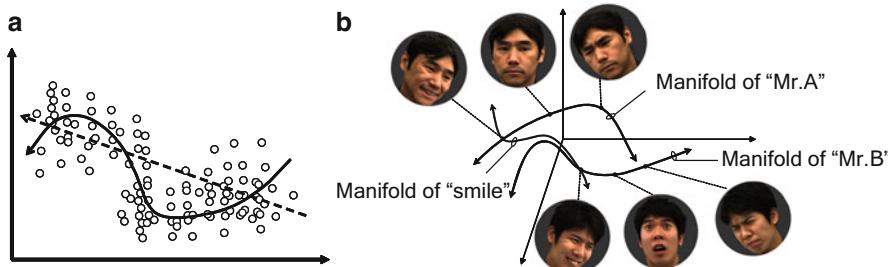

Nonlinear dimensionality reduction is a powerful tool for pattern recognition and computer vision despite of its higher computational cost than linear methods. Conventional linear dimensionality reduction methods have been extended to nonlinear equivalents through the kernel technique, i.e., kernel PCA [14] and kernel version of LDA [1, 8]. By replacing the inner products of feature vectors $(\mathbf{x}_i, \mathbf{x}_j)$ to $k(\mathbf{x}_i, \mathbf{x}_j)$ in the procedure of linear methods, where k is any kernel function, various nonlinear transforms can be achieved depending on the kernel function selected and its parameters.

dimensionality reduction (b) Various embedded manifolds in a face space

Many novel techniques of nonlinear dimensionality reduction have been proposed; they are collectively called manifold learning [4, 11]. Pioneering works of manifold learning are Isomap [15] and locally linear embedding (LLE) [12, 13] (Fig. 2).

Isomap is a manifold learning algorithm that preserves the geodesic distance between all feature vectors. The distance is approximately obtained as the shortest path distance by tracking nearest neighbors. In Isomap, these pair-wise geodesic distances between feature vectors are applied to classic MDS (Fig. 3).

LLE, on the other hand, targets low-dimensional manifolds that preserve local geometric relationships between neighbors, so as to minimize cost function $E(\mathbf{w})$,

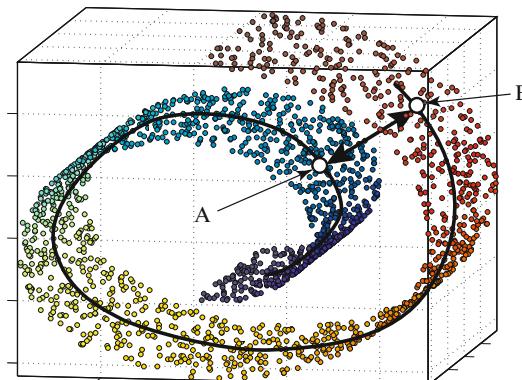

$$E(\mathbf{w}) = \sum_i \left(\mathbf{x}_i - \sum_j \mathbf{w}_{ij} \mathbf{x}_j \right)^2 \quad (6)$$

where \mathbf{x}_{ij} denote neighbors of \mathbf{x}_i and v_{wj} denote the linear weights that satisfy $\sum_j v_{wj} = 1$. Each point \mathbf{x}_i in the d -dimensional space is mapped onto point \mathbf{y}_i in the d' -dimensional space by minimizing the cost function $C(\mathbf{y})$,

$$C(\mathbf{y}) = \sum_i \left(\mathbf{y}_i - \sum_j \mathbf{w}_{ij} \mathbf{y}_j \right)^2 \quad (7)$$

where \mathbf{w}_{ij} are the weights that minimize $E(\mathbf{w})$. Isomap, LLE, and graph Laplacian [3] are variations of kernel PCA with special kernel functions [6].

Another nonlinear method is the feed-forward neural network trained to approximate the identity function [5, 7]. When the trained network has fewer hidden layer units than input and output layer units, the output signals of the hidden layer units can be considered as an encoded vector of the original input pattern vector.

Definition

Discriminative random fields (DRFs) are probabilistic discriminative graphical models for classification that allow contextual interactions among labels as well as the observed data using arbitrary discriminative classifiers.

Background

Natural image data shows significant dependencies that should be modeled appropriately to achieve good classification of image entities such as pixels, regions, objects, or the entire image itself. Such dependencies are commonly referred to as *context* in vision. For example, due to local smoothness of natural images, neighboring pixels tend to have similar labels (except at the discontinuities). Different semantic regions in a scene follow plausible spatial configurations, for example, sky tends to occur above water or vegetation. For parts-based object recognition, different parts of an object such as handle, keypad, and front panel in a phone are related to each other through geometric constraints. In fact, the contextual interactions for object recognition are not limited to the parts of an object. These may include interactions among various objects themselves. For example, the presence of a monitor screen increases the probability of having a keyboard or a mouse nearby. The challenge is how to model these different types of context, which include complex dependencies in the observed image data as well as the labels, in a principled manner. Discriminative graphical models provide a solid platform to achieve that.

Traditional generative graphical models, that is, Markov random fields (MRFs) suffer from three main problems, which are overcome by DRFs: First, for computational tractability, the observations are assumed to be conditionally independent in MRFs. This assumption is too restrictive for many natural image analysis applications. Second, interaction among labels in MRFs arises from prior over labeling and hence do not depend on the observed data. This

prohibits one from modeling data-dependent interactions in labels that are necessary for a variety of tasks. For example, while implementing local smoothness of labels in image segmentation, it may be desirable to use observed data to modulate the smoothness according to the image intensity gradients. Further, in parts-based object detection to model interactions among object parts, one needs observed data to enforce geometric constraints. DRFs allow interactions among labels based on unrestricted use of observations as necessary. This step is crucial to develop models that can incorporate interactions of different types within the same framework.

Finally, MRFs are used in a probabilistic generative framework that models the joint probability of the observed data and the corresponding labels. However, for classification purposes, one needs to estimate the posterior over labels given the observations, that is, $P(x|y)$, where y is observed data and x are corresponding labels. In a generative MRF framework, one expends efforts to model the joint distribution $p(x|y)$, which involves implicit modeling of the observations. In a discriminative framework, one models the distribution $P(x|y)$ directly. A major advantage of doing this is that the true underlying generative model may be quite complex even though the class posterior is simple. This means that the generative approach may spend a lot of resources on modeling the generative models which are not particularly relevant to the task of inferring the class labels. Moreover, learning the class density models may become even harder when the training data is limited. The discriminative approach saves one from making simplistic assumptions about the data.

Discriminative Random Field (DRF)

Discriminative random fields (DRFs) are discriminative graphical models based on conditional random fields (CRFs), originally proposed by Lafferty et al. [1] in the context of segmentation and labeling of 1D text sequences. CRFs are discriminative models that directly model the

conditional distribution over labels, that is, $P(\mathbf{x}|\mathbf{y})$ as a Markov random field. This approach allows one to capture arbitrary dependencies between the observations without resorting to any model approximations. DRFs are 2D versions of 1D CRFs, which allow the use of arbitrary discriminative classifiers to model different types of interactions in labels and data, leading to more flexible and powerful generalization of CRFs. These were introduced in vision by Kumar and Hebert [2, 3].

Let the observed data from an input image be given by $\mathbf{y} = \{\mathbf{y}_i\}_{i \in S}$ where \mathbf{y}_i is the data from i th site and $\mathbf{y}_i \in \Re^c$. The corresponding labels at the image sites are given by $\mathbf{x} = \{x_i\}_{i \in S}$. In a binary classification problem, $x_i \in \{-1, 1\}$. It is easy to extend the formulation to multiclass labeling problems as mentioned later. The random variables \mathbf{x} and \mathbf{y} are jointly distributed, but in a discriminative framework, a conditional model $P(\mathbf{x}|\mathbf{y})$ is constructed from the observations and labels, and the marginal $p(\mathbf{y})$ is not modeled

explicitly. DRFs follow the definition of CRFs given by Lafferty et al. [1].

Definition 1 CRF: Let $G = (S, E)$ be a graph such that \mathbf{x} is indexed by the vertices of G . Then (\mathbf{x}, \mathbf{y}) is said to be a conditional random field if, when conditioned on \mathbf{y} , the random variables x_i obey the Markov property with respect to the graph: $P(x_i|\mathbf{y}, \mathbf{x}_{S-\{i\}}) = P(x_i|\mathbf{y}, \mathbf{x}_{\mathcal{N}_i})$, where $S - \{i\}$ is the set of all the nodes in the graph except the node i , \mathcal{N}_i is the set of neighbors of the node i in G , and \mathbf{x}_{Ω} represents the set of labels at the nodes in set Ω .

Thus, a DRF is a random field globally conditioned on the observations \mathbf{y} . The condition of positivity requiring $P(\mathbf{x}|\mathbf{y}) > 0$, $\forall \mathbf{x}$ has been assumed implicitly. Using the Hammersley-Clifford theorem [4] and assuming only up to pairwise clique potentials to be nonzero, the conditional distribution over all the labels \mathbf{x} given the observations \mathbf{y} in a DRF can be written as

$$P(\mathbf{x}|\mathbf{y}) = \frac{1}{Z} \exp \left(\sum_{i \in S} A_i(x_i, \mathbf{y}) + \sum_{i \in S} \sum_{j \in \mathcal{N}_i} I_{ij}(x_i, x_j, \mathbf{y}) \right), \quad (1)$$

where Z is a normalizing constant known as the partition function, and $-A_i$ and $-I_{ij}$ are the unary and pairwise potentials, respectively. With a slight abuse of notation, refer A_i as the *association potential* and I_{ij} as the *interaction potential*.

Assuming the random field given in Eq. (1) to be homogeneous, the functional forms of A_i and I_{ij} are independent of the location i . Furthermore, assuming the field to be isotropic implies that

the label interactions are nondirectional. In other words, I_{ij} is independent of the relative locations of sites i and j . Thus, subsequently, one can drop the subscripts and simply use the notation A and I to denote the two potentials. In fact, the assumption of isotropy can be easily relaxed at the cost of a few additional parameters. Henceforth, consider the DRF model of the following form:

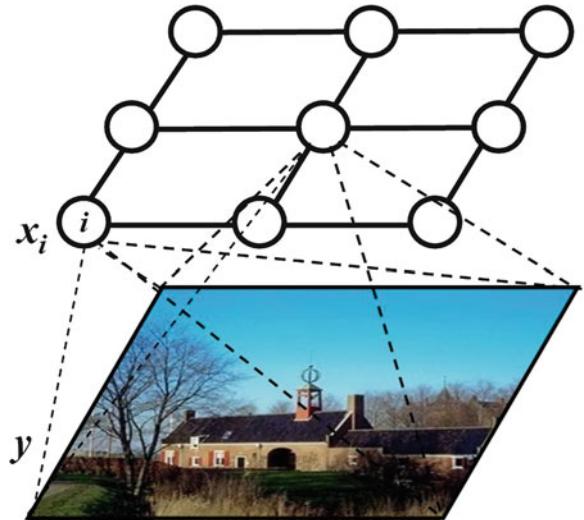

$$P(\mathbf{x}|\mathbf{y}) = \frac{1}{Z} \exp \left(\sum_{i \in S} A(x_i, \mathbf{y}) + \sum_{i \in S} \sum_{j \in \mathcal{N}_i} I(x_i, x_j, \mathbf{y}) \right). \quad (2)$$

Figure 1 illustrates a typical DRF for an example image analysis task of man-made structure detection. Given an input image \mathbf{y} shown in the

bottom layer, suppose the goal is to label each image site (in this case a 16×16 image block) whether it contains a man-made structure or not.

Discriminative Random Fields, Fig. 1

An illustration of a typical DRF for an example task of man-made structure detection in natural images. The aim is to label each site, that is, each 16×16 image block whether it is a man-made structure or not. The top layer represents the labels on all the image sites. Note that each site i can potentially use features from the whole image y unlike the traditional MRFs

D

The top layer represents the labels \mathbf{x} on all the image sites. Note that each site i can potentially use features from the whole image \mathbf{y} unlike the traditional MRFs. In addition, DRFs allow to use image data to model interactions between two neighboring sites i and j . The following sections describe how the unary and the pairwise potentials are designed in DRFs.

Association Potential

In the DRF framework, the association potential, $A(x_i, \mathbf{y})$, can be seen as a measure of how likely a site i will take label x_i given image \mathbf{y} , ignoring the effects of other sites in the image (Fig. 2). Suppose $f(\cdot)$ is a function that maps an arbitrary patch in an image to a feature vector such that $f : \mathcal{Y}_p \rightarrow \mathbb{R}^l$. Here, \mathcal{Y}_p is the set of all possible patches in all possible images. Let $\omega_i(\mathbf{y})$ be an arbitrary patch in the neighborhood of site i in image \mathbf{y} from which a feature vector $f(\omega_i(\mathbf{y}))$ is extracted. Note that the neighborhood used for the patch $\omega_i(\mathbf{y})$ need not be the same as the label neighborhood \mathcal{N}_i . Indeed, $\omega_i(\mathbf{y})$ can potentially be the whole image itself. For clarity, denote the feature vector $f(\omega_i(\mathbf{y}))$ at each site i by $f_i(\mathbf{y})$. The subscript i indicates the difference just in the feature vectors at different sites, *not* in the functional form of $f(\cdot)$. Then, $A(x_i, \mathbf{y})$ is modeled using a local discriminative model that outputs the association of the site i with class x_i as

$$A(x_i, \mathbf{y}) = \log P'(x_i | f_i(\mathbf{y})), \quad (3)$$

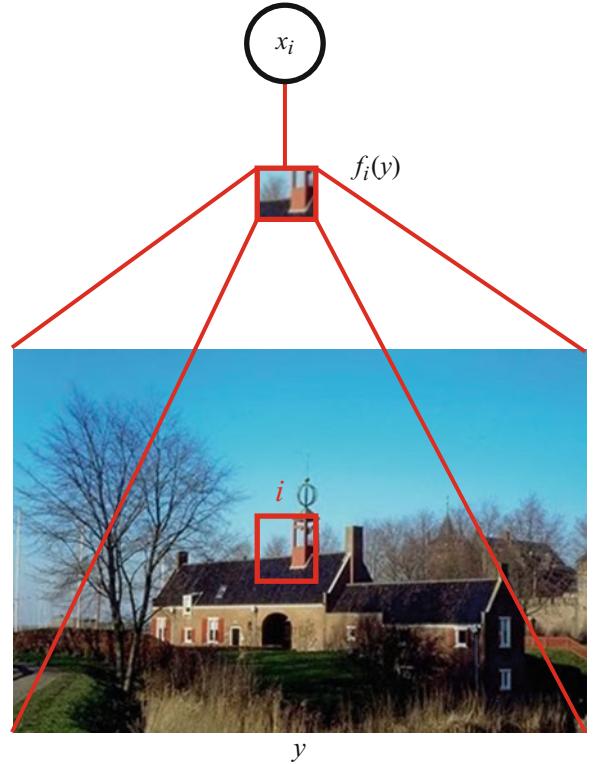

where $P'(x_i | f_i(\mathbf{y}))$ is the local class conditional at site i . This form allows one to use an arbitrary domain-specific probabilistic discriminative classifier for a given task. This can be seen as a parallel to the traditional MRF models where one can use arbitrary local generative classifier to model the unary potential. One possible choice of $P'(\cdot)$ is generalized linear models (GLM), which are used extensively in statistics to model the class posteriors. Logistic function is a commonly used link in GLMs, although other choices such as probit link exist. Using a logistic function, the local class conditional can be written as

$$\begin{aligned} P'(x_i = 1 | f_i(\mathbf{y})) &= \frac{1}{1 + e^{-(w_0 + w_1^T f_i(\mathbf{y}))}} \\ &= \sigma(w_0 + w_1^T f_i(\mathbf{y})), \end{aligned} \quad (4)$$

where $\mathbf{w} = \{w_0, w_1\}$ are the model parameters. This form of $P'(\cdot)$ will yield a linear decision boundary in the feature space spanned by vectors $f_i(\mathbf{y})$. To extend the logistic model to induce a nonlinear decision boundary, a transformed feature vector at each site i can be defined as $\mathbf{h}_i(\mathbf{y}) = [1, \phi_1(f_i(\mathbf{y})), \dots, \phi_R(f_i(\mathbf{y}))]^T$ where $\phi_k(\cdot)$ are arbitrary nonlinear functions. These functions can be seen as explicit kernel mapping of the

Discriminative Random Fields, Fig. 2

Given a feature vector $f_i(y)$ at site i , the association potential in DRFs can be seen as a measure of how likely the site i will take label x_i , ignoring the effects of other sites in the image. Note that the feature vector $f_i(y)$ can be constructed by pooling arbitrarily complex dependencies in the observed data y .

original feature vector into a high dimensional space. The first element of the transformed vector is kept as 1 to accommodate the bias parameter w_0 . Further, since $x_i \in \{-1, 1\}$, the probability in Eq. (4) can be compactly expressed as

$$P'(x_i | y) = \sigma(x_i \mathbf{w}^T \mathbf{h}_i(y)). \quad (5)$$

Finally, for this choice of $P'(\cdot)$, the association potential can be written as,

$$A(x_i, y) = \log(\sigma(x_i \mathbf{w}^T \mathbf{h}_i(y))) \quad (6)$$

This transformation ensures that the DRF is equivalent to a logistic classifier if the interaction potential in Eq. (2) is set to zero. Besides GLMs, discriminative classifiers based on SVM, neural network, and boosting have been successfully used in modeling association potential in the literature. Note that in Eq. (6), the transformed feature vector at each site i , that is, $\mathbf{h}_i(y)$ is a function of the whole set of observations y . This allows one

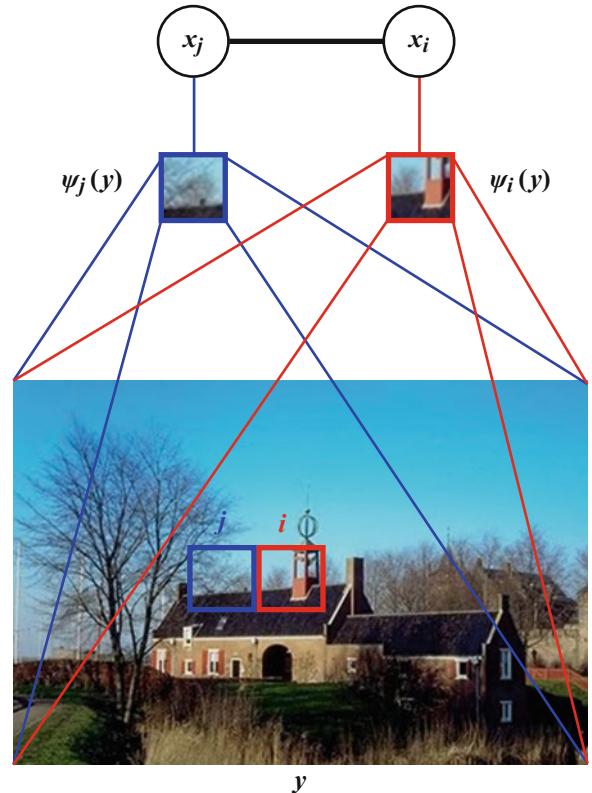

to pool arbitrarily complex dependencies in the observed data for the purpose of classification. On the contrary, the assumption of conditional independence of the data in the traditional MRF framework allows one to use data only from a particular site, that is, y_i , to design the log-density, which acts as the association potential.

Interaction Potential

In the DRF framework, the interaction potential can be seen as a measure of how the labels at neighboring sites i and j interact given the observed image y (Fig. 3). In contrast to generative MRFs, the interaction potential in DRFs is a function of observations y . Suppose $\psi(\cdot)$ is a function that maps an arbitrary patch in an image to a feature vector such that $\mathcal{Y}_p \rightarrow \Re^V$. Let $\Omega_i(y)$ be an arbitrary patch in the neighborhood of site i in image y from which a feature vector $\psi(\Omega_i(y))$ is extracted. Note that the neighborhood used for the patch $\Omega_i(y)$ need not be the same as the label neighborhood \mathcal{N}_i . For clarity, denote the feature vector $\psi(\Omega_i(y))$ at site i by $\psi_i(y)$.

Discriminative Random Fields, Fig. 3

Fig. 3 Given feature vectors $\psi_i(y)$ and $\psi_j(y)$ at two neighboring sites i and j , respectively, the interaction potential can be seen as a measure of how the labels at sites i and j influence each other. Note that such interaction in labels is dependent on the observed image data y , unlike the traditional generative MRFs

D

Similarly, denote the feature vector at site j by $\psi_j(y)$. Again, to emphasize, the subscripts i and j indicate the difference just in the feature vectors at different sites, *not* in the functional form of $\psi(\cdot)$. Given the features at two different sites, the basic idea is to learn a pairwise discriminative model $P''(x_i = x_j | \psi_i(y), \psi_j(y))$. Note that by choosing the function ψ_i to be different from f_i , used in Eq. (4), information different from f_i can be used to model the relations between pairs of sites.

For a pair of sites (i, j) , let $\mu_{ij}(\psi_i(y), \psi_j(y))$ be a new feature vector such that $\mu_{ij} : \Re^V \times \Re^V \rightarrow \Re^q$. Denoting this feature vector as $\mu_{ij}(y)$ for simplification, the interaction potential is modeled as

$$I(x_i, x_j, y) = x_i x_j \mathbf{v}^T \mu_{ij}(y), \quad (7)$$

where \mathbf{v} are the model parameters. Note that the first component of $\mu_{ij}(y)$ is fixed to be 1 to accommodate the bias parameter. There are two interesting properties of the interaction potential

given in Eq. (7). First, if the association potential at each site and the interaction potentials for all the pairwise cliques except the pair (i, j) are set to zero in Eq. (2), the DRF acts as a logistic classifier which yields the probability of the site pair to have the same labels given the observed data. Of course, one can generalize the form in Eq. (7) as

$$I(x_i, x_j, y) = \log P''(x_i, x_j | \psi_i(y), \psi_j(y)), \quad (8)$$

similar to the association potential and can use arbitrary pairwise discriminative classifier to define this term. The second property of the interaction potential form given in Eq. (7) is that it generalizes the Ising model. The original Ising form is recovered if all the components of vector \mathbf{v} other than the bias parameter are set to zero in Eq. (7). A geometric interpretation of interaction potential is that it partitions the space induced by the relational features $\mu_{ij}(y)$

between the pairs that have the same labels and the ones that have different labels. Hence, Eq. (7) acts as a data-dependent discontinuity adaptive model that will moderate smoothing when the data from the two sites is “different.” The data-dependent smoothing can especially be useful to absorb the errors in modeling the association potential. Anisotropy can be easily included in the DRF model by parameterizing the interaction potentials of different directional pairwise cliques with different sets of parameters \mathbf{v} .

Parameter Learning and Inference

For 1D sequential CRFs proposed by Lafferty et al. [1], exact maximum likelihood parameter learning is feasible because the induced graph does not contain loops. However, in typical DRFs, the underlying graph contains loops, and it is usually infeasible to exactly maximize the likelihood with respect to the parameters. Therefore, a critical issue in applying DRFs to image-based applications is the design of effective parameter learning techniques that can operate on arbitrary graphs.

Maximum Likelihood Parameter Learning

Let θ be the set of unknown DRF parameters where $\theta = \{\mathbf{w}, \mathbf{v}\}$. Given M i.i.d. labeled training images, the maximum likelihood estimates of the parameters are given by maximizing the log-likelihood $l(\theta) = \sum_{m=1}^M \log P(\mathbf{x}^m | \mathbf{y}^m, \theta)$, that is,

$$\hat{\theta} = \operatorname{argmax}_{\theta} \sum_{m=1}^M \left\{ \sum_{i \in S^m} \log \sigma(x_i^m \mathbf{w}^T \mathbf{h}_i(\mathbf{y}^m)) + \sum_{i \in S^m} \sum_{j \in \mathcal{N}_i} x_i^m x_j^m \mathbf{v}^T \boldsymbol{\mu}_{ij}(\mathbf{y}^m) - \log Z^m \right\}, \quad (9)$$

where the partition function for the m th image is

$$Z^m = \sum_{\mathbf{x}} \exp \left\{ \sum_{i \in S^m} \log \sigma(x_i \mathbf{w}^T \mathbf{h}_i(\mathbf{y}^m)) + \sum_{i \in S^m} \sum_{j \in \mathcal{N}_i} x_i x_j \mathbf{v}^T \boldsymbol{\mu}_{ij}(\mathbf{y}^m) \right\}.$$

Note that Z^m is a function of the parameters θ and the observed data \mathbf{y}^m . For learning the parameters using gradient ascent, the derivatives of the log-likelihood are

$$\frac{\partial l(\theta)}{\partial \mathbf{w}} = \frac{1}{2} \sum_m \sum_{i \in S^m} (x_i^m - \langle x_i \rangle_{\theta; \mathbf{y}^m}) \mathbf{h}_i(\mathbf{y}^m), \quad (10)$$

$$\begin{aligned} \frac{\partial l(\theta)}{\partial \mathbf{v}} \\ = \sum_m \sum_{i \in S^m} \sum_{j \in \mathcal{N}_i} (x_i^m x_j^m - \langle x_i x_j \rangle_{\theta; \mathbf{y}^m}) \boldsymbol{\mu}_{ij}(\mathbf{y}^m). \end{aligned} \quad (11)$$

Here, $\langle \cdot \rangle_{\theta; \mathbf{y}^m}$ denotes expectation with $P(\mathbf{x} | \mathbf{y}^m, \theta)$. Ignoring $\boldsymbol{\mu}_{ij}(\mathbf{y}^m)$, gradient ascent with Eq. (11) resembles the problem of learning in Boltzmann machines.

For arbitrary graphs with loops, the expectations in Eqs. (10) and (11) cannot be computed exactly due to the combinatorial size of the label space. Sampling procedures such as Markov Chain Monte Carlo (MCMC) can be used to approximate the true expectations. Unfortunately, MCMC techniques have two main problems: a long “burn-in” period (which makes them slow) and high variance in estimates. Although several techniques have been suggested to approximate the expectations, two popular methods are described below (see [5] for other choices and a detailed comparison).

Pseudo-marginal Approximation (PMA)

It is easy to see if true marginal distributions $P_i(x_i | \mathbf{y}, \theta)$ at each site, i , and $P_{ij}(x_i, x_j | \mathbf{y}, \theta)$ at each pair of sites i and $j \in \mathcal{N}_i$ are known, one can compute exact expectations as

$$\begin{aligned} \langle x_i \rangle_{\theta; \mathbf{y}} &= \sum_{x_i} x_i P_i(x_i | \mathbf{y}, \theta) \text{ and } \langle x_i x_j \rangle_{\theta; \mathbf{y}} \\ &= \sum_{x_i, x_j} x_i x_j P_{ij}(x_i, x_j | \mathbf{y}, \theta). \end{aligned}$$

Since computing exact marginal distributions is in general infeasible, a standard approach is to replace the actual marginals by pseudo-marginals. For instance, one can use loopy belief propagation (BP) to get these pseudo-marginals. It has been shown in practice that for many applications, loopy BP provides good estimates of the marginals.

Saddle Point Approximation (SPA)

In saddle point approximation (SPA), one makes a discrete approximation of the expectations by directly using best estimates of labels at a given setting of parameters. This is equivalent to approximating the partition function (Z) such that the summation over all the label configurations \mathbf{x} in Z is replaced by the largest term in the sum, which occurs at the most probable label configuration. In other words, if

$$\hat{\mathbf{x}} = \arg \max_{\mathbf{x}} P(\mathbf{x}|\mathbf{y}, \theta),$$

then according to SPA,

$$Z \approx \exp \left\{ \sum_{i \in S} \log \sigma(\hat{x}_i \mathbf{w}^T \mathbf{h}_i(\mathbf{y})) + \sum_{i \in S} \sum_{j \in \mathcal{N}_i} \hat{x}_i \hat{x}_j \mathbf{v}^T \boldsymbol{\mu}_{ij}(\mathbf{y}) \right\}.$$

This leads to a very simple approximation to the expectation, that is, $\langle x_i \rangle_{\theta; \mathbf{y}} \approx \hat{x}_i$. Further assuming a mean-field type decoupling, that is, $\langle x_i x_j \rangle_{\theta; \mathbf{y}} = \langle x_i \rangle_{\theta; \mathbf{y}} \langle x_j \rangle_{\theta; \mathbf{y}}$, it also follows that $\langle x_i x_j \rangle_{\theta; \mathbf{y}} \approx \hat{x}_i \hat{x}_j$. Readers familiar with perceptron learning rules can readily see that with such an approximation, the updates in Eq. (10) are very similar to perceptron updates.

However, this discrete approximation raises a critical question: Will the gradient ascent of the likelihood with such gradients converge? It has been shown empirically that while the approximate gradient ascent is not strictly convergent in general, it is weakly convergent in that it oscillates within a set of good parameters or converges to a good parameter with isolated large

deviations. In fact, one can show that this weak-convergence behavior is tied to the empirical error of the model [5]. To pick a good parameter setting, one can use any of the popular heuristics used for perceptron learning with inseparable data. For instance, one can let the algorithm run up to some fixed number of iterations and pick the parameter setting that minimizes the empirical error. Even though lack of strict convergence can be seen as a drawback of SPA, the main advantage of these methods is very fast learning of parameters with performance similar to or better than pseudo-marginal methods.

D

Inference

Given a new test image \mathbf{y} , the problem of inference is to find the optimal labels \mathbf{x} over the image sites, where optimality is defined with respect to a given cost function. Maximum a posteriori (MAP) solution is a widely used estimate that is optimal with respect to the zero-one cost function defined as

$$C(\mathbf{x}, \mathbf{x}^*) = 1 - \delta(\mathbf{x} - \mathbf{x}^*), \quad (12)$$

where \mathbf{x}^* is the true label configuration, and $\delta(\mathbf{x} - \mathbf{x}^*)$ is 1 if $\mathbf{x} = \mathbf{x}^*$, and 0 otherwise. The MAP solution is defined as

$$\hat{\mathbf{x}} = \arg \max_{\mathbf{x}} P(\mathbf{x}|\mathbf{y}, \theta).$$

For binary classifications, the MAP estimate can be computed exactly for an undirected graph using the max-flow/min-cut type of algorithms if the probability distribution meets certain conditions [6]. For the DRF model, since max-flow algorithms do not allow negative interaction between the sites, the data-dependent smoothing for each clique is set to be $\mathbf{v}^T \boldsymbol{\mu}_{ij}(\mathbf{y}) = \max \{0, \mathbf{v}^T \boldsymbol{\mu}_{ij}(\mathbf{y})\}$, yielding an approximate MAP solution.

An alternative to the MAP solution is the maximum posterior marginal (MPM) solution which is optimal for the sitewise zero-one cost function defined as

$$C(\mathbf{x}, \mathbf{x}^*) = \sum_{i \in S} (1 - \delta(\mathbf{x}_i - \mathbf{x}_i^*)), \quad (13)$$

where x_i^* is the true label at the i th site. The MPM solution at each site is defined as

$$\begin{aligned} \hat{\mathbf{x}}_i &= \arg \max_{\mathbf{x}_i} P_i(\mathbf{x}_i | \mathbf{y}, \theta), \quad \text{where } P_i(\mathbf{x}_i | \mathbf{y}, \theta) \\ &= \sum_{x - x_i} P(x | \mathbf{y}, \theta), \end{aligned}$$

and $x - x_i$ denotes all the node variables except for node i . The MPM computation requires marginalization over a large number of variables which is generally NP-hard. However, as discussed before, one can use loopy BP to obtain an estimate of the MPM solution.

Application

DRFs and related models have been applied to a wide variety of problems in computer vision to incorporate context in, for example, image denoising, scene segmentation and region classification, object recognition, and video tagging.

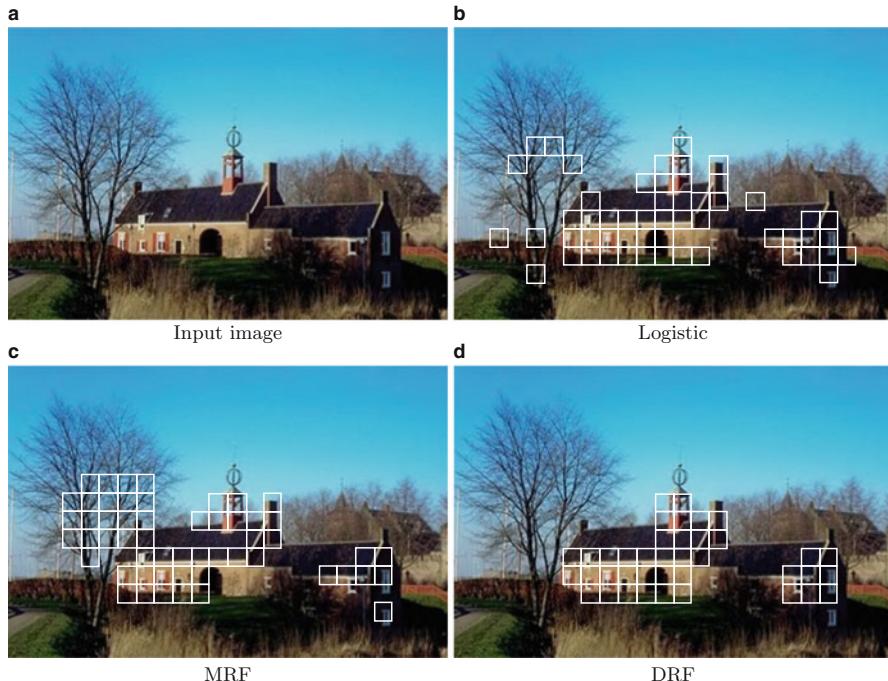

Experimental Results

Here is an application of binary DRFs to the problem of man-made structure detection in natural scenes. It is a difficult problem due to presence of significant clutter and wide variability in the appearance of man-made structure as well as the background. The training and the test set contained 108 and 129 images, respectively, from the Corel image database. Each image is divided into nonoverlapping 16×16 pixels blocks. Each block forms a site in the graph. The whole training set contained 36,269 blocks from the *non-structured* class and 3,004 blocks from the *structured* class. Histograms over gradient orientations were used to extract heaved central-shift

moment-based 14-dimensional feature vector. In the unary classifier, an explicit quadratic kernel is used to map the feature vector into a 119-dimensional space. The pairwise data vector is obtained by concatenating the unary vectors at two sites. The parameters of the DRF model were learned using the maximum likelihood framework as described before.

For an input test image given in Fig. 4a, the *structure* detection results from three methods are shown in Fig. 4. The blocks identified as *structured* have been shown enclosed within an artificial boundary. It can be noted that for similar detection rates, the number of false positives have significantly reduced for the DRF-based detection. Locally, different branches may yield features similar to those from the man-made structures. The logistic classifier does not enforce smoothness in labels, which led to increased isolated false positives. However, the MRF solution with Ising model simply smooths the labels without taking observations into account resulting in a smoothed false-positive region around the tree branches.

To carry out the quantitative evaluations, the detection rates and the number of false positives per image for each technique are compared. At first data, interactions are not allowed for any method by extracting features from individual sites. The comparative results for the three methods are given in Table 1 next to “MRF”, “Logistic—” and “DRF—”. For comparison purposes, the false-positive rate of the logistic classifier is fixed to be the same as the DRF in all the experiments. For similar false positives, the detection rates of the traditional MRF and the DRF are higher than the logistic classifier due to the label interaction. However, the higher detection rate of the DRF in comparison to the MRF indicates the gain due to the use of discriminative models in the association and interaction potentials. In the next experiment, to take advantage of the power of the DRF framework, data interaction was allowed for both the logistic classifier as well as the DRF (“Logistic” and “DRF” in Table 1). The DRF detection rate increases substantially,

Discriminative Random Fields, Fig. 4 Structure detection results on a test example for different methods. For similar detection rates, DRF reduces the false positives considerably. (a) Input image, (b) logistic, (c) MRF, and (d) DRF

Discriminative Random Fields, Table 1 Detection rates (DR) and false positives (FP) for the test set containing 129 images (49, 536 sites). FP for logistic classifier were kept to be the same as for DRF for DR comparison. Superscript ‘–’ indicates no neighborhood data interaction was used

| | MRF | Logistic– | DRF– | Logistic | DRF |
|----------------|-------|-----------|-------|----------|-------|
| DR (%) | 58.35 | 47.50 | 61.79 | 60.80 | 72.54 |
| FP (per image) | 2.44 | 2.28 | 2.28 | 1.76 | 1.76 |

and the false positives decrease further indicating the importance of allowing the data interaction in addition to the label interaction.

Extensions and Related Work

A large number of extensions of the basic binary DRFs have been proposed. For instance, *multi-*

class DRFs allow label sets consisting of more than two labels and *hierarchical DRFs* incorporate context at multiple levels [7]. For example, for parts-based object detection, local context is the geometric relationship among parts of an object, while the relative spatial configurations of different objects (e.g., monitor, keyboard, and mouse) provides the global context. Learning in DRFs was extended to a semi-supervised paradigm by Lee et al. [8], while a Hidden-DRF model with latent variables was proposed in [9].

Open Problems

Hierarchical DRFs are of great interest since such models are quite powerful and can parse scenes at multiple levels of granularity. Robust parameter learning and inference in such models is a very challenging open problem.

Definition

In practical applications, classification or detection algorithms trained on a particular dataset do not generalize well to novel datasets. Domain adaptation methods try to reduce the performance degradation due to domain shift [1, 2].

Background

The study of sparse representation of signals and images has attracted tremendous interest over the last decade. This is partly due to the fact that signals or images of interest, though high dimensional, can often be coded using few representative atoms in some dictionary. Olshausen and Field in their seminal work [3] introduced the idea of learning dictionary from data instead of using off-the-shelf bases. Since then, data-driven dictionaries have been shown to work well for both image restoration and classification tasks [4].

Given a set of examples $\mathbf{Y} = [\mathbf{y}_1, \dots, \mathbf{y}_n]$, the goal of dictionary learning algorithms such as KSVD and the method of optimal directions (MOD) [4] is to find a dictionary \mathbf{D} and a sparse matrix \mathbf{X} that minimize the following representation error:

$$(\hat{\mathbf{D}}, \hat{\mathbf{X}}) = \arg \min_{\mathbf{D}, \mathbf{X}} \|\mathbf{Y} - \mathbf{DX}\|_F^2 \text{ s. t. } \|\mathbf{x}_i\|_0 \leq T_0 \quad \forall i, \quad (1)$$

where \mathbf{x}_i represent the columns of \mathbf{X} , $\|\mathbf{A}\|_F$ denotes the Frobenius norm of \mathbf{A} , and T_0 denotes the sparsity level and $\|\mathbf{x}\|_0 := \#\{j : x_j \neq 0\}$, which is a count of the number of nonzero elements in \mathbf{x} . Both MOD and KSVD are iterative methods that alternate between sparse-coding and dictionary update steps [4]. First, a dictionary \mathbf{D} with ℓ_2 normalized columns is initialized. Then, the main iteration is composed of the following two stages:

- *Sparse coding*: In this step, \mathbf{D} is fixed, and the following optimization problem is solved to compute the representation vector \mathbf{x}_i for each example \mathbf{y}_i :

$$i=1, \dots, n, \quad \min_{\mathbf{x}_i} \|\mathbf{y}_i - \mathbf{D}\mathbf{x}_i\|_2^2 \text{ s. t. } \|\mathbf{x}_i\|_0 \leq T_0.$$

- *Dictionary update*: This is where both MOD and KSVD algorithms differ. The MOD algorithm updates all the atoms simultaneously by solving an optimization problem whose solution is given by $\mathbf{D} = \mathbf{Y}\mathbf{X}^\dagger$, where \mathbf{X}^\dagger denotes the Moore-Penrose pseudo-inverse. Even though the MOD algorithm is very effective and usually converges in a few iterations, it suffers from the high complexity of the matrix inversion step as discussed in [4].

In the case of KSVD, the dictionary update is performed atom-by-atom in a computationally efficient way rather than using a matrix inversion. It has been observed that the KSVD algorithm requires fewer iterations to converge than the MOD method.

Theory

The efficiency of dictionaries in a wide range of computer vision and image processing applications can be attributed to the robust discriminant representations that they provide by adapting to particular data samples. However, the learned dictionary may not be optimal if the target data has a different distribution than the data used for training. Several dictionary learning-based

methods have been proposed in the literature to deal with this domain shift problem [5–10].

In particular, when designing dictionaries, training and testing domains may be different, e.g., different viewpoints and illumination conditions. As a result, dictionary designed for one domain might not be optimal for another. In [5], a function learning framework is presented for the task of transforming a dictionary learned from one visual domain to the other while maintaining a domain-invariant sparse representation of a signal. An overview of this method is shown in Fig. 1.

Denote P signals observed in N different domains as $\{\mathbf{Y}_1, \dots, \mathbf{Y}_N\}$, where $\mathbf{Y}_i = [\mathbf{y}_{i1}, \dots, \mathbf{y}_{iP}]$, $\mathbf{y}_{ip} \in \mathbb{R}^n$. Thus, \mathbf{y}_{ip} denotes the p^{th} signal observed in the i^{th} domain. Let \mathbf{D}_i denote the dictionary for the i^{th} domain, where $\mathbf{D}_i = [\mathbf{d}_{i1} \dots \mathbf{d}_{iK}]$, $\mathbf{d}_{ik} \in \mathbb{R}^n$. The domain dictionary learning problem can be formulated as

$$\arg \min_{\{\mathbf{D}_i\}_i^N, \mathbf{X}} \sum_i^N \|\mathbf{Y}_i - \mathbf{D}_i \mathbf{X}\|_F^2 \text{ s.t. } \forall p \quad \|\mathbf{x}_p\|_0 \leq T_0, \quad (2)$$

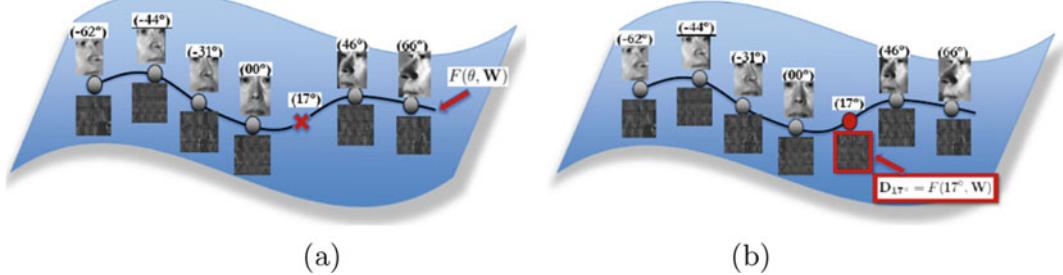

where $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_P]$, $\mathbf{x}_p \in \mathbb{R}^K$, are the sparse codes and T_0 is a sparsity constant. The set of domain dictionary $\{\mathbf{D}_i\}_i^N$ learned through (2) enable the same sparse codes \mathbf{x}_p for a signal \mathbf{y}_p observed across N different domains to achieve domain adaptation.

A parametric function is used to model domain dictionaries \mathbf{D}_i as follows:

$$\mathbf{D}_i = F(\boldsymbol{\theta}_i, \mathbf{W}), \quad (3)$$

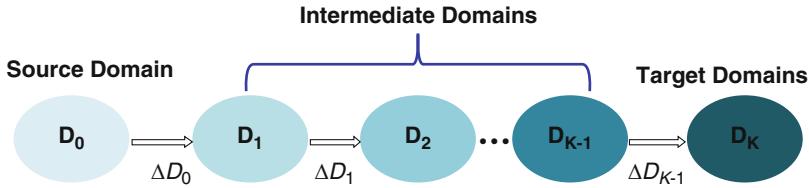

where $\boldsymbol{\theta}_i$ denotes a vector of domain parameters, e.g., viewpoint angles, illumination conditions, etc., and \mathbf{W} denotes the dictionary function parameters [5]. Applying (3) to (2), one can formulate the domain dictionary function learning as follows:

$$\begin{aligned} & \arg \min_{\mathbf{W}, \mathbf{X}} \sum_i^N \|\mathbf{Y}_i - F(\boldsymbol{\theta}_i, \mathbf{W}) \mathbf{X}\|_F^2 \\ & \text{s.t. } \forall p \quad \|\mathbf{x}_p\|_0 \leq T_0. \end{aligned} \quad (4)$$

Domain Adaptation Using Dictionaries, Fig. 1
Overview of the domain-adaptive dictionary learning approach proposed in [5]. Consider example dictionaries corresponding to faces at different azimuths. (a) shows a depiction of example dictionaries over a curve on a dictionary manifold. Given example dictionaries,

the approach presented in [5] learns the underlying dictionary function $F(\theta, \mathbf{W})$. In (b), the dictionary corresponding to a domain associated with observations is obtained by evaluating the learned dictionary function at corresponding domain parameters

Domain Adaptation Using Dictionaries, Fig. 2 An overview of the dictionary-based domain adaptation method [7]

Various linear and nonlinear dictionary function learning models are considered in [5], and the optimization problem is solved using a simple three-step procedure. See [5] for more details on the optimization of (4) and experimental results on various datasets.

Another dictionary-based domain adaptation method was proposed in [7]. Given labeled data in the source domain and unlabeled data in the target domain, the idea is to learn a set of intermediate domains and target domain to capture the intrinsic domain shift between two domains. Figure 2 shows an overview of this method.

Starting from the source domain dictionary \mathbf{D}_0 , the intermediate domain dictionaries $\{\mathbf{D}_k\}_{k=1}^K$ are sequentially learned to gradually adapt to the target data. The final dictionary \mathbf{D}_K which best represents the target data in terms of reconstruction error is taken as the target domain dictionary. Given the k th domain dictionary $\mathbf{D}_k, k \in [0, K-1]$, the next domain dictionary

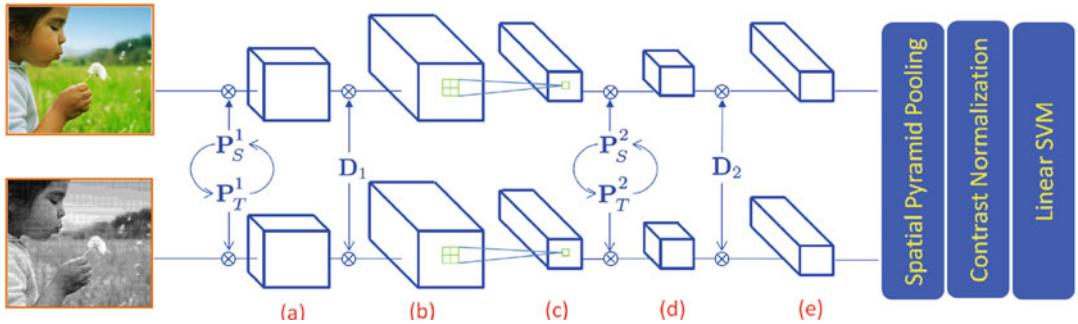

\mathbf{D}_{k+1} is learned based on its coherence with \mathbf{D}_k and the remaining residue of the target data. Specifically, the target data \mathbf{T}_u are decomposed with \mathbf{D}_k , and the residue \mathbf{J}_k are obtained by solving the following optimization problem:

$$\mathbf{X}_k = \arg \min_{\mathbf{X}} \|\mathbf{T}_u - \mathbf{D}_k \mathbf{X}\|_F^2 \text{ s.t. } \forall \|\mathbf{x}_i\|_0 \leq T_0, \quad (5)$$

$$\mathbf{J}_k = \|\mathbf{T}_u - \mathbf{D}_k \mathbf{X}_k\|_F^2, \quad (6)$$

where \mathbf{X}_k are the sparse coefficient, \mathbf{x}_i is a column of \mathbf{X}_k , and T_0 is the sparsity parameter. \mathbf{D}_{k+1} is then obtained by estimating $\Delta\mathbf{D}_k$ which is the adjustment in the dictionary atoms between \mathbf{D}_{k+1} and \mathbf{D}_k :

$$\min_{\Delta\mathbf{D}_k} \|\mathbf{J}_k - \Delta\mathbf{D}_k \mathbf{X}_k\|_F^2 + \lambda \|\Delta\mathbf{D}_k\|_F^2, \quad (7)$$

Domain Adaptation Using Dictionaries, Fig. 3 An illustration of domain adaptation using a sparse and hierarchical network (DASH-N) algorithm [8]. The source domain is RGB images, and the target domain is halftone images. First, images are divided into small overlapping patches. These patches are vectorized while maintaining their spatial arrangements. (a) Performing contrast normalization and dimensionality reduction using \mathbf{P}_S for source images and \mathbf{P}_T for target images. The circular

feedbacks between \mathbf{P}_S and \mathbf{P}_T indicate that these two transformations are learned jointly. (b) Obtaining sparse codes using the common dictionary \mathbf{D}_1 . (c) Performing max pooling. The process then repeats for layer 2 (d and e), except that the input is the sparse codes from layer 1 instead of pixel intensities. At the final stage, spatial pyramid with max pooling are used to create image descriptors. Classification is done using linear support vector machine

where λ is a parameter. An efficient optimization scheme is proposed for solving the above optimization problem. More details can be found in [7].

Another recent work for visual domain adaptation using hierarchical networks was recently proposed by Nguyen et al. in [8]. Their method jointly learns a hierarchy of features together with transformations that address the mismatch between different domains. This method was motivated by [11] in which multilayer sparse coding networks are proposed for building feature hierarchies layer by layer using sparse codes and spatial pooling. Figure 3 shows an overview of the sparse hierarchical domain adaptation method [8]. The network contains multiple layers, each of which contains three sub-layers. The first sub-layer performs contrast normalization and dimensionality reduction on the input data. Sparse coding is carried out in the second sub-layer. In the final sub-layer, adjacent features are max-pooled together to produce a new feature. Output from one layer becomes the input to the next layer. This method can be viewed as a generalization of the domain-adaptive dictionary learning framework [6] using hierarchical networks. Extension of this

method to multiple source domains has also been presented in [8].

Open Problems

Theoretical analysis of domain adaptation using dictionaries is an interesting and open research problem.

Definition

Dynamic programming is a paradigm used in algorithms for solving optimization problems. It relies on the construction of nested subproblems such that the solution of the main problem can be obtained from the solutions of the subproblems.

Background

The paradigm was introduced by the mathematician Richard Bellman in the 1940s and applied in control theory [1].

Theory

The applicability of the paradigm relies on the following two assumptions.

Optimal substructure means that a system of nested subproblems can be constructed in such a way that the solution of the main problem can be obtained from the solutions of these subproblems.

Overlapping subproblems mean that the smaller subproblems in the next level are only slightly smaller, and moreover the set of these subproblems is small as well. This distinguishes DP from “divide-and-conquer” methods.

The method starts by solving the smallest subproblems directly. The obtained results are stored

and used for solving the bigger subproblems in the next higher level. Applying this principle for each step avoids expensive recursions.

The following two algorithms illustrate applications of the DP paradigm.

Viterbi Algorithm

The task is to find the maximal value of a function F which depends on n discrete variables $x_1, x_2, \dots, x_n \in K$ with finite domain K . The function has the form

$$\begin{aligned} F(x_1, \dots, x_n) &= f_1(x_1, x_2) + f_2(x_2, x_3) + \dots \\ &\quad + f_{n-1}(x_{n-1}, x_n). \end{aligned} \quad (1)$$

An appropriate nested system of subproblems is defined by

$$\phi_i(k) = \max_{x_1, \dots, x_i} [f_1(x_1, x_2) + \dots + f_i(x_i, k)] \quad (2)$$

for all $i = 1, \dots, n - 1$ and all $k \in K$. It is quite obvious that the solutions for $\phi_{i+1}()$ can be obtained from those for $\phi_i()$ by

$$\phi_{i+1}(k) = \max_{k' \in K} [\phi_i(k') + f_{i+1}(k', k)] \quad (3)$$

The solutions of the simplest subproblems $\phi_1(k)$ are found simply by enumeration, and similarly, the solution of the main problem is eventually obtained by solving $\max_k \phi_{n-1}(k)$.

Additional memory space is required if the task is to calculate a maximizer (x_1^*, \dots, x_n^*) of f rather than its maximal value. In such a case, a “pointer”

$$p_{i+1}(k) = \operatorname{argmax}_{k' \in K} [\phi_i(k') + f_{i+1}(k', k)] \quad (4)$$

has to be stored for each $i = 1, \dots, n - 1$ and each $k \in K$. The required maximizer is found simply by backtracking in this list, i.e., $x_i^* = p_{i+1}(x_{i+1}^*)$.

Floyd Warshall Algorithm

The task is to compute the shortest paths for all pairs of vertices in a weighted graph (V, E, w) . It is assumed for simplicity that all nonexistent

edges are included but have infinite length. Let $S(i, j), i, j \in V$, denote the length of the shortest path connecting vertex i with vertex j . The nested system of subproblems is defined as follows. Let $S(i, j, k)$ denote the length of the shortest path connecting vertex i with vertex j which is passing only through vertices of the subset $V_k = \{1, 2, \dots, k\} \subset V$. In other words, $S(i, j, k)$ is the length of the shortest path connecting i and j in the subgraph induced by the vertex set $\{i, j\} \cup V_k$. Again, it is easy to see that $S(i, j, k + 1)$ can be computed from $S(., ., k)$. The sought-after shortest path either passes through vertices from V_k only or otherwise is composed from a first part connecting vertices i and $k + 1$ and a second part connecting vertices $k + 1$ and j . This leads to

$$\begin{aligned} S(i, j, k + 1) &= \min \{S(i, j, k), S(i, k + 1, k) \\ &\quad + S(k + 1, j, k)\}. \end{aligned} \quad (5)$$

The solutions of the smallest subproblems are obviously $S(i, j, 0) = w(i, j)$.

The algorithm has time complexity $\mathcal{O}(|V|^3)$ and space complexity $\mathcal{O}(|V|^2)$ and provides the lengths of the shortest paths between all pairs of vertices. A simple modification of the algorithm allows to reconstruct the shortest path for each pair of vertices. The key idea is to store an additional matrix of size $|V| \times |V|$, whose elements represent the largest index of intermediate vertices in the shortest path connecting vertices i and j . This matrix is initialized and updated along with matrix S . Once calculated, it allows to reconstruct the shortest path between each pair of vertices recursively.

A more comprehensive analysis of DP and other examples can be found, e.g., in [2, 3].

Edge Detection

James H. Elde

Centre for Vision Research, York University,
Toronto, ON, Canada

Related Concepts

- ▶ [Boundary Detection](#)
- ▶ [Scale Selection](#)

Definition

Edge detection is the process of labeling the image pixels that lie on the boundaries where abrupt intensity discontinuity occurs.

Background

The light projected from a visual scene into an eye or camera is typically piecewise smooth as a function of visual angle. Since nearby points on a surface tend to have similar attitude, reflectance, and illumination, the pixels to which these surface points project tend to have similar intensity. This rule is broken when two adjacent pixels project from points on either side of an occlusion boundary, since the points now project from different surfaces that may well have different attitude, reflectance, and illumination, and typically

an abrupt change in image intensity results. Intensity edges also arise when neighboring pixels project from points on the same surface that happens to straddle a surface crease, pigment change, or shadow boundary.

Since these abrupt changes in image intensity correspond to significant physical events in the scene, the problem of reliably detecting and localizing these edges is an important and fundamental early vision problem. While detection of object boundaries (occlusion edges) is sometimes seen as the main goal, reliable detection of surface creases and reflectance edges also has clear importance for shape estimation and object recognition, and even cast shadows provide important information about relief, surface contact, and scene layout.

Since edges are sparse, edge detection is also motivated from a differential image coding viewpoint: a large fraction of the information in an image can be captured by coding just the locations, 2D orientations, and intensity changes of these edges.

The problem of edge detection dates back to the first days of computer vision: back to Roberts' thesis at least [20]. In its simplest form, the goal is to label the image pixels that lie on (or very near) a step discontinuity in the image. This definition has been generalized in a number of useful ways: to allow for possible blurring of the step discontinuity, due to shading or defocus, for example, and to require an estimate of the local 2D orientation of the edge as well as its location.

- Biological basis [9]
- History [20]
- Problem definition [1, 2, 5, 6, 13, 15, 18]

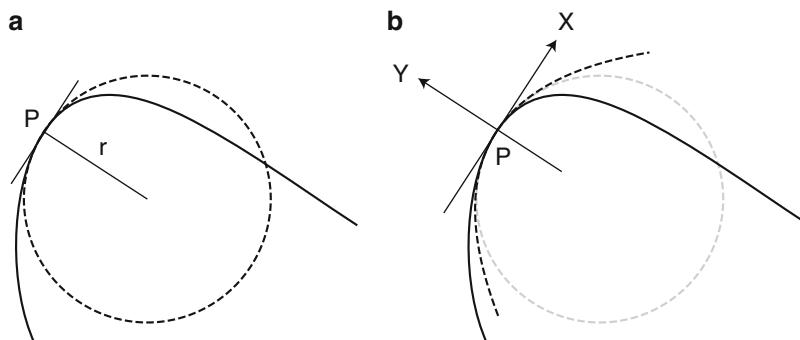

Theory and Application

Roberts based his edge detector on a simple 2 pixel \times 2 pixel discrete differential operator related to the gradient magnitude (Fig. 1). Since the operator relies upon only 4 pixels, the results are highly sensitive to noise and are dominated by the fine structure of the image. Over the intervening years, most edge detection algorithms have continued to rely on a first stage of local differential filtering but have innovated in the design of smoothing kernels to increase signal-to-noise ratio, in the order of the differential operators used, and in how they are combined. This local differential filtering approach aligns well with physiological data showing that neurons early in the primate visual pathway can to some degree be approximated as stabilized low-order differential operators [9].

By far the most popular smoothing kernel has been the 2D Gaussian $G(x, y) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{x^2+y^2}{2\sigma^2}\right)$. Marr and Hildreth [17] proposed the use of second-order isotropic Laplacian-of-Gaussian (“Mexican hat”) filters $\nabla^2 G(x, y)$. The $\nabla^2 G$ filter produces a signed response that crosses zero precisely at the

location of an (ideal) step edge, and Marr and Hildreth proposed that edges thus be identified with such zero crossings. Due to the isotropy of the $\nabla^2 G$ filter, the response is invariant to the orientation of the edge, a desirable property, since edges can occur at any orientation. Marr and Hildreth also observed that different edges occur at different scales, and so employed $\nabla^2 G$ filters over a range of scales σ . Observing that spurious zero crossings at a single scale can occur due to interference between multiple distinct edges, Marr and Hildreth proposed a *scale combination rule*: edges are deemed valid only if zero crossings at the same location and orientation are found at more than one scale.

Marr and Hildreth obtained orientation invariance by using isotropic filters and approximate scale invariance by combining information across scales. However, these invariance properties came at the price of detection and localization performance. This became clear partly through the work of John Canny [2], who used a variational approach to determine an edge detector that would be (nearly) optimal precisely in terms of detection rate and localization performance, while avoiding multiple responses to the same edge. The outcome was an edge detection filter that is well approximated by a first-derivative-of-Gaussian function. Canny used two such filters to estimate stabilized partial derivatives and hence the local gradient vector ∇G :

Edge Detection, Fig. 1 Edge detection example [4–6]. Top left: Original greyscale image. Top right: Edge map. Bottom left: Reconstruction of original image from bright-

ness and contrast stored only at edge locations. Bottom right: Reconstruction including edge blur information

$$\nabla G = \begin{pmatrix} G_x \\ G_y \end{pmatrix}, \text{ where } G_x = \frac{\partial G}{\partial x} \text{ and } G_y = \frac{\partial G}{\partial y}$$

The first-derivative-of-Gaussian filter can be shown to be steerable [7]: the filter can be synthesized at any orientation from a linear combination of the two basis filters G_x and G_y . Thus, Canny's approach amounts to computing the first derivative in the gradient direction at every pixel of the smoothed image. In this sense, the approach still enjoys the orientation invariance property emphasized by Marr and Hildreth: a rotation of the edge in the image will not change the estimated gradient magnitude. Canny's approach, however, delivers higher signal-to-noise because the filter more closely approximates the shape of an extended edge in the tangent direction. While Marr and Hildreth's $\nabla^2 G$ operator computes the second derivative along the edge, Canny's ∇G operator locally integrates along the edge over the support of the Gaussian kernel.

While Marr and Hildreth localized edges at the zero crossings of the $\nabla^2 G$ response, Canny localized edges at maxima of the gradient magnitude, taken in the gradient direction, found using a process called *non-maximum suppression*. Since not all of the resulting maxima correspond to significant edges, a threshold on the gradient magnitude must be applied to reduce the false positive rate. Canny devised a clever heuristic technique, dubbed *thresholding with hysteresis*, that removes many false positives without unduly affecting the hit rate (proportion of correct detections). The technique exploits the fact that real weak edges are often chain-connected along a contour to stronger edges, while false positives are more likely to be isolated. The technique employs two thresholds: all edges that are above the low threshold and chain-connected to edges above the high threshold are identified as edges.

The Canny edge detector may well be the most widely used algorithm in the history of computer vision. Its early adoption is likely derived in part from the open availability of the source code, but its continuing widespread use reflects the fact that it continues to perform well in comparison to more recent algorithms.

While most versions of Canny's algorithm in use detect edges only at a single scale, in fact both Marr and Hildreth and Canny recognized the problem of scale, but dealt with it in slightly different ways. While Marr and Hildreth conjunctively combined responses across scale (zero crossings of the $\nabla^2 G$ response must be found at multiple scales at the same location and orientation to signal an edge), Canny proposed to *disjunctively* combine edges detected at different scales. This raises the *multiple response problem*: how do we know whether two extremal responses, at different scales but similar locations and orientations, signal two distinct edges in the image, or a single edge corrupted by noise? Canny proposed a *feature synthesis* method to deal with this problem, that signals the larger scale edge only if it could not be satisfactorily explained by the smaller scale responses in a local neighborhood.

Canny's proposed technique localizes edges using the smallest scale at which they are detected, an approach that Canny justified based upon his variational optimization, and this motivated the later development of *edge focusing* techniques [1] in which edges are detected at coarse scales and then tracked through scale space to finer scales for better localization. As it turns out, Canny's one-dimensional analysis does not generalize to two dimensions: Elder and Zucker [5, 6] later showed that for an ideal step or blurred step edge corrupted by noise, localization improves monotonically with increasing scale. This result highlights the difference between theory and practice: since edges in real images are always finite in extent, often curved, and surrounded by other kinds of image structure, neither detection nor localization is likely to be optimized by maximizing scale.

Elder and Zucker pointed out that while it is difficult to model all of the real-world effects that limit the effectiveness of large filters, the small-scale problem is tractable, since performance is limited by noise that can be modeled as white, and for which parameters can be estimated. Based on this observation, they proposed a method for selecting the scale of differential operators called *local scale control*, in which scales are search

from fine to coarse to determine the *minimum reliable scale*, that is the smallest scale at which the sign of the derivative measurement is statistically reliable. This approach avoids spurious responses to noise, while minimizing bias due to the finite extent of the edge, curvature, and interference from neighbouring image structure. They also demonstrated methods for subpixel localization down to roughly 1/20 of a pixel precision [5].

A different scale selection approach for edge detection was proposed at roughly the same time by Lindeberg [15]. Lindeberg's method selects the scale maximizing the response of so-called γ -normalized differential operators. This approach has the property that the scales selected for an ideal, noise-free, isolated, blurred straight edge of infinite extent will be proportional to the blur scale of the edge, and independent of the edge contrast. Thus, small scales should be selected for sharp edges, and larger scales for blurred edges. Unlike the local scale control approach of Elder and Zucker, the selection of scale is not related to the signal-to-noise ratio: in general a large-scale filter will have a smaller response to an ideal edge than a small-scale filter, even when the signal-to-noise for the two filters is the same. As a result of this bias to smaller scales, many noisy edges are detected, and these must be eliminated using some form of post hoc thresholding.

These studies also raised issues around the order of differential operators to employ. While Canny localized edges at gradient maxima, Elder and Zucker localized edges at zero crossings of the second derivative, steered in the gradient direction. Specifically edges are localized at the boundary between two pixels where the sign of the second derivative changes from positive to negative in the gradient direction (this avoids detections of minima in the gradient magnitude). Where the same scales used for these two operators, the results would be identical. However, the Elder and Zucker approach tunes the scales of the two operators independently, based upon the signal-to-noise properties of the operators, and as a result the gradient maxima and second derivative zero crossings are decoupled.

While the statistical testing method cannot be used to distinguish real and spurious maxima, it can be used to test for response sign, and hence to detect zero crossings. Thus, the use of the second derivative here is critical. Lindeberg [15] has argued for explicit calculation and testing of the sign of the third derivative, but this is equivalent to checking the sign of the second derivative on either side of the zero crossing. However, Elder and Zucker do show that explicit computation of the third derivative is useful for estimating the blur of an edge, which may be useful for discriminating different types of edges, and for recovering depth from defocus.

In their 1980s paper [17], Marr and Hildreth speculated about the possibility that the locations and gradient magnitudes at oriented zero crossings over multiple scales might constitute a complete encoding of the image, allowing, in principle, for the image to be perfectly reconstructed from the edge representation. While this may seem to be going in the wrong direction from a computer vision point of view, the question is important because it addresses whether an edge code could serve as a *complete* early visual representation, providing sufficient information for all higher-level algorithms.

Since Marr and Hildreth's original conjecture, there have been numerous theoretical and empirical studies exploring the possible completeness of an edge code. Mallat and Zhong [16] demonstrated excellent reconstruction results based upon such a code. However, since edges are represented at many scales, and at the finest scales edge density is very high, this code is highly overcomplete. More compact codes can be derived, but at the expense of noticeable artifact in the reconstruction.

Elder [4] explored an alternative reconstruction approach based upon their edge representation. Rather than storing information from all scales at each edge point, only the location, 2-bit orientation, contrast, brightness, and blur of each edge point were stored, resulting in a far more compact code. Reconstruction is excellent as long as both the intensity and the blur information are employed in the reconstruction.

Since edge detection is often just the first computational step in a computer vision pipeline, and applications may have real-time requirements, efficiency has always been a factor in the design of edge detection algorithms. Both Marr and Hildreth [17] and Canny [2] deliberately employed filters that were $x-y$ separable, allowing 2D convolutions to be computed by composing much cheaper 1D convolutions. Rachid Deriche [3] further improved upon these efficiency by developing recursive filters based upon Canny's original design criteria, allowing very fast implementation on sequential hardware. More recent algorithms have tended to rely upon steerable filters [7] that allow oriented operators to be implemented using only a few basis functions.

While linear filtering forms the front end of most edge detection algorithms, a number of interesting non-linear techniques have been studied. In fact this has a long tradition, going back to early work that sees the problem as model fitting [10] and includes active contour ("snake") methods for fitting semi-local deformable contour models to visual data [12]. While effective in many applications, active contour methods tend to have more parameters to tune, and results are sensitive to these and to initial conditions.

Still to include:

- Scale [13]
- Color edge detection [14]
- Nonlinear filtering [11]
- Nonlocal methods [19]
- Evaluation [8, 13, 18]
- Redefinition in terms of "salient" boundaries [13, 18]

[Visualized locus method](#)

Definition

Stacking up a sequence of images in the order of shooting time, a 3D image having a time axis which is the thickness direction of just one book is obtained. This 3D image is called a spatiotemporal image. If the temporal change of the image is slow, the spatiotemporal image has continuity in the time axis direction as strong as in the image axis directions. An epipolar plane is composed of two camera viewpoints at the start and end times of the moving images and a 3D point on the object. If the camera moves in translation, this object point is constrained on the epipolar plane. When the spatiotemporal image is cut along the epipolar plane, the projection of the object point draws a locus on this cross section. This spatiotemporal cross-sectional image is called an epipolar plane image (EPI). By analyzing the EPI, it is possible to track the objects and recover the 3D structure of the scene by the ego-motion of the camera.

Background

Digital image processing, which began in the 1960s, was mainly performed for static images, and moving image analysis emerged as a challenging theme in the late 1970s. Correspondence of successive images and reconstruction of a 3D scene have been recognized as the main issues of the moving image analysis. At that

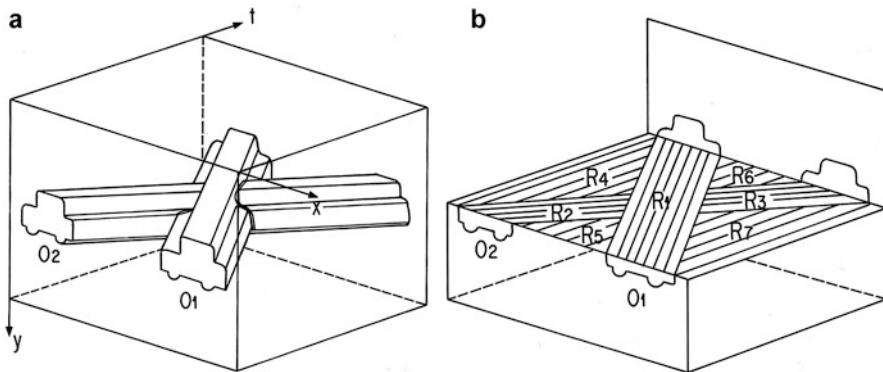

time, image pattern matching and spatiotemporal gradient methods were considered to be effective means for finding correspondence between images, but both became difficult when the apparent shape of the object changed due to occlusion.

Theory

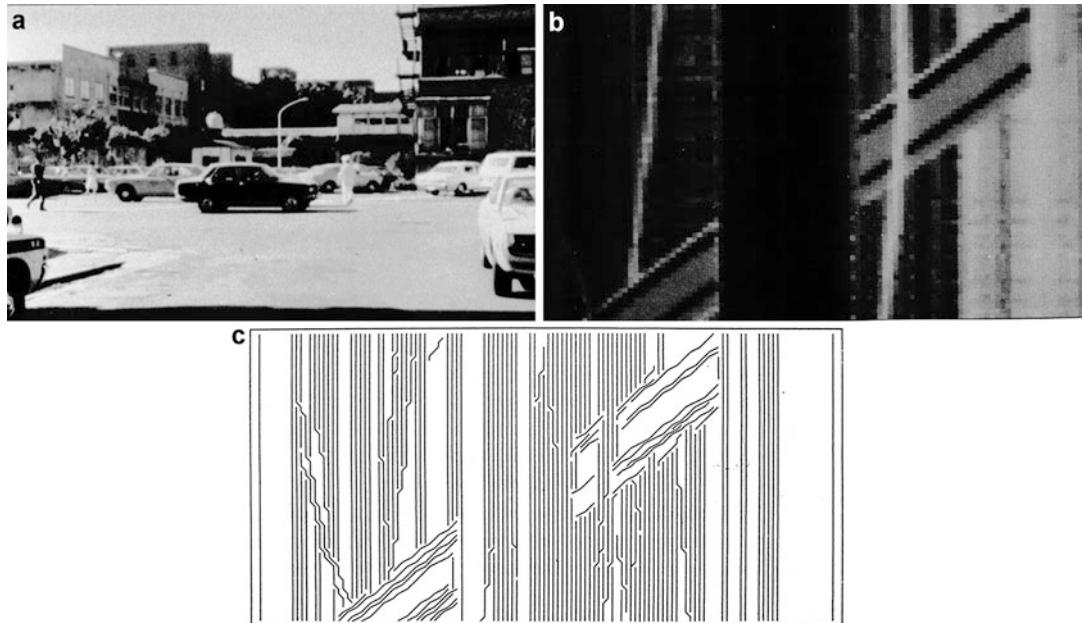

The EPI analysis appeared in 1981 as a tracking method that does not use apparent image patterns [1]. We show basic idea of this method on object tracking and structure from ego-motion.

Suppose that a video camera is set at the roadside and a moving image of the vehicles moving from side to side is captured. Make a spatiotemporal image from this moving image as shown in Fig. 1a. In the spatiotemporal image, the vehicle pattern constitutes a 3D sweeping area. In the horizontal cross section of the spatiotemporal image, the locus of the feature points appears as a striped pattern as shown in Fig. 1b. This locus can be traced with edge detection. Despite the apparent change of the tracking object due to occlusion, make it possible to perform tracking on a pixel-by-pixel basis by edge detection on the spatiotemporal cross-sectional image. Also, the apparent movement speed can be measured by finding the inclination of the locus with respect to the time axis.

The spatiotemporal cross-sectional image which is an EPI obtained from the actual outdoor scene is shown in Fig. 2b, and one frame of the outdoor scene is shown in Fig. 2a. This spatiotemporal cross-sectional image was taken around 1979. At that time, technology for inputting moving images to a computer was not established, and scenes were shot with a 16 mm movie camera, and each frame was input to the computer with a drum scanner. The horizontal axis of the EPI is the x-axis of the image, and the vertical axis is the time axis. The resolution is low and the image quality is not good. Despite this, it can be seen that the black band in the middle is the loci of the black vehicle, and the white band from the upper right to the lower left is the loci of the light color vehicle. By following these loci

Ego-Motion and EPI Analysis, Fig. 1 (a) A spatiotemporal image by stacking up a moving image in the order of shooting time. (b) An epipolar plane image (EPI) obtained from horizontal cross section of the spatiotemporal image

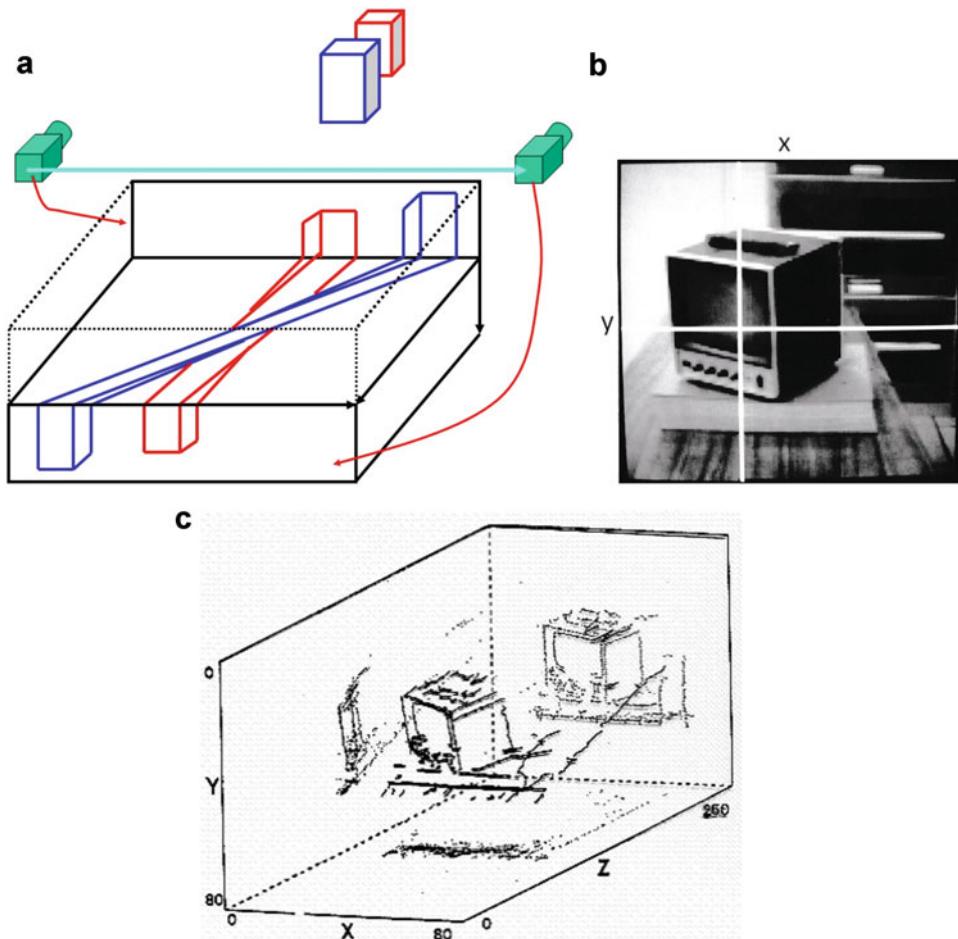

Ego-Motion and EPI Analysis, Fig. 2 (a) One frame of the moving image in outdoor traffic scene. (b) An EPI from horizontal cross section of the spatiotemporal image. (c) Loci are obtained from the edge detection. By tracing the locus, it is possible to track the vehicle in pixel by

pixel despite pattern change by the occlusion. Moreover, the behavior of the traffic scene can be interpreted from the loci. That is, a light-colored vehicle is passing behind a parked black vehicle. (From [1])

detected as Fig. 2c, tracking can be performed on the pixel basis. As a result, it can be interpreted that the light color vehicle is passing behind the parked black vehicle.

By moving the camera with respect to the static scene, the 3D structure of the scene can be

obtained [2]. In Fig. 3a, two cubes are placed in front of the camera. An EPI is obtained via a spatiotemporal image taken while moving the camera from left to right. Motion parallax appeared in this EPI. That is, the inclination of the locus with respect to the time axis on the EPI is inversely

Ego-Motion and EPI Analysis, Fig. 3 (a) The camera is moving from left to right while looking at the two cubes. At this time, motion parallax is seen on EPI. (b) A monitor

as a target object. (c) Reconstructed point cloud of the monitor and their projections on the bottom, side, and back views (©1986IEICE [2])

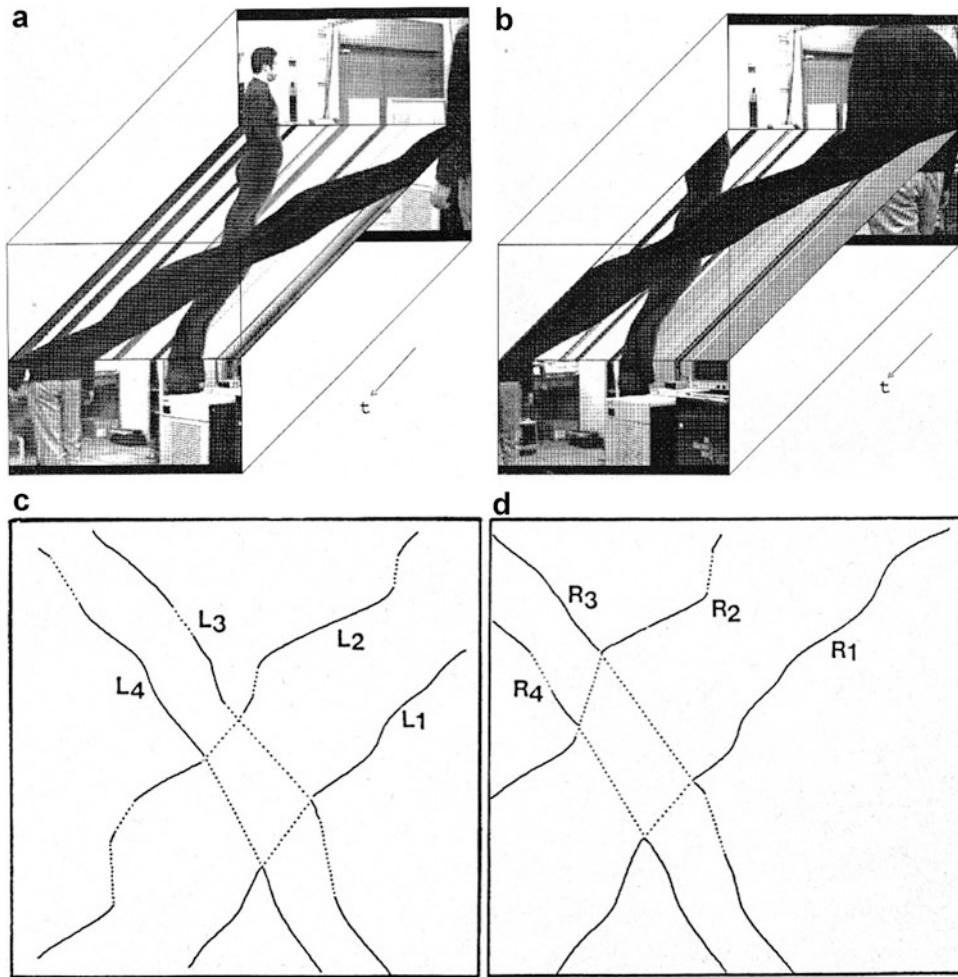

proportional to the depth from the camera to the object. Therefore, the depth of the scene can be obtained by measuring the inclination of the loci. A depth can also be obtained from a pair of stereo images viewed at the start and end points of the camera. However, the apparent arrangement of the two cubes is reversed in the two images. This makes stereo correspondence point search difficult. EPI analysis is an approach that circumvents this difficulty.

Actually, recovery of the 3D shape of a monitor by this method is shown in Fig. 3c. The 3D point cloud of the restored monitor is plotted in the 3D space and is projected on the bottom, side, and back coordinate planes. However, a

horizontal edge of the object does not appear on the horizontal EPI when moving the camera in the horizontal direction. This horizontal edge appeared on the vertical EPI of the spatiotemporal image when the camera moves in the vertical direction. A complete 3D structure of the monitor is obtained by integrating 3D point clouds recovered from the horizontal and vertical EPIs.

Applications

The conditions under which feature points appear as loci on the spatiotemporal cross-sectional image have been clarified in detail in [3]. That

Ego-Motion and EPI Analysis, Fig. 4 (a) EPI from the left camera, (b) EPI from the right camera, (c) Loci on the left EPI, (d) Loci on the right EPI. (From [4])

is, when the camera translates in the scene, the locus of the feature point appears on the cross-sectional image of spatiotemporal image cut by the epipolar plane created from the point on the object and the viewpoints of the camera. Due to this, the spatiotemporal cross-sectional image in which the locus of feature points appears is named EPI. Since the late 1980s, many applied researches on EPI have been launched. Out of them, let's introduce stereo matching, 3D map of town, modeling whole object, and dynamic panorama.

Perspective of the objects can be qualitatively known from the occluding relationship of loci

on the EPI. However, to know quantitatively, a stereo camera is required. Assume a standard stereo camera with parallel optical axes. The EPIs from the left and right cameras are shown in (a) and (b) of Fig. 4, respectively. The corresponding loci of passing pedestrians extracted on the left and right EPIs are drawn in (c) and (d) of Fig. 4, respectively. Suppose that a point x_l on the left image corresponds to a point x_r on the right image, $x_l > x_r$. Since this relationship holds on anytime, $x_l(t) > x_r(t)$ where t denotes time. The locus L_2 on the left EPI can correspond to the loci R_2 , R_3 , and R_4 on the right EPI at the initial time, as they satisfy the condition $x_l > x_r$.

However, with the passage of time, R_3 and R_4 cannot satisfy $x_l(t) > x_r(t)$, and eventually L_2 corresponds to only R_2 . By using loci on EPI, the correspondence problem between stereo images can be solved without using image patterns [4].

The buildings, trees, and streetlights extend vertically. Knowing the location of these vertical lines on the ground, we can get an approximate map of the town. If the brightness on the vertical line is constant, its projection draws a locus on the EPI, and the locus becomes a clue to know the position of the vertical line. Usage of a straight line instead of a 3D point is an alleviation of the establishment condition of EPI. This can be done with a perspective camera, but using an omni-camera, we can efficiently build 3D map of a large-scale scene such as an urban city [5]. The omni-camera is a system in which a scene projected on a hyperbolic convex mirror is captured with a normal camera, and if the mirror's symmetry axis is directed right down, an omni-dimensional image of the scene is obtained. When the omni-camera mounted on the vehicle has moved, an omni-directional spatiotemporal image is shown in Fig. 5a. In the image, a vertical ridge of a building and a roadside tree are projected as a straight line toward the center of the image. Cutting this omni-directional spatiotemporal image by a plane parallel to the time axis and moving direction, the vertical ridge and tree appear as linear loci on the spatiotemporal

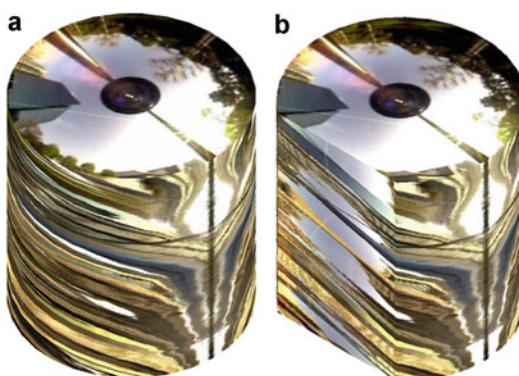

cross-sectional image as shown in Fig. 5b. The positions of building corner and trees can be obtained from the slope and intercept of the loci.

To obtain the entire shape of an object, use the moving image obtained by rotating the camera around the object like the moon rotating around the earth or self-rotating the object in front of the camera. If the rotational speed is constant, a feature point on the object draws a sinusoidal curve on the EPI. However, in order for a locus to appear on the EPI, it is necessary to keep the camera sufficiently apart from the object so that the camera would be modeled by orthographic or weak perspective projection.

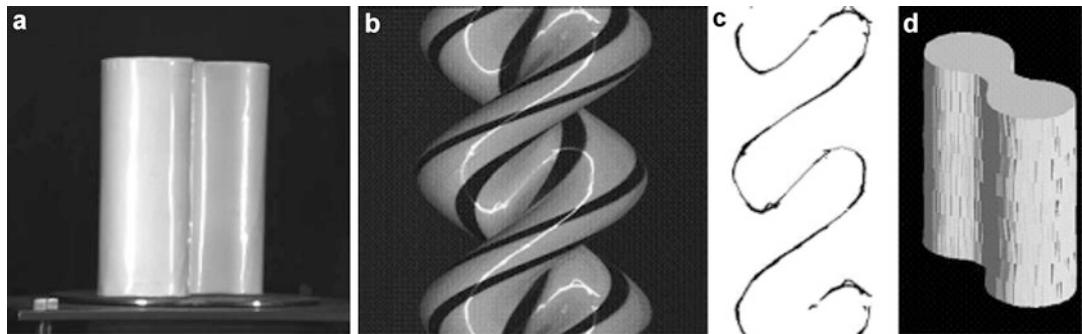

A sinusoidal curve is expressed by amplitude and phase. Although it is conceivable to directly fit the sinusoidal curve to the EPI to obtain the two parameters, it is easier to use the Hough transformation to the 2D parameter space [6]. The amplitude and phase of the extracted sinusoidal curve is a polar coordinate representation of the object shape.

If the specular reflection component of the object surface is prominent, it is observed as a highlight. Since the highlight does not correspond to a particular point on the object surface, its locus on the EPI does not generally draw a sinusoidal curve. As the object rotates, the highlight position moves on the surface of the object and is a function of the rotation angle. Thus, this function represents the shape of the object. This function is known to satisfy first-order differential equation [7], which has a closed form solution. However, an initial value is required. When the highlight locus intersects the sinusoidal locus on the EPI, the shape value obtained from the sinusoidal locus is used as the initial value. Figure 6b shows curves corresponding to feature points and highlights, and (d) shows reconstruction of the object with a specular reflection.

There are various usages in cross sections other than EPI of spatiotemporal images. One of them is a slit photography used in the judgment of arrival order in horse racing. Shoot the goal post through the vertical slit, and roll up the film at the same time as the horse passes, and the images of each horse will be taken in order. This image is the same as a vertical cross-sectional

Ego-Motion and EPI Analysis, Fig. 5 (a) Omni-directional spatiotemporal image, (b) A spatiotemporal cross-sectional image of the omni-directional spatiotemporal image. (From [5])

Ego-Motion and EPI Analysis, Fig. 6 (a) A target object with a specula reflection. (b) On the EPI, a sinusoidal curve corresponds to a black slit pattern on the object

image of the spatiotemporal image from a camera shooting the goal. However, depending on the speed of the horse, the image will stretch or shrink in the direction of move. That is, the image shrinks if the horse is fast and stretches if it is slow. The stretch and shrink can be corrected by measuring the velocity from the horizontal EPI of the spatiotemporal image.

Mosaicing is a technology for creating a panoramic image with a wide field of view by combining images in a moving image obtained by panning or tilting a camera. In [8], a moving image is shot by tilting a camera from bottom to top of a tree. If the horizontal cross-sectional image of the spatiotemporal image is corrected at the tilt speed, a panoramic image of the entire tree can be obtained. A panoramic moving image can be obtained by shifting the cross section position in the up direction. This is called dynamosaicing [9].

Open Problems

EPI may also serve to elucidate human visual function. In the primary visual cortex in the human brain, there is a column that selectively responds to the slope of the stripe with visual stimuli from a static image [10]. It is also known that there is a column that selectively responds to the magnitude of the speed by visual stimulation from a moving image [11]. However, the mechanism of each column is not clear. According to

surface, while a highlight draws the white curve which is not sinusoidal. (c) The highlight curve. (d) The recovered target object. (From [7])

Occam's razor principle that a simple explanation is excellent, suppose an EPI is to be made in the brain from the temporal stimuli, the mechanism of the two columns may be explained by one principle.

As a post-EPI approach, if a 3D region corresponding to a target object in a spatiotemporal image can be directly extracted, it is possible to track freely moving objects unconstrained by EPI conditions. This idea [12] has been proposed earlier but is not a general approach. This approach should be further developed as there are many potential applications.

Definition

The eigenspace method is an image recognition technique that achieves object recognition, object detection, and parameter estimation from images using the distances between input and gallery images in a low-dimensional eigenspace. Here, the eigenspace is constructed based on a statistical method, such as principal component analysis or Karhunen-Loëve transform, so that the variation in the appearances of target objects can be represented in a low-dimensional space efficiently. In particular, a technique called the parametric eigenspace method represents the rotation and translation of a target object or a light source as a manifold in an eigenspace. Accordingly, this method performs object recognition and parameter estimation using distances in the manifold.

Background

Appearance-based object recognition is a technique that recognizes a target object by matching between input and preregistered gallery images. One of the simplest methods to achieve this image matching calculates the distances between the pixel values of these images. However, it is difficult for many applications to apply this method due to two problems: (1) Processing time needed to calculate the distance between images increases depending on the size of the images. (2) Memory space needed to store the gallery images of target objects grows depending on the number of the objects.

Principal component analysis (PCA) can be used as one of the unsupervised dimensionality reduction techniques that transform a sample set of high-dimensional vectors to the set of low-dimensional vectors with minimum information loss. This technique first calculates eigenvectors that are at right angles to each other and maximizes the variances in their directions; it then constructs a low-dimensional eigenspace defined by a small number of eigenvectors. The low-dimensional vectors are obtained by

projecting the high-dimensional vectors to the eigenspace. An eigenspace method constructs a low-dimensional eigenspace from preregistered gallery images of target objects and calculates the distances between input and gallery images in the low-dimensional space. Thus the eigenspace method can reduce the processing time and memory space efficiently without degrading the recognition performance.

Theory

An image recognition procedure using an eigenspace method is divided into learning and recognition stages. The learning stage, which is performed beforehand, constructs a low-dimensional eigenspace from a large number of learning images of target objects and then projects each learning image to the eigenspace. On the other hand, the recognition stage projects an input image of a target object to the eigenspace and then recognizes the input object by matching between input and learning images in the low-dimensional space.

Learning stage For each learning image, the method first normalizes the image size so that the number of pixels can be N , and it represents them as N -dimensional vectors $\mathbf{x}_1, \dots, \mathbf{x}_M$. M represents the number of learning images. Here, we assume that each target object has one learning image; therefore, M also represents the number of target objects. A matrix X is constructed as follows:

$$X = \begin{bmatrix} \frac{\mathbf{x}_1 - \mathbf{c}}{\|\mathbf{x}_1 - \mathbf{c}\|} & \dots & \frac{\mathbf{x}_M - \mathbf{c}}{\|\mathbf{x}_M - \mathbf{c}\|} \end{bmatrix}, \quad (1)$$

$$\mathbf{c} = \frac{1}{M} \sum_{m=1}^M \mathbf{x}_m. \quad (2)$$

Eigenvectors are obtained by solving the following eigenequation:

$$XX^T \mathbf{u}_i = \lambda_i \mathbf{u}_i, \quad (3)$$

where \mathbf{u}_i represents an eigenvector of XX^T corresponding to an eigenvalue λ_i . Eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_N$ are arranged in descending order of their eigenvalues. The method constructs a low-dimensional eigenspace from $k (\ll N)$ eigenvectors corresponding to the k largest eigenvalues and then obtains k -dimensional vectors \mathbf{f}_m by projecting N -dimensional vectors \mathbf{x}_m to the eigenspace using the following equation:

$$\mathbf{f}_m = [\mathbf{u}_1 \cdots \mathbf{u}_k]^T \frac{\mathbf{x}_m - \mathbf{c}}{\|\mathbf{x}_m - \mathbf{c}\|}. \quad (4)$$

Consequently, the memory space needed to store the learning images can be greatly reduced.

Recognition stage In the same manner as in the learning stage, the method first normalizes the image size of an input image and represents it as an N -dimensional vector \mathbf{y} . The method then obtains a k -dimensional vector \mathbf{g} by projecting \mathbf{y} to the low-dimensional eigenspace constructed in the learning stage using the following equation:

$$\mathbf{g} = [\mathbf{u}_1 \cdots \mathbf{u}_k]^T \frac{\mathbf{y} - \mathbf{c}}{\|\mathbf{y} - \mathbf{c}\|}. \quad (5)$$

The method recognizes the input object as an object \hat{m} that minimizes the distance between the input image \mathbf{g} and the learning image \mathbf{f}_m using the following equation:

$$\hat{m} = \arg \min_m \|\mathbf{g} - \mathbf{f}_m\|^2. \quad (6)$$

Accordingly, the processing time needed to calculate the distance between the images can be greatly reduced.

Based on an efficient representation of human face images using PCA as proposed by [1,2] proposed a method using “eigenfaces” to detect and recognize human faces in images. This method calculates a small number of eigenvectors from a large number of learning face images and measures the distances between input and learning face images in a low-dimensional eigenspace. The eigenvectors calculated from the face images are called eigenfaces. Since this method was

Eigenspace Methods, Fig. 1 Image samples in an object image set containing object images with different horizontal poses

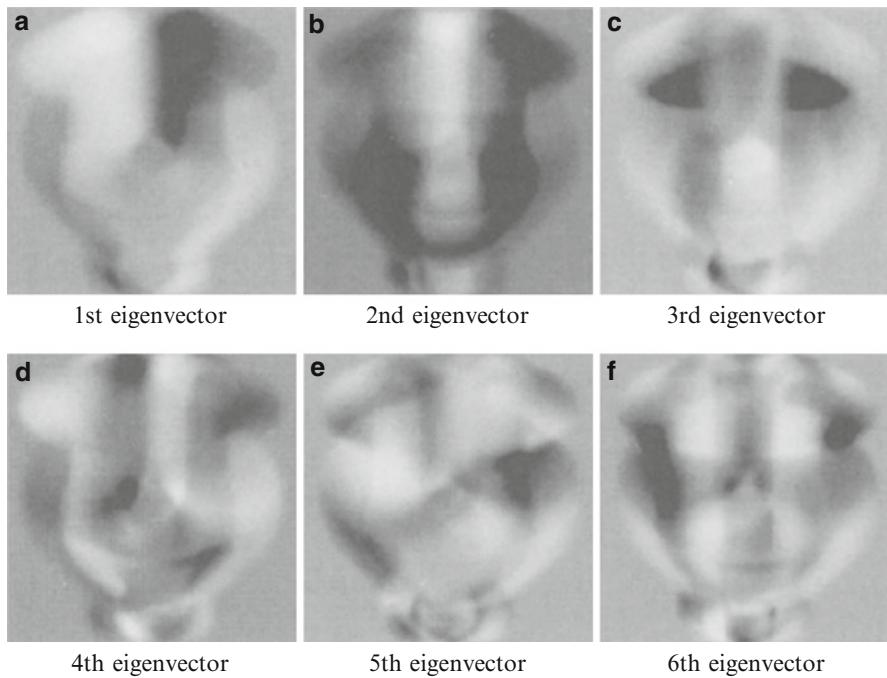

reported, image recognition using the eigenspace method has become an active area of research.

Murase and Nayar [3] proposed a “parametric eigenspace method” for recognizing three-dimensional objects and estimating their poses simultaneously. This method constructs a manifold as a smooth curved line approximated from a point set in an eigenspace for each target object. The point set is obtained by projecting learning images with various poses to the eigenspace. Object recognition and pose estimation are achieved by calculating the distances between an input image and manifolds. In order to achieve object recognition and pose estimation simultaneously, two types of eigenspaces are constructed: a universal eigenspace from the learning images of all target objects and an object eigenspace for each target object. The method first recognizes an object in the universal eigenspace and then estimates a pose of the object in the object eigenspace. Figure 1 shows samples in an object image set containing object images with different horizontal poses, and Fig. 2 shows eigenvectors that were calculated from the image set. On the other hand, the closed smooth curve

shown in Fig. 3 represents a manifold in the object eigenspace that was constructed from the eigenvectors. The manifold was approximated from the points that were obtained by projecting the image in the image set shown in Fig. 1 to the eigenspace.

Ohba and Ikeuchi [4] proposed a method using “eigen window” to recognize partially occluded objects accurately and estimate their poses. The method extracts multiple local regions with high detectability, uniqueness, and reliability from an object region in each learning image. Eigen windows are constructed from the extracted local regions by PCA. Object recognition and pose estimation are achieved by matching between the eigen windows and local regions extracted from an input image in a similar way.

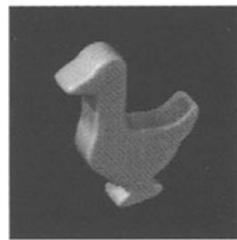

In addition to the approaches described above, there have been a number of techniques related to the eigenspace method. These include techniques of density estimation of samples in a high-dimensional space [5], non-linear expansion of PCA [6, 7], image recognition using two-dimensional PCA [8], and image recognition using high-order tensors [9].

Eigenspace Methods, Fig. 2 Eigenvectors calculated from the object image set shown in Fig. 1. (a)–(f) represent the first through sixth eigenvectors, respectively

Eigenspace Methods,

Fig. 3 A manifold in the object eigenspace constructed from the eigenvectors shown in Fig. 2. Transition of object appearances according to the horizontal pose parameter θ_1 draws a closed smooth curve in the eigenspace

Application

The eigenspace method is used as a fundamental technique in arbitrary computer vision applications, such as object recognition, detection, and tracking, because the method works effectively despite its algorithm being quite simple.

- ▶ [Fundamental Matrix](#)

Definition

The 8-point algorithm is a linear technique to estimate the essential matrix or the fundamental matrix from eight or more point correspondences.

Background

When dealing with multiple images, it is essential to determine the relative geometry between them, which is known as the epipolar geometry. Between two images of a scene, given a pair of

corresponding image points $(\mathbf{m}_i, \mathbf{m}'_i)$, the following epipolar constraint must be satisfied:

$$\tilde{\mathbf{m}}'_i^T \mathbf{M} \tilde{\mathbf{m}}_i = 0, \quad (1)$$

where $\tilde{\mathbf{m}}_i = \begin{bmatrix} \mathbf{m}_i \\ 1 \end{bmatrix}$ is point \mathbf{m}_i in homogeneous coordinates. Similarly, $\tilde{\mathbf{m}}'_i$ is point \mathbf{m}'_i in homogeneous coordinates. Matrix \mathbf{M} is a 3×3 matrix. If the images are calibrated with known intrinsic camera parameters and the image points are expressed in the normalized image coordinate system, then matrix \mathbf{M} is known as the *essential matrix*, and is usually denoted by \mathbf{E} ; otherwise, matrix \mathbf{M} is known as the *fundamental matrix* and is usually denoted by \mathbf{F} . Both essential matrix and fundamental matrix must satisfy certain properties, but the common property is that it is a rank-2 matrix, i.e., the determinant of matrix \mathbf{M} is equal to zero.

Theory

The 8-point algorithm ignores the constraints on the elements of matrix \mathbf{M} and treats them independently. Let us define a 9-D vector \mathbf{x} using the elements of matrix \mathbf{M} such that

$$\mathbf{x} = [M_{11}, M_{21}, M_{31}, M_{12}, M_{22}, M_{32}, M_{13}, M_{22}, M_{33}]^T, \quad (2)$$

where M_{ij} is the (i,j) element of matrix \mathbf{M} . Let $\mathbf{m} = [u, v]^T$. Then, the epipolar constraint (Eq. 1) can be rewritten as

$$\mathbf{a}_i^T \mathbf{x} = 0, \quad (3)$$

where

$$\mathbf{a}_i = [u_i \ \tilde{\mathbf{m}}'_i^T, v_i \tilde{\mathbf{m}}'_i^T, \tilde{\mathbf{m}}'_i^T]^T. \quad (4)$$

It is clear that \mathbf{x} can only be determined up to a scale factor.

Given eight or more point correspondences, \mathbf{x} can be determined as follows. Each point correspondence yields one epipolar equation (Eq. 1). With N ($N \geq 8$) point correspondences, we can stack them together into a vector equation as follows:

$$\mathbf{A}^T \mathbf{x} = \mathbf{0}, \quad (5)$$

with $\mathbf{A} = [\mathbf{a}_1, \dots, \mathbf{a}_N]$. The solution to \mathbf{x} can be obtained by minimizing the least squares, subject to $\|\mathbf{x}\| = 1$. With Lagrange multiplier, this is equivalent to minimizing

$$\|\mathbf{A}^T \mathbf{x}\|^2 + \lambda (1 - \|\mathbf{x}\|^2). \quad (6)$$

With simple algebra, it can be found that the solution to \mathbf{x} is the eigenvector of the 9×9 matrix $\mathbf{A}\mathbf{A}^T$ associated with the smallest eigenvalue.

When the image coordinates (u_i, v_i) are in pixels, the elements of matrix \mathbf{A} have orders of difference in value, and matrix $\mathbf{A}\mathbf{A}^T$ may not be well conditioned. One remedy is to pre-normalize the image points, and several solutions are examined in [1]. One simplest approach is to perform a scaling and translation such that all image coordinates are within $[-1, 1]$. Compared with using directly the pixel coordinates, significant improvement in accuracy has been observed.

The matrix \mathbf{M} estimated above is obtained by ignoring its property. For example, the estimated \mathbf{M} is usually not rank-2. To obtain the closest rank-2 matrix, “closest” in terms of Frobenius norm, we perform a singular value decomposition on \mathbf{M} , i.e.,

$$\mathbf{M} = \mathbf{U}\mathbf{S}\mathbf{V}, \quad (7)$$

where $\mathbf{S} = \text{diag}(s_1, s_2, s_3)$ with $s_1 \geq s_2 \geq s_3 \geq 0$. Replacing the smallest singular value by zero, i.e., $\hat{\mathbf{S}} = \text{diag}(s_1, s_2, 0)$, then

$$\mathbf{U}\hat{\mathbf{S}}\mathbf{V} \equiv \hat{\mathbf{M}} \quad (8)$$

is the optimal rank-2 matrix.

For more details about the epipolar geometry, the reader is referred to [2, 3]. The reader is

referred to [4] for a review of various methods for determining the epipolar geometry (the essential matrix and the fundamental matrix), to [5] for a study of the relationship between various optimization criteria, and to [6] for how to obtain a more robust Euclidean motion and structure estimation via the estimation of fundamental matrix.

Ellipse matching

Definition

Fit one or more ellipses to a set of image points.

Background

Fitting geometric primitives to image data is a basic task in pattern recognition and computer vision. The fitting allows reduction and simplification of image data to a higher level with certain physical meanings. One of the most important primitive models is ellipse, which, being a projective projection of a circle, is of great importance for a variety of computer vision-related applications.

Ellipse fitting methods can be roughly divided into two categories: least square fitting and voting/clustering. Least square fitting, though usually fast to implement, requires the image data pre-segmented and is sensitive to outliers. On the other hand, voting techniques can detect multiple ellipses at once and exhibit some robustness against noise, but suffers from a heavier computational and memory load. Furthermore, most of standard ellipse fitting methods cannot be directly used in real-world applications involving a noisy environment. Thus, the arc finding based techniques will also be described in the entry, with emphasis on ellipse fitting in complicated images, though, strictly speaking, they cannot be taken as a counterpart of the above two categories.

Due to space limitation, there are some other techniques that cannot be covered by the entry, but with some references listed in the recommended reading, such as the moment [1] and genetic algorithm [2] based methods.

Theory

Least Square Fitting

Least square fitting is realized by minimizing some distance measure between ellipse and image data as follows:

$$\Theta = \arg \min_{\Theta} \sum_{i=1}^N \mathcal{D}(\Theta, \mathbf{x}_i)^2, \quad (1)$$

where $\mathcal{D}(\Theta, \mathbf{x}_i)$ denotes some distance between pixel $\mathbf{x}_i = [x_i, y_i]^T$ and the ellipse specified by Θ .

There are two main distance measures for ellipse fitting: geometric distance and algebraic distance. In efficiency, the algebraic distance based techniques outperform its counterpart because a direct solution of Eq. (1) is obtainable by using algebraic distance. However, the algebraic fitting suffers from the drawback of bias estimation and unclear physical interpretations on the estimated errors and fitting parameters. For instance, some algebraic fitting results are not invariant to the coordinates transformation of image data.

Geometric Fitting

An ellipse takes the following equation:

$$\frac{[(x - x_0) \cos \phi + (y - y_0) \sin \phi]^2}{a^2} + \frac{[(x - x_0) \sin \phi + (y - y_0) \cos \phi]^2}{b^2} = 1, \quad (2)$$

where x_0, y_0 are coordinates of center, ϕ is the orientation, and a, b are the semiaxis, as shown in Fig. 1. Geometric distance, also known as shortest or orthogonal distance, is defined by the distance between one image point and its orthogonal projection upon the ellipse, as illustrated by $D_1(\mathbf{x}_i) = \|\mathbf{x}_i - \mathbf{x}_{i1}\|$ in Fig. 1. In such a setting, the ellipse fitted becomes actually a principal curve, which is best in the sense of mean square reconstruction error minimization. However, the distance D_1 is analytically intractable. There exist some techniques to tackle the problem, unavoidably involving some iterative numerical algorithm.

Ahn et al. [3] use a Gaussian-Newton algorithm for geometric fitting, by implicitly describing the orthogonal projection point \mathbf{x}_{i1} . A temporary coordinate system uv is introduced as follows:

$$\mathbf{u} = \mathbf{R}(\mathbf{x} - \mathbf{x}_0), \quad (3)$$

where $\mathbf{R} = \begin{pmatrix} \cos \phi & \sin \phi \\ -\sin \phi & \cos \phi \end{pmatrix}$ is a rotation matrix. In coordinate system uv , the ellipse is transformed with center at the origin and without

rotation, i.e., with the simple formulation as

$$f_1(u, v) = \frac{u^2}{a^2} + \frac{v^2}{b^2} - 1 = 0. \quad (4)$$

For a data point \mathbf{u}_i , the tangent line through its projection point \mathbf{u}_{i1} on the ellipse is perpendicular to the line connecting the two points \mathbf{u}_i and \mathbf{u}_{i1} :

$$f_2(u, v) = b^2 u(v_i - v) - a^2 v(u_i - u) = 0 \quad (5)$$

Then, a generalized Newton method is employed to find \mathbf{u}_{i1} as follows:

$$\begin{aligned} \mathbf{Q}_n \Delta \mathbf{u} &= -\mathbf{f}(\mathbf{u}_n) \\ \mathbf{u}_{n+1} &= \mathbf{u}_n + \Delta \mathbf{u} \end{aligned} \quad (6)$$

where $\mathbf{f} \triangleq (f_1, f_2)^T$, and the Jacobian matrix

$$\mathbf{Q} = \begin{pmatrix} b^2 u, & a^2 v \\ (a^2 - b^2)v + b^2 v_i, & (a^2 - b^2)u - a^2 u_i \end{pmatrix}. \quad (7)$$

It is noted several solutions (maximum to 4) could be found by the iteration above. In order to get the right one, one can choose a proper initial value as

$$\mathbf{u}_0 = 0.5(\mathbf{u}_{i2} + \mathbf{u}_{i3}),$$

where $\mathbf{u}_{i2} = \mathbf{u}_i \frac{ab}{\sqrt{b^2 u_i^2 + a^2 v_i^2}}$ and $\mathbf{u}_{i3} = \begin{cases} (u_i, \text{sign}(v_i) \frac{b}{a} \sqrt{a^2 - u_i^2})^T & \text{if } |u_i| < a, \\ (\text{sign}(u_i)a, 0)^T & \text{else.} \end{cases}$

illustrated in Fig. 1.

Once \mathbf{u}_1 has been found, through a backward transformation of Eq. (3), the error distance vector becomes

$$\mathbf{D}_1(\mathbf{x}_i) = \mathbf{x}_i - \mathbf{x}_{i1} = \mathbf{R}^{-1}(\mathbf{u}_i - \mathbf{u}_{i1}) \quad (8)$$

By implicitly describing the orthogonal projection \mathbf{u}_1 through f_1 and f_2 defined by Eqs. (4) and (5), the Jacobian matrix with respect to the five parameters $\boldsymbol{\theta} = (x_0, y_0, a, b, \phi)^T$ is as follows:

$$\mathbf{J}_{\mathbf{x}_{i1}, \boldsymbol{\theta}} = (\mathbf{R}^{-1} \mathbf{Q}^{-1} \mathbf{B})|_{\mathbf{u}=\mathbf{u}_1}, \quad (9)$$

where \mathbf{Q} is given by Eq. (7), and $\mathbf{B} = (\mathbf{B}_1, \mathbf{B}_2, \mathbf{B}_3, \mathbf{B}_4, \mathbf{B}_5)$ with

$$\begin{aligned} \mathbf{B}_1 &= (b^2 u \cos \phi - a^2 v \sin \phi, b^2(v_i - v) \cos \phi \\ &\quad + a^2(u_i - u) \sin \phi)^T, \\ \mathbf{B}_2 &= (b^2 u \sin \phi + a^2 v \cos \phi, b^2(v_i - v) \sin \phi \\ &\quad - a^2(u_i - u) \cos \phi)^T, \\ \mathbf{B}_3 &= (a(b^2 - v^2), 2av(u_i - u))^T, \\ \mathbf{B}_4 &= (b(a^2 - u^2), -2bu(v_i - b))^T, \\ \mathbf{B}_5 &= ((a^2 - b^2)uv, (a^2 - b^2)(u^2 - v^2 \\ &\quad - uu_i + vv_i))^T. \end{aligned}$$

Finally, based on equations (8) and (9), the fitting can be accomplished by a Gaussian-Newton iteration as

$$\boldsymbol{\theta}_{n+1} = \boldsymbol{\theta}_n + \lambda \mathbf{J}_{\mathbf{x}_{i1}, \boldsymbol{\theta}}^{-1} \mathbf{D}_1(\mathbf{x}_i), \quad (10)$$

where λ denotes a step-size.

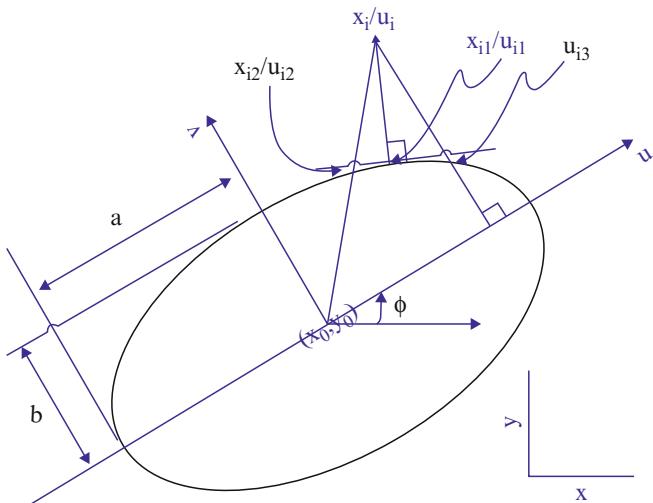

Instead of the shortest distance, an alternative approach was proposed to use radial distance, as illustrated by $D_2(\mathbf{x}_i) = \|\mathbf{x}_i - \mathbf{x}_{i2}\|$ in Fig. 1, where \mathbf{x}_{i2} is the intersection of the ellipse and the radial line passing through \mathbf{x}_i . Distance D_2 is analytically obtained as [4]

$$D_2(\boldsymbol{\Theta}, \mathbf{x}) = \left| \frac{ab}{\sqrt{(\kappa)}} - 1 \right| \sqrt{(x - x_0)^2 + (y - y_0)^2} \quad (11)$$

with $\kappa \triangleq a^2(\cos \phi(y - y_0) - \sin \phi(x - x_0))^2 + b^2(\cos \phi(x - x_0) + \sin \phi(y - y_0))^2$. However, solution of Eq. (1) can still not be directly reached. Usually, some iterative technique is still required to get the fitting results, such as stochastic gradient algorithm.

Some other developments on geometric fitting are referred to [5, 6].

Ellipse Fitting, Fig. 1 An ellipse with center at (x_0, y_0) , orientation ϕ and semiaxis a and b . The projection of point x_i , or \mathbf{u}_i in coordinate system uv , upon the ellipse is the point with the shortest distance on the ellipse, denoted by x_{i1} (\mathbf{u}_{i1})

Algebraic Fitting

In fact, a more commonly used distance measure for ellipse fitting is algebraic distance, which defines the distance by the second order polynomial

$$\mathcal{D}(\Theta, \mathbf{u}) = ax^2 + bxy + cy^2 + dx + ey + f, \quad (12)$$

with the constraint

$$b^2 - 4ac < 0, \quad (13)$$

and with $\Theta = [a, b, c, d, e, f]^T$. The problem of Eq.(1) with the distance measure given by Eq.(12) has been extensively studied in the name of conic fitting. In order to fit an ellipse, though the general problem of conic fitting could be solved directly, the constraint of Eq.(13) generally makes the methods iterative. By constraining $b^2 - 4ac = -1$ and by transferring the problem to solving a generalized eigensystem, Fitzgibbon et al. [7] propose a fast and direct ellipse fitting method. Specifically, the problem is reformulated as

$$\min_{\Theta} \|\mathbf{D}\Theta\|^2 \text{ subject to } \Theta^T \mathbf{C}\Theta = 1, \quad (14)$$

where $\mathbf{D} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_N]^T$ with $\mathbf{u}_i = [x^2, xy, y^2, x, y, 1]$, and the constraint matrix \mathbf{C} is defined as

$$\mathbf{C} = \begin{pmatrix} 0 & 0 & 2 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 \\ 2 & 0 & 0 & 0 & 0 & 0 \\ \mathbf{0} & & & & & \end{pmatrix}, \quad (15)$$

where $\mathbf{0} \in \mathbb{R}^{3 \times 6}$ is a null matrix. By introducing Lagrange multipliers λ and differentiating, the conditions for the optimal Θ become

$$\mathbf{S}\Theta = \lambda \mathbf{C}\Theta,$$

$$\Theta^T \mathbf{C}\Theta = 1, \quad (16)$$

where $\mathbf{S} = \mathbf{D}^T \mathbf{D}$. Thus, problem (14) can be solved by finding the eigenvector Θ_i of the generalized eigensystem defined by Eq.(16). It is also noted that there are six solution-pairs (λ_i, Θ_i) . By definition, the one corresponding to the minimal positive eigenvalue λ_i is chosen as the solution, because

$$\|\mathbf{D}\Theta\|^2 = \Theta^T \mathbf{D}^T \mathbf{D}\Theta = \Theta^T \mathbf{S}\Theta = \lambda \Theta^T \mathbf{C}\Theta = \lambda. \quad (17)$$

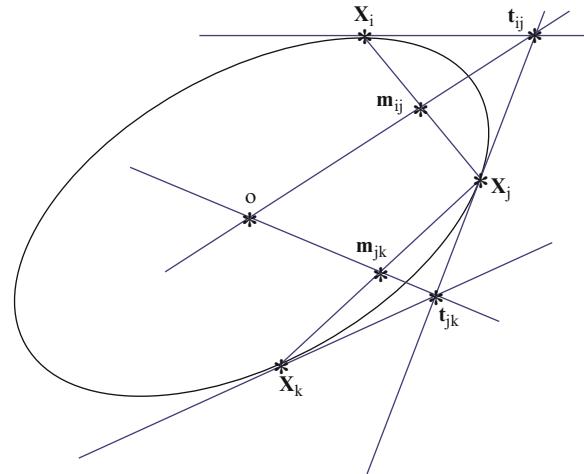

Some other developments on algebraic fitting are referred to [8, 9].

Voting Based Techniques

Different from the least square fitting techniques which can fit only one primitive, the voting based methods, consisting of mainly the Hough

Ellipse Fitting, Fig. 2

Intersection of lines $\overline{t_{ij}m_{ij}}$ and $\overline{t_{jk}m_{jk}}$ is the center of the ellipse

E

transform, can detect multiple primitives at once. Even for single ellipse fitting, the Hough transform based techniques are more robust against outliers. On the other hand, however, Hough transform usually suffers from a larger computational and memory load, due to the fact that an ellipse involves five parameters. To alleviate the problem, there exist some modifications of the original method.

One popular way to tackle the problem is to decompose the five-dimensional space into several sub-space with lower dimensions, thanks to some special geometric features of ellipse. A common decomposition method is first to locate the center of the ellipse and then to specify the remaining three parameters. The center of an ellipse can be located in several ways, based on different geometric features of ellipse.

One geometric feature of ellipse frequently used is described as follows [10]. Let \mathbf{x}_i and \mathbf{x}_j be the two points on an ellipse, and find their midpoint $\mathbf{m}_{ij} = \frac{1}{2}(\mathbf{x}_i + \mathbf{x}_j)$ and the intersection point \mathbf{t}_{ij} of their tangent lines, as illustrated in Fig. 2. Then, the line connecting the two points \mathbf{m}_{ij} and \mathbf{t}_{ij} is a radial line that passes through the center of the ellipse. That is, any point pairs on an ellipse with unparallel tangents can produce a radial line. Consequently, the center candidates can be located in the following way:

1. generate the radial lines based on every point pairs in the image;

2. define a two-dimensional histogram on $x - y$ plane of the image, and record each radial line by incrementing the histogram bin through which the line passes;
3. find all local maxima in the two-dimensional histogram as the center candidates.

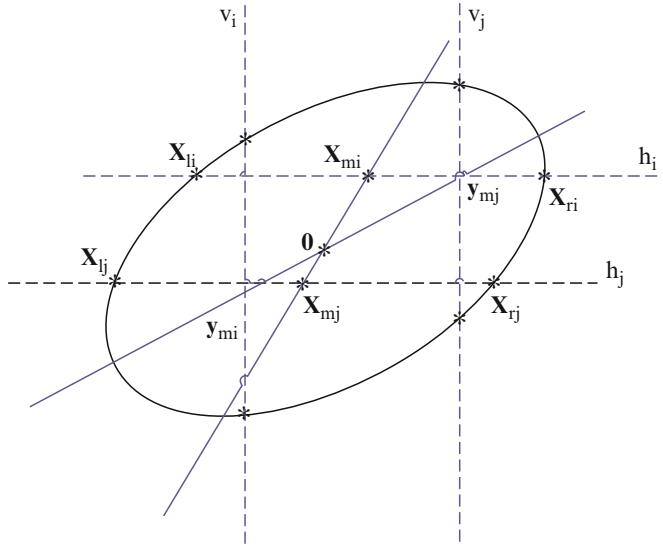

Another interesting feature of ellipse arises from its symmetry [11]. For two horizontal lines h_i and h_j , their intersections with an ellipse are denoted by \mathbf{x}_{li} , \mathbf{x}_{ri} and \mathbf{x}_{lj} , \mathbf{x}_{rj} , respectively, as illustrated in Fig. 3. The line $\overline{\mathbf{x}_{mi}\mathbf{x}_{mj}}$ will pass through the center of the ellipse, where the midpoint $\mathbf{x}_{mi} \triangleq \frac{1}{2}(\mathbf{x}_{li} + \mathbf{x}_{ri})$ and $\mathbf{x}_{mj} \triangleq \frac{1}{2}(\mathbf{x}_{lj} + \mathbf{x}_{rj})$. Similarly, for two vertical lines v_i and v_j , the line $\overline{\mathbf{y}_{mi}\mathbf{y}_{mj}}$ also passes through the center of the ellipse, where line $\overline{\mathbf{y}_{mi}\mathbf{y}_{mj}}$ is gotten in a similar way as $\overline{\mathbf{x}_{mi}\mathbf{x}_{mj}}$. Thus, intersection of the two lines $\overline{\mathbf{x}_{mi}\mathbf{x}_{mj}}$ and $\overline{\mathbf{y}_{mi}\mathbf{y}_{mj}}$ gives the center of the ellipse. Based on the geometric feature, a center detection method is given as follows:

1. fully horizontally scan the image, and find the midpoints \mathbf{m}_{hi} of every possible point pairs on each scanning line;
2. a two-dimensional Hough transform is applied to find all of the lines l_h formed by the midpoints \mathbf{m}_{hi} ($i = 1, 2, \dots$);
3. all lines l_v are found in a similar way as above on vertical scanning;
4. every intersection of l_h and l_v gives a center candidate.

Ellipse Fitting, Fig. 3

Intersection of lines

$\overline{x_{mi}x_{mj}}$ and $\overline{y_{mi}y_{mj}}$ is the center of the ellipse

Once the center candidates have been extracted, detection of the three remaining parameters can be reached through a standard voting process in an accumulator space or can be further decomposed into detection of orientation and semiaxis, respectively. A typical decomposition strategy for the three parameters is to find first axis ratio $\frac{a}{b}$ and orientation ϕ , and then axis length [12]. Axis ratio and orientation satisfy the following relationship:

$$\frac{a^2}{b^2} = \frac{(x_i - x_0) \cos \phi + (y_i - y_0) \sin \phi}{(x_i - x_0) \sin \phi - (y_i - y_0) \cos \phi} \tan(\theta_i - \phi + \frac{\pi}{2}), \quad (18)$$

where θ_i denotes the angle of the tangent line through x_i , and x_0, y_0 have been extracted in the previous stage. Thus, a two-dimensional plane can be built based on Eq. (18) for each point on the ellipse, and consequently the axis ratio and orientation can be estimated by finding the maxima in the plane. It is noted that, for each one center candidate, only the data points that participate in the extraction of center are used in the above voting process.

Finally, ellipse fitting can be accomplished by specifying a or b . Taking a as an example as follows, this satisfies

$$a = \sqrt{(x_i - x_0)^2 + \gamma(y_i - y_0)^2} \quad (19)$$

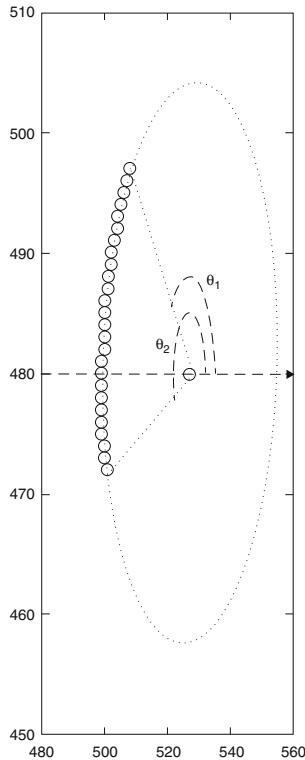

where $\gamma \triangleq \frac{a}{b}$ is gotten in the previous step. Hence, voting on a one-dimensional accumulator by the data points pertaining to each candidate will retrieve the axis length of the target.

There are also some improvements of the Hough transform that are used to alleviate the computational load, such as the randomized Hough transform. Because discussion on the variants of Hough transform is out of the scope of the current entry, readers are referred to some other related entries or some recommended readings such as [13].

Some other developments on voting based fitting are referred to [14, 15].

Arc Finding Based Techniques

Arc finding based techniques accomplish ellipse fitting by finding elliptic arcs in the edge map. Thus, they in general require edge detection as a preprocessing. Arc finding is of particular interest for ellipse fitting, thanks to the fact that any fragment/elliptic arc (longer than five pixels) of an ellipse can retrieve the whole one. This makes such techniques suitable for ellipse fitting in complicated image because it is usually easier to extract arcs than a whole ellipse from an edge map. Arc finding based ellipse fitting generally takes the following three steps: arc finding, arc fitting and grouping, and ellipse fitting.

Ellipse Fitting, Fig. 4 The beginning and ending angles of an elliptic arc

In order to extract ellipse, the arc found should be a *neat* curve without any branches. A simple approach to get neat curve is described as follows [4]: first, a thinning operator is applied to make the edge with one pixel width; second, delete those pixels that have more than two pixels in its 8-neighbor field; finally, a standard chain finding algorithm is used to find neat curves.

Each curve is further fitted by an ellipse, by using a geometric fitting technique mentioned above. The reason for choosing geometric fitting lies in that, first, geometric fitting provides a proper criterion (error measure) to evaluate the curve to be a qualified elliptic arc or not, and second, geometric fitting gives a more accurate result than algebraic fitting and Hough transform on a small elliptic fragment, which is frequently encountered since the neat curve finding tends to break the curves with branches into several shorter ones. Finally, each curve is characterized by an 8-dimensional vector

$$[x_0, y_0, a, b, \phi, e, \theta_1, \theta_2]^T, \quad (20)$$

where $e = \frac{1}{N} \sum_{i=1}^N \mathcal{D}(\Theta, \mathbf{x}_i)^2$ denotes the mean square fitting error and θ_1 and θ_2 denote its beginning and ending angles, i.e., its direction, as illustrated in Fig. 4. The curves whose fitting error is smaller than a pre-defined threshold are chosen as qualified elliptic arcs. The elliptic arcs belonging to one same ellipse are then grouped together according to the following two rules:

- their positions and shapes are close to each other, by the first five parameters;
- they are mutually complementary in direction to form an entire ellipse, by the last two parameters.

During the arc grouping, the data points belonging to each single ellipse are also segmented. Consequently, each ellipse can be finally fitted by least square fitting on these segmented point sets individually.

It is noticed that the arc finding methods employ an integrated framework since its fitting technique comes from least square fitting. However, such integration seems to be unavoidable in real applications, especially in unstructured environments that usually involve heavy noises.

Some other developments on arc finding based techniques are referred to [16, 17].

Open Problems

Statistical bias of algebraic fitting make the fitting results tend to shrink, especially on small fragments or on data points with heavier noises. Although there are some works on general conic fitting to remove the bias [18], discussion on direct ellipse fitting is lacking. Since direct algebraic fitting seems to be the fastest algorithm for ellipse fitting, it is of theoretical and practical significance to make some progress on removing bias in the fitting process.

On the other hand, although there are some methods proposed for ellipse fitting in complicated images, it still remains a big challenge to fit ellipse in uncontrolled real-world environments.

Experimental Results

It is not intended to demonstrate all of the algorithms described above. Only two experimental results are given, with the first one to demonstrate the bias of algebraic fitting on a small elliptic

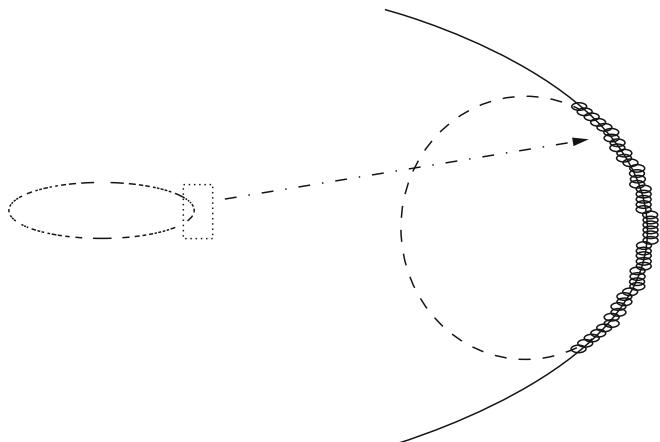

arc and the second one to give one glimpse of state-of-the-art real-world application in noisy environments of ellipse fitting.

Image points used in the first experiments are fetched from a small elliptic fragment, as shown in Fig. 5. The dash ellipse is the fitting result of algebraic fitting, which shrinks to be smaller than the right one as denoted by the bigger solid ellipse that is resulted from geometric fitting.

Two real-world applications of ellipse fitting on holes of gear and blood cells are shown in Figs. 6 and 7, respectively.

Definition

Energy minimization is a subtopic of optimization, where we minimize some energy/cost function by suitable algorithms. The type of energy is twofold: continuous and discrete.

Background

In computer vision problems, we often encounter situations of minimizing energy functions (or cost functions) that are designed to estimate, reconstruct, or process something. There are two major categories of energy minimization. One is that the target can be represented as a vector in the N -dimensional Euclidean space, i.e., the case of continuous energy. For example, if the target is a gray scale image and if each pixel value is handled as a real value, then the image can be treated as an N -dimensional vector, where N is the number of the pixels. The other is that the target takes a discrete value, i.e., the case of discrete energy. A typical example is image segmentation with discrete labels.

The research on continuous energy minimization algorithms has a long history, and there exist many types of algorithms. Roughly speaking, they can be divided into first-order and second-order methods. In general, the convergence rate of second-order methods is faster than that of first-order ones. However, since the dimensions of the problem tend to be large in computer vision applications, first-order methods are mainly used thanks to their scalability. In addition, we often adopt nonsmooth functions, such as ℓ_1 norm, to leverage a-priori knowledge and structure, e.g., sparsity and low-rankness, for characterizing reasonable results. Therefore, minimization algorithms should be flexible in handling such non-smooth functions. In this chapter, we review popular algorithms that satisfy these requirements.

For discrete energy minimization, there are two major algorithms for solving the problem in an exact or approximate manner; one is a graph cut algorithm, and the other is a message propagation algorithm. Each algorithm has a long

history, and their superiority also depends on the formulation of the concrete problem. Hence, it is significant to know an overview of both algorithms to efficiently solve discrete energy minimization problems in computer vision. This chapter also summarizes the procedure of these algorithms and some simple guidelines for choosing them.

Continuous Energy Minimization

Theory and Method

Basic Tools

A function $f : \mathbb{R}^N \rightarrow (-\infty, \infty]$ is said to be convex if $\forall \mathbf{x}, \mathbf{y} \in \mathbb{R}^N$ and $\lambda \in (0, 1)$, $f(\lambda \mathbf{x} + (1 - \lambda) \mathbf{y}) \leq \lambda f(\mathbf{x}) + (1 - \lambda) f(\mathbf{y})$. We also introduce the proximity operator (or proximal mapping) [2] of a convex function f as follows:

$$\text{prox}_{\gamma f}(\mathbf{y}) := \underset{\mathbf{x}}{\operatorname{argmin}} f(\mathbf{x}) + \frac{1}{2\gamma} \|\mathbf{y} - \mathbf{x}\|^2, \quad (1)$$

where $\gamma > 0$. We call f proximable if the proximity operator of f can be computed efficiently. A typical example is the ℓ_1 norm, i.e., $f(\mathbf{x}) = \|\mathbf{x}\|_1 := \sum_{i=1}^N |x_i|$. In this case the proximity operator is reduced to the so-called soft-thresholding operator, given by

$$[\text{prox}_{\gamma \|\cdot\|_1}(\mathbf{x})]_i = \text{sign}(x_i) \max\{|x_i| - \gamma, 0\}. \quad (2)$$

In what follows, we introduce the so-called proximal splitting algorithms, which have been used in many computer vision applications. Basically, we assume that energies to be minimized are convex. It should be noted that these algorithms can also be applied to nonconvex energies, but in this case their global convergence is not guaranteed in general.

Proximal Gradient Method

Consider the following minimization problem:

$$\min_{\mathbf{x}} f(\mathbf{x}) + g(\mathbf{x}), \quad (3)$$

where f is a smooth convex function and its gradient ∇f is β -Lipschitz continuous ($\beta > 0$) and g is a proximable convex function. The proximal gradient method (or proximal forward-backward splitting method) [8, 17] solves Prob. (3) by the following procedure: for given $\gamma \in (0, \frac{2}{\beta})$ and $\mathbf{x}^{(0)}$, iterate

$$\mathbf{x}^{(n+1)} := \text{prox}_{\gamma g}(\mathbf{x}^{(n)} - \gamma \nabla f(\mathbf{x}^{(n)})). \quad (4)$$

E

If we set $g := 0$, then the algorithm is reduced to the well-known steepest descent method. The proximal gradient method can be accelerated by Nesterov's optimal gradient scheme, where the resulting algorithm is called FISTA [3].

Alternating Direction Method of Multipliers

Consider a more involved minimization problem:

$$\min_{\mathbf{x}} f(\mathbf{x}) + g(\mathbf{L}\mathbf{x}), \quad (5)$$

where f is a quadratic function, g is a proximable convex function, and \mathbf{L} is a linear operator (or simply a matrix). We show the algorithm of the alternating direction method of multipliers (ADMM) [4, 10] for solving Prob. (5) as follows: for given $\gamma > 0$, $\mathbf{y}^{(0)}$ and $\mathbf{z}^{(0)}$, iterate

$$\begin{cases} \mathbf{x}^{(n+1)} = \underset{\mathbf{x}}{\operatorname{argmin}} f(\mathbf{x}) + \frac{1}{2\gamma} \|\mathbf{z}^{(n)} - \mathbf{L}\mathbf{x} - \mathbf{y}^{(n)}\|^2 \\ \mathbf{z}^{(n+1)} = \text{prox}_{\gamma g}(\mathbf{L}\mathbf{x}^{(n+1)} + \mathbf{y}^{(n)}) \\ \mathbf{y}^{(n+1)} = \mathbf{y}^{(n)} + \mathbf{L}\mathbf{x}^{(n+1)} - \mathbf{z}^{(n+1)} \end{cases}. \quad (6)$$

In Algorithm (6), step 1 is the minimization of the sum of g and a quadratic function. We should note that the matrix \mathbf{L} is applied to the objective variable \mathbf{x} in the quadratic function. If \mathbf{L} is an identity matrix \mathbf{I} , then from the definition of the proximity operator, step 1 is identical to $\text{prox}_{\gamma f}$. However, in many cases we have to treat $\mathbf{L} \neq \mathbf{I}$, so f must be a quadratic or simpler function in order to solve this subproblem in closed form. Even for such a simple f , we need to calculate the operator inversion associated with \mathbf{L} , which might be computational bottleneck.

Primal-Dual Splitting Method

Consider a more general case of Prob. (5), where f is (possibly) nonsmooth but proximable. A primal-dual splitting method (or primal-dual hybrid gradient method) [7] can handle the case by the following algorithm: for given $\gamma_1, \gamma_2 > 0$ satisfying $\gamma_1\gamma_2\|\mathbf{L}\|^2 < 1$, $\mathbf{x}^{(0)}$ and $\mathbf{y}^{(0)}$, iterate

$$\begin{cases} \mathbf{x}^{(n+1)} = \text{prox}_{\gamma_1 g}(\mathbf{x}^{(n)} - \gamma_1 \mathbf{L}^\top \mathbf{y}^{(n)}) \\ \mathbf{y}^{(n+1)} = \text{prox}_{\gamma_2 h^*}(\mathbf{y}^{(n)} + \gamma_2 \mathbf{L}(2\mathbf{x}^{(n+1)} - \mathbf{x}^{(n)})) \end{cases} \quad (7)$$

Here, $\|\mathbf{L}\|$ is the operator norm of \mathbf{L} . The function h^* is the convex conjugate of h , and its proximity operator can be computed via the proximity operator of h as follows:

$$\text{prox}_{\gamma h^*}(\mathbf{x}) = \mathbf{x} - \gamma \text{prox}_{\frac{1}{\gamma} h}(\frac{1}{\gamma} \mathbf{x}). \quad (8)$$

It is worth noting that the algorithm does not require any operator inversion associated with \mathbf{L} , which is a clear advantage over ADMM. On the other hand, the empirical convergence speed of the primal-dual splitting method is a bit slower than that of ADMM.

Application

LASSO

Let us consider the following linear regression model:

$$\mathbf{y} = \mathbf{X}\bar{\boldsymbol{\beta}} + \mathbf{n}, \quad (9)$$

where $\bar{\boldsymbol{\beta}}$ is an unknown parameter vector we wish to estimate/learn, \mathbf{X} is a feature matrix, \mathbf{y} is an observation vector, and \mathbf{n} is an error vector. Here we assume that $\bar{\boldsymbol{\beta}}$ is sparse, meaning that only a few number of entries of $\bar{\boldsymbol{\beta}}$ have large absolute values and the others are exactly or nearly zero.

Then, LASSO (least absolute shrinkage and selection operator) [21] estimates $\bar{\boldsymbol{\beta}}$ by solving the following convex optimization problem:

$$\min_{\boldsymbol{\beta}} \frac{1}{2} \|\mathbf{X}\boldsymbol{\beta} - \mathbf{y}\|^2 + \lambda \|\boldsymbol{\beta}\|_1, \quad (10)$$

where the first term is the least-square criterion and the second term is a sparse regularization via

the ℓ_1 norm, i.e., the sum of the absolute values of the entries of $\boldsymbol{\beta}$. The hyperparameter $\lambda > 0$ controls the degree of sparsity.

Although the structure of Prob. (10) appears to be simple at first glance, it cannot be solved by gradient descent-type algorithms because the ℓ_1 norm is not differentiable. In addition, in computer vision applications, the dimension of $\boldsymbol{\beta}$ is often very large, which limits the use of algorithms that require complex procedures.

This difficult situation was broken by the so-called iterative shrinkage and thresholding algorithm (ISTA) [9], known as a typical realization of the proximal gradient method. By setting $f(\boldsymbol{\beta}) := \frac{1}{2} \|\mathbf{X}\boldsymbol{\beta} - \mathbf{y}\|^2$ and $g(\boldsymbol{\beta}) := \|\boldsymbol{\beta}\|_1$ in Prob. (3), ISTA is given by

$$\boldsymbol{\beta}^{(n+1)} = \text{prox}_{\gamma\lambda\|\cdot\|_1}(\boldsymbol{\beta}^{(n)} - \gamma(\mathbf{X}^\top \mathbf{X}\boldsymbol{\beta}^{(n+1)} - \mathbf{X}^\top \mathbf{y})), \quad (11)$$

where the proximity operator of the ℓ_1 norm is reduced to the soft-thresholding operation in (2).

LASSO and its extensions, such as group LASSO and fused LASSO, have been widely used in computer vision applications, for example, sparse coding [14], foreground modeling [22], and saliency detection [19].

Total Variation Regularization

Regularization for natural images plays an important role in many low-level computer vision problems, such as denoising/smoothing, deblurring, and computational imaging.

Total variation (TV) [18] would be one of the most popular regularization techniques, which is defined, for an image $\mathbf{u} \in \mathbb{R}^N$ of N pixels, by

$$\text{TV}(\mathbf{u}) := \|\mathbf{Du}\|_{1,2} = \sum_{i=1}^N \sqrt{d_{v,i}^2 + d_{h,i}^2}, \quad (12)$$

where $\mathbf{D} : \mathbb{R}^N \rightarrow \mathbb{R}^{2N}$ is a local difference operator and $d_{v,i}$ and $d_{h,i}$ are the local vertical and horizontal differences at the i -th pixel, respectively. Here, $\|\cdot\|_{1,2}$ denotes the mixed $\ell_{1,2}$ norm, which is used for taking the ℓ_2 norm of the two differences at each pixel and then summing them up by the ℓ_1 norm. TV models

piecewise-smooth structure in natural images, i.e., only differences around edges take large absolute values and otherwise nearly zero.

Consider imaging inverse problems of the form:

$$\mathbf{v} = \Phi \bar{\mathbf{u}} + \mathbf{n}, \quad (13)$$

where $\bar{\mathbf{u}}$ is a latent image we wish to estimate, Φ is a matrix representing observation/degradation process, \mathbf{n} is a sensor noise, and \mathbf{v} is an observation vector.

Then, total variation regularization for imaging is formulated as follows:

$$\min_{\mathbf{u}} \frac{1}{2} \|\Phi \mathbf{u} - \mathbf{v}\|^2 + \lambda \text{TV}(\mathbf{u}), \quad (14)$$

where the first term is ℓ_2 data-fidelity and $\lambda > 0$ controls the smoothness of the estimated image.

$$\begin{cases} \mathbf{u}^{(n+1)} = \underset{\mathbf{u}}{\operatorname{argmin}} \frac{1}{2} \|\Phi \mathbf{u} - \mathbf{v}\|^2 + \frac{1}{2\gamma} \|\mathbf{z}^{(n)} - \mathbf{D}\mathbf{u} - \mathbf{y}^{(n)}\|^2 \\ \mathbf{z}^{(n+1)} = \operatorname{prox}_{\gamma \lambda \|\cdot\|_{1,2}}(\mathbf{D}\mathbf{u}^{(n+1)} + \mathbf{y}^{(n)}) \\ \mathbf{y}^{(n+1)} = \mathbf{y}^{(n)} + \mathbf{D}\mathbf{u}^{(n+1)} - \mathbf{z}^{(n+1)} \end{cases}. \quad (18)$$

The update of \mathbf{u} is reduced to a quadratic minimization, where we need to solve matrix inversion involving $\Phi^\top \Phi + \frac{1}{\gamma} \mathbf{D}^\top \mathbf{D}$. This can be efficiently calculated if the matrix can be diagonalized via a fast transform, e.g., FFT. Otherwise, this step might be a computational bottleneck because the size of the matrix is very large in imaging applications. The update of \mathbf{z} is the computation of the proximity operator of the $\ell_{1,2}$ norm, which is equivalent to a group-wise soft-thresholding operation. The general form is given as follows:

$$[\operatorname{prox}_{\gamma \|\cdot\|_{1,2}}(\mathbf{x})]_{\mathfrak{g}} = \max \left\{ 1 - \frac{\gamma}{\|\mathbf{x}_{\mathfrak{g}}\|}, 0 \right\} \mathbf{x}_{\mathfrak{g}}, \quad (19)$$

where $\mathbf{x}_{\mathfrak{g}}$ denotes a non-overlapped subvector of \mathbf{x} with an index \mathfrak{g} (\mathfrak{G} is the set of all indices). In the TV regularization case, each subvector consists of the vertical and horizontal differences at each pixel, i.e., $\mathbf{x}_{\mathfrak{g}} \in \mathbb{R}^2$.

Since this problem looks similar to Prob. (10), one may think that this problem can also be solved by the proximal gradient method. However, Prob. (14) is indeed much more difficult than Prob. (10) because the proximity operator of TV cannot be computed in closed form. Fortunately, ADMM and the primal-dual splitting method can handle such a problem by leveraging the matrix \mathbf{L} in (5).

Specifically, in the case of ADMM, by letting

$$f(\mathbf{u}) := \frac{1}{2} \|\Phi \mathbf{u} - \mathbf{v}\|^2, \quad (15)$$

$$g(\mathbf{z}) := \lambda \|\mathbf{z}\|_{1,2}, \quad (16)$$

$$\mathbf{L} := \mathbf{D}, \quad (17)$$

the resulting algorithm is given by

In the case of the primal-dual splitting method, by letting

$$f(\mathbf{u}) := 0, \quad (20)$$

$$g(\mathbf{y}_1, \mathbf{y}_2) := \frac{1}{2} \|\mathbf{y}_1 - \mathbf{v}\|^2 + \lambda \|\mathbf{y}_2\|_{1,2}, \quad (21)$$

$$\mathbf{L} := (\Phi^\top \mathbf{D}^\top)^\top, \quad (22)$$

the resulting algorithm is given by

$$\begin{cases} \mathbf{u}^{(n+1)} = \mathbf{u}^{(n)} - \gamma_1 (\Phi^\top \mathbf{y}_1^{(n)} + \mathbf{D}^\top \mathbf{y}_2^{(n)}) \\ \tilde{\mathbf{y}}_1^{(n+1)} = \mathbf{y}_1^{(n)} + \gamma_2 \Phi (2\mathbf{u}^{(n+1)} - \mathbf{u}^{(n)}) \\ \tilde{\mathbf{y}}_2^{(n+1)} = \mathbf{y}_2^{(n)} + \gamma_2 \mathbf{D} (2\mathbf{u}^{(n+1)} - \mathbf{u}^{(n)}) \\ \mathbf{y}_1^{(n+1)} = \tilde{\mathbf{y}}_1^{(n+1)} - \gamma_2 \operatorname{prox}_{\frac{1}{2\gamma_2} \|\cdot\|^2} (\frac{1}{\gamma_2} \tilde{\mathbf{y}}_1^{(n+1)}) \\ \mathbf{y}_2^{(n+1)} = \tilde{\mathbf{y}}_2^{(n+1)} - \gamma_2 \operatorname{prox}_{\frac{\lambda}{\gamma_2} \|\cdot\|_{1,2}} (\frac{1}{\gamma_2} \tilde{\mathbf{y}}_2^{(n+1)}) \end{cases}. \quad (23)$$

The update of \mathbf{y}_1 is reduced to a very simple quadratic minimization without matrix inversion, and the update of \mathbf{y}_2 is given in (19). What should

be noted is that this algorithm is completely free from matrix inversion unlike the ADMM case.

The extensions of TV to color and multichannel images have been widely studied in the computer vision field [6, 11, 16], and these advanced regularization methods can also be optimized by ADMM and the primal-dual splitting method.

Discrete Energy Minimization

Theory and Method

We introduce the algorithms for minimizing a discrete energy function used in computer vision. Although obtaining a global optimum solution of a discrete energy function is generally hard, if a given discrete energy function satisfies several conditions described later, the global optimal solution for the minimization problem can be computed in polynomial time with “graph cut” and “min-sum.” Also, even if the given discrete energy function does not satisfy these conditions, the minimization problem of the energy function can be approximately solved by applying the above-mentioned algorithms.

To solve the discrete minimization problem using these algorithms, we need to design a discrete energy function to which the above methods can be applied. In the following we discuss the form of the discrete energy function which is a premise of these algorithms. Suppose N variables and define the set of them as $x = \{x_1, x_2, \dots, x_N\}$. Using these variables we also introduce an undirected graph representing the correlation between variables as $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$. $\mathcal{V} = \{1, \dots, N\}$ represents a set of nodes, and each element of \mathcal{V} corresponds to the index of variable x_i . $(i, j) \in \mathcal{E}$ represents a set of edges in the graph. If there is an edge between nodes i and j , it indicates that they have an influence on each other. With this graph notation, a discrete energy function can be represented by

$$E(x) = \sum_{i \in \mathcal{V}} f_i(x_i) + \sum_{(i, j) \in \mathcal{E}} f_{ij}(x_i, x_j), \quad (24)$$

where $f_i(x_i)$ is called “data term” or “unary potential” and defines how each node is easy to

take state x_i . $f_{ij}(x_i, x_j)$ is called a “smoothness term” or “pairwise potential” and describes the relationship between nodes i and j . The discrete algorithms introduced in the following focus on the minimization problem of energy functions defined in this way.

Graph Cut

Graph Cuts are well-known algorithms for efficiently solving discrete energy function minimization problems [5]. Originally, in the domain of graph theory, several algorithms such as Edmonds-Karp and Ford-Fulkerson were known as methods for efficiently solving the minimum cut problem of a flow network. Graph cut focuses on these algorithms, replaces the minimization problem of the discrete energy function with the minimum cut problem of the equivalent flow network, and solves the energy minimization problem indirectly by applying the above algorithms.

One of the interesting properties of graph cuts is that if the given discrete energy function satisfies a specific condition, its global optimum can be efficiently computed. Suppose a discrete energy function where all variables in a graph take binary values (i.e., $x_i \in \{0, 1\}$ for all i). If the smoothing term $f_{ij}(x_i, x_j)$ satisfies the following inequality, the global optimum of the energy function can be obtained with the graph cut algorithms:

$$f_{ij}(0, 0) + f_{ij}(1, 1) \leq f_{ij}(0, 1) + f_{ij}(1, 0) \quad (25)$$

The energy function that satisfies the above inequality is called a “submodular” energy function.

If the given energy function satisfies the above condition, the energy function of any binary energy function can be transformed into a flow network. See [13] for the specific method of this transformation.

Min-Sum Algorithm

Min-sum is a type of generalized algorithm called belief propagation and finds the minimization

problem of a given energy function exactly (or approximately).

All the algorithms of belief propagation including min-sum indirectly solve problems by computing an abstract function on an edge of an undirected graph of a given graphical model called “message.” Specifically, in the belief propagation, there exist two messages $m_{ij}(x_j)$ and $m_{ji}(x_i)$ at the edge on nodes i and j . By computing these messages according to the updating equation described later, we can solve the minimization problem of the given energy function.

As an important property of the belief propagation, it is well-known that the belief propagation can compute the exact solution if the given graphical model does not contain any loops (i.e., the graph has a tree structure). Also, even if the given graphical model contains loops, it is empirically known that it can compute the approximate solution by updating all the messages iteratively according to a specific procedure.

Application

α Expansion, $\alpha\text{-}\beta$ Swap

Even when a given energy function is multi-label energy function where each variable takes L discrete values represented as $x_i \in \{1, \dots, L\}$, we can compute the approximate solution of this minimization problem by iteratively applying graph cut algorithms for binary energy function.

One of the most famous algorithms is α expansion. The α expansion first initializes all x_i 's with appropriate values and then solves the binary problem of whether the current x_i is in the current state or transitions to α . That is, while x_i takes a discrete L value in the original energy function, α expansion gives this x_i a new constraint where it can only take the current value or α . Repeating this procedure until convergence while changing α , we finally obtain an approximate solution of the discrete energy function.

Since the converted binary energy functions used in α expansion also needs to fulfill the submodular condition, regarding α expansion the smoothness term must be satisfied the following inequality for all x_i , x_j , and α :

$$f_{ij}(x_i, x_j) + f_{ij}(\alpha, \alpha) \leq f_{ij}(x_i, \alpha) + f_{ij}(\alpha, x_j). \quad (26)$$

Similar to α expansion, $\alpha\text{-}\beta$ is another famous algorithm for approximately solving the minimization problem of the discrete energy function by choosing the target label appropriately for each iteration. The specific procedure is as follows. First, it initializes all x_i 's with appropriate values. Next, it chooses the two labels represented by α and β , extracts variables in which the current value is α or β , and solves the binary optimization problem of whether the current x_i is in the current state or transition to a different state. Finally, it repeats this procedure until convergence while changing α and β .

E

Min-Sum in the Case Where Graph Is a Tree Structure

As we described before, the min-sum is an algorithm for finding the value that minimizes the given energy function. The min-sum algorithm can be derived by specialization of generalized distributive law [1] or taking the limit on a temperature parameter of sum-product algorithm [12]. For simplicity, we only describe the process of computing messages. Suppose that there is an undirected edge between node i and j . The min-sum algorithm defines a directed message $m_{ij}(x_j)$ from i to j and another directed message $m_{ji}(x_i)$ from j to i . These messages can be computed by the following equation:

$$\begin{aligned} m_{ij}(x_j) &\leftarrow \min_{x_i} f_i(x_i) + f_{ij}(x_i, x_j) \\ &+ \sum_{k \in \mathcal{N}_{i \setminus j}} m_{ki}(x_i), \end{aligned} \quad (27)$$

where \mathcal{N}_i is a set of nodes adjacent to node j . Thus, $\mathcal{N}_{i \setminus j}$ means a set obtained by removing j from \mathcal{N}_i .

The computation of the messages is divided into the following two paths: (i) a path in which the message propagates from the leaf node to the root and (ii) a path in which the message propagates from the root node to the leaf. If the node i is a leaf, the message m_{ij} can be computed exactly since $\mathcal{N}_{i \setminus j}$ in Equation (27) is an empty

set. Once m_{ij} is determined, the message from leaf node to root can be calculated from this message as well. After repeating these procedures and calculating all messages from leaves to the root, the min-sum algorithm computes messages from the root to leaves in the same manner.

Finally, it computes \mathbf{x}^* that minimizes the given energy function from all the messages. The element of node i of \mathbf{x}^* can be computed by

$$x_i^* = \operatorname{argmin}_{x_i} f_i(x_i) + \sum_{k \in \mathcal{N}_i} m_{ki}(x_i). \quad (28)$$

The Viterbi algorithm is known as an algorithm for MAP estimation of hidden Markov models, and it is equivalent to the min-sum algorithm in the case where the graph is a chain. That is, the min-sum algorithm can also be regarded as a generalization of the Viterbi algorithm.

Loopy Belief Propagation

The belief propagation was originally proposed as an algorithm for a graphical model without a loop, but later Murphy et al. pointed out that it is possible to get an approximate solution by iteratively repeating the procedure similar to the belief propagation even for a graphical model containing loops. This method is generally called “loopy belief propagation” (LBP).

We describe the concrete procedure of LBP. The LBP first initializes all the messages m_{ij} with appropriate distributions. Next, it updates all messages according to the Equation (27) and repeats this procedure a number of times until the messages converge. Finally, it estimates the minimum value of the given energy function with Equation (28).

The convergence of messages in the LBP-based methods, including the min-sum algorithm, is not generally guaranteed. Thus, depending on the structure of the graphical model, the message update by Equation (27) may oscillate without convergence.

Comparison Between Graph Cut and Min-Sum Algorithm

Graph cut and min-sum have different strength areas. The min-sum algorithm can find a global

optimal solution of the minimization problem regardless of the property of the energy function if the graphical model is a tree structure. On the other hand, if the energy function is binary and satisfies the above submodularity, the graph cut can find the global optimum regardless of the structure of the graphical model.

It is reported that the graph cut showed better performance than min-sum in the area where both algorithms do not work well, i.e., when the energy function is a multi-valued one and the corresponding graphical model contains loops [15]. However, when using tree-reweighted belief propagation (an extension of min-sum), its performance is comparable to that of the graph cut.

When solving real problems in computer vision, how to design data terms and smoothness terms is often more important than which algorithm to use [20]. In particular, the design of the data terms has a major impact on the overall performance, so many practical studies in computer vision focuses on the data term, and actual optimization itself uses graph cut or min-sum.

Definition

Epipolar constraint states that in stereovision with two cameras, given a point in one image, its corresponding point in the other image must lie on a line, known as the *epipolar line*. This constraint arises from the fact that the pair of corresponding image points and the optical centers of the two cameras must lie on a plane (known as *coplanarity constraint*), and the intersection of this plane with the image plane is the epipolar line.

Definition

Epipolar geometry describes the geometric relationship between two camera systems. It is captured by a 3×3 matrix known as *essential matrix* for calibrated cameras and as *fundamental matrix* for uncalibrated cameras. It states that for a point observed in one camera, its corresponding point in the other camera must lie on a line. This is known as the *epipolar constraint*. It reduces the search space of correspondences from two dimensions to one dimension. In motion and structure from motion, this constraint is also known as *coplanarity constraint* because the optical centers of the cameras and a pair of corresponding image points must lie in a single plane.

Background

The epipolar geometry exists between any two camera systems. Consider the case of two cameras as shown in Fig. 1. Let C and C' be the optical centers of the first and second cameras, respectively. Given a point \mathbf{m} in the first image, its corresponding point in the second image is constrained to lie on a line called the *epipolar line* of \mathbf{m} , denoted by $\mathbf{l}'_{\mathbf{m}}$. The line $\mathbf{l}'_{\mathbf{m}}$ is the intersection of the plane Π' , defined by \mathbf{m} , C , and C' (known as the *epipolar plane*), with the second image plane \mathcal{I}' . This is because image point \mathbf{m} may correspond to an arbitrary point on the semi-line CM (M may be at infinity) and that the projection of CM on \mathcal{I}' is the line $\mathbf{l}'_{\mathbf{m}}$. Furthermore, one observes that all epipolar lines of the points in the first image pass through a common point \mathbf{e}' , which is called the *epipole*. Epipole \mathbf{e}' is the intersection of the line CC' with the image plane \mathcal{I}' . This can be easily understood as follows. For each point \mathbf{m}_k in the first image \mathcal{I} , its epipolar line $\mathbf{l}'_{\mathbf{m}_k}$ in \mathcal{I}' is the intersection

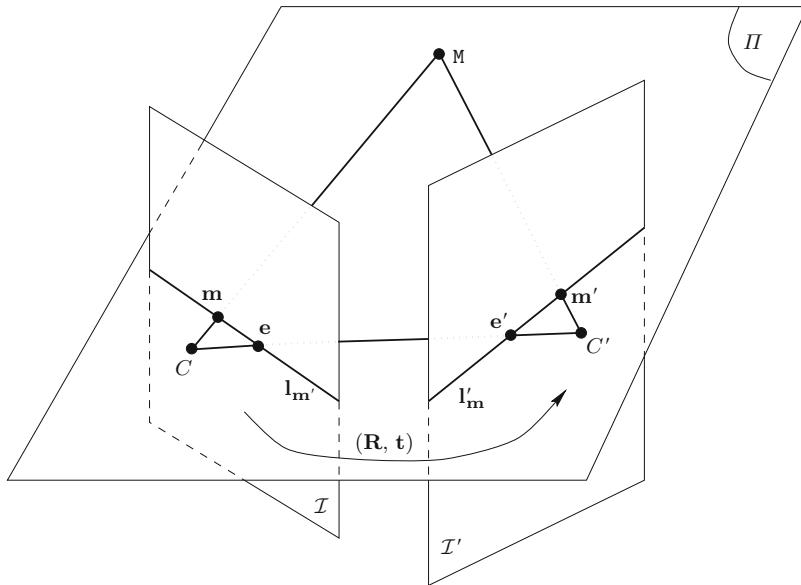

of the plane Π^k , defined by \mathbf{m}_k , C , and C' , with image plane \mathcal{I}' . All epipolar planes Π^k thus form a pencil of planes containing the line CC' . They must intersect \mathcal{I}' at a common point, which is \mathbf{e}' . Finally, one can easily see the symmetry of the epipolar geometry. The corresponding point in the first image of each point \mathbf{m}'_k lying on $\mathbf{l}'_{\mathbf{m}_k}$ must lie on the epipolar line $\mathbf{l}_{\mathbf{m}'_k}$, which is the intersection of the same plane Π^k with the first image plane \mathcal{I} . All epipolar lines form a pencil containing the epipole \mathbf{e} , which is the intersection of the line CC' with the image plane \mathcal{I} . The symmetry leads to the following observation. If \mathbf{m} (a point in \mathcal{I}) and \mathbf{m}' (a point in \mathcal{I}') correspond to a single physical point M in space, then \mathbf{m} , \mathbf{m}' , C , and C' must lie in a single plane. This is the well-known *coplanarity constraint* in solving motion and structure from motion problems when the intrinsic parameters of the cameras are known [1].

The computational significance in matching different views is that for a point in the first image, its correspondence in the second image must lie on the epipolar line in the second image, and then the search space for a correspondence is reduced from 2 dimensions to 1 dimension. This is called the *epipolar constraint*.

If the line linking the two optical centers is parallel to one or both of the image planes, then the epipole in one or both of the images goes to infinity, and the epipolar lines are parallel to each other. Additionally, if the line linking the two optical centers is parallel with the horizontal scanlines of the cameras, then the epipolar lines become horizontal, too. This is the assumption of many stereo algorithms which have horizontal epipolar lines.

Theory

Before proceeding further, the reader is referred to the entry ▶ [“Camera Parameters \(Intrinsic, Extrinsic\)”](#) for the description of camera perspective projection matrix and intrinsic and extrinsic parameters. It is assumed that the reader is familiar with the notation used in that entry.

Epipolar Geometry, Fig. 1 The epipolar geometry

Assume that the second camera is brought from the position of the first camera through a rotation \mathbf{R} followed by a translation \mathbf{t} . Thus, any point (X, Y, Z) in the first camera coordinate system has coordinates (X', Y', Z') in the second camera coordinate system such that

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \mathbf{R} \begin{bmatrix} X' \\ Y' \\ Z' \end{bmatrix} + \mathbf{t} \quad (1)$$

where

$$\mathbf{R} = \begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix} \text{ and } \mathbf{t} = \begin{bmatrix} t_X \\ t_Y \\ t_Z \end{bmatrix}.$$

\mathbf{R} has nine components but there are only three degrees of freedom. There are six constraints on \mathbf{R} . Indeed, a rotation matrix \mathbf{R} must satisfy

$$\mathbf{R}\mathbf{R}^T = \mathbf{I}, \quad (2)$$

and

$$\det(\mathbf{R}) = 1. \quad (3)$$

See, for example [2], for more details on the different representations of the rotation and its properties.

In the following, we first derive the epipolar equation with the normalized image coordinates, then extend it to include the pixel image coordinates, and finally formulate in terms of camera perspective projection matrices.

Working with Normalized Image Coordinates

The two images of a space point $\mathbf{X} = [X, Y, Z]^T$ are $[x, y, 1]^T$ and $[x', y', 1]^T$ in the first and second normalized images, respectively. They are denoted by $\tilde{\mathbf{x}}$ and $\tilde{\mathbf{x}}'$. Let $\mathbf{X}' = [X', Y', Z']^T$ be the coordinates of the same space point in the second camera coordinate system. From the pinhole model, we have

$$\begin{aligned} \tilde{\mathbf{x}} &= \mathbf{X}/Z, \\ \tilde{\mathbf{x}}' &= \mathbf{X}'/Z'. \end{aligned}$$

Eliminating the structure parameters \mathbf{X} and \mathbf{X}' using Eq. (1), we obtain

$$\tilde{\mathbf{x}} = \frac{1}{Z} (\mathbf{Z}' \mathbf{R} \tilde{\mathbf{x}}' + \mathbf{t}),$$

which contains still two unknown structure parameters Z and Z' . The cross product of the above equation with vector \mathbf{t} yields

$$\mathbf{t} \times \tilde{\mathbf{x}} = \frac{Z'}{Z} \mathbf{t} \times \mathbf{R}\tilde{\mathbf{x}}.$$

Its dot product (or inner product) with $\tilde{\mathbf{x}}$ gives

$$\tilde{\mathbf{x}}^T \mathbf{t} \times (\mathbf{R}\tilde{\mathbf{x}}') = 0. \quad (4)$$

Here, the quantity Z'/Z has been removed.

Equation (4) is very important in solving motion and structure from motion. Geometrically, it is very clear. The three vectors CC' , $C\tilde{\mathbf{x}}$, and $C'\tilde{\mathbf{x}}'$ are coplanar. When expressed in the first camera coordinate system, they are equal to \mathbf{t} , $\tilde{\mathbf{x}}$, and $\mathbf{R}\tilde{\mathbf{x}}'$, respectively. The coplanarity of the three vectors implies that their mixed product should be equal to 0, which gives Eq. (4).

Let us define a mapping $[\cdot]_{\times}$ from a 3D vector to a 3×3 *antisymmetric matrix* (also called *skew symmetric matrix*):

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}_{\times} = \begin{bmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{bmatrix}. \quad (5)$$

It is clear that

$$[\mathbf{t}]_{\times} = -[\mathbf{t}]_{\times}^T. \quad (6)$$

Using this mapping, we can express the cross product of two vectors by the matrix multiplication of a 3×3 matrix and a three-vector: $\mathbf{t} \times \tilde{\mathbf{x}} = [\mathbf{t}]_{\times} \tilde{\mathbf{x}}, \forall \tilde{\mathbf{x}}$. Equation (4) can then be rewritten as

$$\tilde{\mathbf{x}}^T \mathbf{E} \tilde{\mathbf{x}}' = 0, \quad (7)$$

where

$$\mathbf{E} = [\mathbf{t}]_{\times} \mathbf{R}. \quad (8)$$

We call this equation the *epipolar equation*.

Matrix \mathbf{E} is known under the name of the *essential matrix*. It was first proposed by Longuet-Higgins [1] for structure from motion. The essential matrix is determined completely

by the rotation and translation between the two cameras. Because $[\mathbf{t}]_{\times}$ is antisymmetric, we have $\det([\mathbf{t}]_{\times}) = 0$. Thus, we have

$$\det(\mathbf{E}) = \det([\mathbf{t}]_{\times}) \det(\mathbf{R}) = 0. \quad (9)$$

For more properties of the essential matrix, see [3, 4].

Before gaining an insight of Eq. (7), we recall how to represent a line in a plane. Any line can be described by an equation of the form

$$ax + by + c = 0. \quad (10)$$

Thus, the line can be represented by a three-vector $\mathbf{l} = [a, b, c]^T$ such that a point $\tilde{\mathbf{x}} = [x, y, 1]^T$ on it must satisfy

$$\tilde{\mathbf{x}}^T \mathbf{l} = 0. \quad (11)$$

Of course, the three-vector \mathbf{l} is only defined up to a scale factor. Multiplying \mathbf{l} by any nonzero scalar λ gives $\lambda\mathbf{l}$, which describes exactly the same line. If a line goes through two given points $\tilde{\mathbf{x}}_1$ and $\tilde{\mathbf{x}}_2$, we have

$$\tilde{\mathbf{x}}_1^T \mathbf{l} = 0 \quad \text{and} \quad \tilde{\mathbf{x}}_2^T \mathbf{l} = 0,$$

and it is easy to see that the line is represented by

$$\mathbf{l} = \tilde{\mathbf{x}}_1 \times \tilde{\mathbf{x}}_2, \quad (12)$$

that is, the cross product of the two point vectors.

For point $\tilde{\mathbf{x}}' = [x', y', 1]^T$ in the second image, its corresponding point X' in space must be on the semi-line $C'X'_{\infty}$ passing through $\tilde{\mathbf{x}}'$, where X'_{∞} is a point at infinity. From the pinhole model, point X' can be represented as

$$X' = \lambda \tilde{\mathbf{x}}' = \lambda \begin{bmatrix} x' \\ y' \\ 1 \end{bmatrix}, \lambda \in (0, \infty).$$

This is in fact the parametric representation of the semi-line $C'X'_{\infty}$. If we express this point in the coordinate system of the first camera, we have

$$X = \mathbf{R}X' + \mathbf{t} = \lambda \mathbf{R}\tilde{\mathbf{x}}' + \mathbf{t}, \lambda \in (0, \infty).$$

The projection of the semi-line $C'X'_\infty$ on the first camera is still a line, denoted by $\mathbf{l}_{x'}$, on which the corresponding point in the first image of point \mathbf{x} must lie. The line $\mathbf{l}_{x'}$ is known as the *epipolar line* of \mathbf{x}' . The epipolar line can be defined by two points. The first point can be obtained by projecting X with $\lambda = 0$, which gives $\tilde{\mathbf{e}} = \frac{1}{t_Z} \mathbf{t}$, where t_Z is the Z-component of the translation vector \mathbf{t} . This is in fact the projection of the optical center C of the second camera on the first camera and is called the *epipole* in the first image. The second point can be obtained by projecting X with $\lambda = \infty$, which gives $\tilde{\mathbf{x}}_\infty = \frac{1}{r_3^T \tilde{\mathbf{x}}'} \mathbf{R} \tilde{\mathbf{x}}'$, where r_3 is the third row of the rotation matrix \mathbf{R} . As described in the last paragraph, the epipolar line $\mathbf{l}_{x'}$ is represented by

$$\mathbf{l}_{x'} = \tilde{\mathbf{e}} \times \tilde{\mathbf{x}}_\infty = \mathbf{t} \times \mathbf{R} \tilde{\mathbf{x}}' = \mathbf{E} \tilde{\mathbf{x}}'. \quad (13)$$

Here we have multiplied the original vector by t_Z and $r_3^T \tilde{\mathbf{x}}'$ because, as we said, a three-vector for a line is only defined up to a scalar factor.

If now we reverse the role of the two cameras, we find that the epipolar geometry is symmetric for the two cameras. For a given point \mathbf{x} in the first image, its corresponding epipolar line in the second image is

$$\mathbf{l}'_{\mathbf{x}} = \mathbf{E}^T \tilde{\mathbf{x}}.$$

It is seen that the transpose of matrix \mathbf{E} , \mathbf{E}^T , defines the epipolar lines in the second image.

From the above discussion, Eq. (7) says nothing more than that point \mathbf{x} is on the epipolar line $\mathbf{l}_{x'}$, that is,

$$\tilde{\mathbf{x}}^T \mathbf{l}_{x'} = 0 \quad \text{with } \mathbf{l}_{x'} = \mathbf{E} \tilde{\mathbf{x}}',$$

or that point \mathbf{x}' is on the epipolar line $\mathbf{l}'_{\mathbf{x}}$, that is,

$$\mathbf{l}'_{\mathbf{x}}^T \tilde{\mathbf{x}}' = 0 \quad \text{with } \mathbf{l}'_{\mathbf{x}} = \mathbf{E}^T \tilde{\mathbf{x}},$$

The epipoles are intersections of all epipolar lines. That is, epipoles satisfy all the epipolar line equations. Let the normalized coordinates of the epipole in the first image be \mathbf{e} . Then, from Eq. (7), \mathbf{e} satisfies

$$\tilde{\mathbf{e}}^T \mathbf{E} \tilde{\mathbf{x}}' = 0 \quad (14)$$

regardless of \mathbf{x}' . This means,

$$\tilde{\mathbf{e}}^T \mathbf{E} = \mathbf{0}^T \quad (15)$$

at anytime. That is,

$$\tilde{\mathbf{e}}^T \mathbf{E} = \tilde{\mathbf{e}}^T [\mathbf{t}]_\times \mathbf{R} = \mathbf{0}^T. \quad (16)$$

E

Since \mathbf{R} is an orthonormal matrix, we have

$$\tilde{\mathbf{e}}^T [\mathbf{t}]_\times = \mathbf{0}. \quad (17)$$

The solution is

$$\tilde{\mathbf{e}} = \left[\frac{t_X}{t_Z}, \frac{t_Y}{t_Z}, 1 \right]^T. \quad (18)$$

This is exactly the projection of the optical center of the second camera onto the first image plane, as we have already explained geometrically. For the second image, we have

$$\mathbf{E} \tilde{\mathbf{e}}' = [\mathbf{t}]_\times \mathbf{R} \tilde{\mathbf{e}}' = \mathbf{0}. \quad (19)$$

Thus,

$$\mathbf{R} \tilde{\mathbf{e}}' = \mathbf{t}. \quad (20)$$

The position of the epipole can then be determined as

$$\tilde{\mathbf{e}}' = \frac{1}{r'_3 \cdot \mathbf{t}} \mathbf{R}^T \mathbf{t} = \left[\frac{\mathbf{r}'_1 \cdot \mathbf{t}}{r'_3 \cdot \mathbf{t}}, \frac{\mathbf{r}'_2 \cdot \mathbf{t}}{r'_3 \cdot \mathbf{t}}, 1 \right]^T, \quad (21)$$

where $\mathbf{r}'_i = [r_{1i}, r_{2i}, r_{3i}]^T$, and $i = 1, 2, 3$ are the column vectors of \mathbf{R} .

For the epipole in the first image to go to infinity, we must have

$$t_Z = 0. \quad (22)$$

This means that the translation of the camera has to be within the focal plane of the first camera. For both epipoles in the two images to go to infinity, then

$$\mathbf{r}'_3 \cdot \mathbf{t} = 0. \quad (23)$$

This implies that the optical center of the first camera lies in the focal plane of the second camera. Furthermore, if we require the two focal planes to be a single one, then besides $t_Z = 0$, r_{13} and r_{23} have to be 0. Since $\mathbf{r}'_i = 1$, we have

$$r_{33} = 1. \quad (24)$$

Thus \mathbf{R} is in the form of

$$\mathbf{E} = [\mathbf{t}]_{\times} \mathbf{R}$$

$$= \begin{bmatrix} 0 & 0 & t_Y \\ 0 & 0 & -t_X \\ -t_Y \cos \theta - t_X \sin \theta & -t_Y \sin \theta + t_X \cos \theta & 0 \end{bmatrix}. \quad (26)$$

If we expand the above equation, it is clear that there is only linear terms of the image coordinates, rather than quadric terms in the original form. That means the epipolar lines are parallel in both images and the orientations are independent of the image points.

Working with Pixel Image Coordinates

If two points \mathbf{m} and \mathbf{m}' , expressed in pixel image coordinates in the first and second camera, are in correspondence, they must satisfy the following equation

$$\tilde{\mathbf{m}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0, \quad (27)$$

where

$$\mathbf{F} = \mathbf{A}^{-T} \mathbf{E} \mathbf{A}^{-1}, \quad (28)$$

and \mathbf{A} and \mathbf{A}' are respectively the of the first and second camera. Equation (27) is easily verified. From the pinhole camera model, the \mathbf{x} are related to the pixel coordinates \mathbf{m} by $\tilde{\mathbf{x}} = \mathbf{A}^{-1} \tilde{\mathbf{m}}$. Plunging it into Eq. (7) yields Eq. (27). This is a fundamental constraint for two pixels to be in correspondence between two images.

As with the normalized image coordinates, the above Eq. (27) can also be derived from the pinhole model. Without loss of generality,

$$\mathbf{R} = \begin{bmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (25)$$

This means that the rotation can be only around the optical axis of the cameras.

Substituting Eq. (22) and (25) for (8), we have

we assume that the world coordinate system coincides with the second camera coordinate system. From the camera perspective projection model, we have

$$s \tilde{\mathbf{m}} = \mathbf{A} [\mathbf{R} \mathbf{t}] \begin{bmatrix} \mathbf{M}' \\ 1 \end{bmatrix}$$

$$s' \tilde{\mathbf{m}}' = \mathbf{A}' [\mathbf{I} \mathbf{0}] \begin{bmatrix} \mathbf{M}' \\ 1 \end{bmatrix}.$$

Eliminating \mathbf{M}' , s , and s' in the above two equations, we obtain, not at all surprising, Eq. (27).

The 3×3 matrix \mathbf{F} is called the *fundamental matrix*. With this fundamental matrix, we can express the epipolar equation for two unnormalized images in the same form as for the normalized images. Since $\det(\mathbf{E}) = 0$,

$$\det(\mathbf{F}) = 0. \quad (29)$$

\mathbf{F} is of rank 2. Besides, it is only defined up to a scalar factor. If \mathbf{F} is multiplied by an arbitrary scalar, Eq. (27) still holds. Therefore, a fundamental matrix has only seven degrees of freedom. There are only seven independent parameters among the nine elements of the fundamental matrix.

We now derive the expression of the epipoles. The epipole \mathbf{e} in the first image is the projection of the optical center C' of the second camera. Since $C' = \mathbf{0}$, from the pinhole model, we have

$$s_e \tilde{\mathbf{e}} = \mathbf{A} [\mathbf{R} \ \mathbf{t}] \begin{bmatrix} 0 \\ 1 \end{bmatrix} = \mathbf{At}, \quad (30)$$

where s_e is a scale factor. Thus, the epipole $\tilde{\mathbf{e}}$ is equal to \mathbf{At} divided by its third element. Similarly, the epipole \mathbf{e}' in the second image is the projection of the optical center C of the first camera. The optical center is determined by

$$\mathbf{A} [\mathbf{R} \ \mathbf{t}] \begin{bmatrix} C \\ 1 \end{bmatrix} = \mathbf{0},$$

which gives

$$C = -\mathbf{R}^{-1}\mathbf{t}.$$

Therefore, the epipole \mathbf{e}' is given by

$$s'_e \tilde{\mathbf{e}}' = \mathbf{A}' [\mathbf{I} \ \mathbf{0}] \begin{bmatrix} C \\ 1 \end{bmatrix} = -\mathbf{A}'\mathbf{R}^{-1}\mathbf{t}, \quad (31)$$

that is, it is equal to $-\mathbf{A}'\mathbf{R}^{-1}\mathbf{t}$ divided by the third element of the vector.

Now we show, for a given point \mathbf{m}' in the second image, how to compute the corresponding epipolar line $\mathbf{l}_{\mathbf{m}'}$ in the first image. It is determined by two points. Besides the epipole \mathbf{e} , we need another point. This point can be the projection of any point $\hat{\mathbf{M}}'$ on the optical ray $\langle C', \tilde{\mathbf{m}}' \rangle$. In particular, we can choose $\hat{\mathbf{M}}'$ such that

$$\tilde{\mathbf{m}}' = \mathbf{A}' [\mathbf{I} \ \mathbf{0}] \begin{bmatrix} \hat{\mathbf{M}}' \\ 1 \end{bmatrix} = \mathbf{A}'\hat{\mathbf{M}}',$$

that is, the scale factor is equal to 1. This gives $\hat{\mathbf{M}}' = \mathbf{A}'^{-1}\tilde{\mathbf{m}}'$. The projection of this point in the first camera, $\hat{\mathbf{m}}$, is given by

$$s_m \tilde{\mathbf{m}} = \mathbf{A} [\mathbf{R} \ \mathbf{t}] \begin{bmatrix} \hat{\mathbf{M}}' \\ 1 \end{bmatrix} = \mathbf{A} (\mathbf{R}\mathbf{A}'^{-1}\tilde{\mathbf{m}}' + \mathbf{t}),$$

where s_m is the scale factor. As already described in Eq. (10) on page 241, a line can be represented

by a three-vector defined *up to a scale factor*. According to Eq. (12), the epipolar line $\mathbf{l}_{\mathbf{m}'}$ is given by

$$\begin{aligned} \mathbf{l}_{\mathbf{m}'} &= s_e s_m \tilde{\mathbf{e}} \times \tilde{\mathbf{m}} \\ &= (\mathbf{At}) \times \left[\mathbf{A} (\mathbf{R}\mathbf{A}'^{-1}\tilde{\mathbf{m}}' + \mathbf{t}) \right] \\ &= (\mathbf{At}) \times (\mathbf{ARA}'^{-1}\tilde{\mathbf{m}}'). \end{aligned}$$

E

It can be shown that $(\mathbf{Ax}) \times (\mathbf{Ay}) = \det(\mathbf{A})\mathbf{A}^{-T}(\mathbf{x} \times \mathbf{y})$ for all vectors \mathbf{x} and \mathbf{y} if matrix \mathbf{A} is invertible. Therefore, we have

$$\mathbf{l}_{\mathbf{m}'} = \mathbf{A}^{-T} \left[\mathbf{t} \times (\mathbf{RA}'^{-1}\tilde{\mathbf{m}}') \right] = \mathbf{F}\tilde{\mathbf{m}'}$$

with \mathbf{F} given by Eq. (28). Then any point \mathbf{m} on the epipolar line of \mathbf{m}' satisfies $\tilde{\mathbf{m}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0$, and this is exactly Eq. (34). Therefore, we obtain geometrically the same equation.

Now we reverse the role of the two images and consider the epipolar line $\mathbf{l}'_{\mathbf{m}}$ in the second image for a given point \mathbf{m} in the first image. Line $\mathbf{l}'_{\mathbf{m}}$ goes through the epipole \mathbf{e}' . We choose the projection of a point $\hat{\mathbf{M}}'$ on the optical ray $\langle C', \tilde{\mathbf{m}}' \rangle$ such that

$$\tilde{\mathbf{m}} = \mathbf{A} [\mathbf{R} \ \mathbf{t}] \begin{bmatrix} \hat{\mathbf{M}}' \\ 1 \end{bmatrix},$$

that is, the scale factor is chosen to be 1. This gives

$$\hat{\mathbf{M}}' = (\mathbf{AR})^{-1}(\tilde{\mathbf{m}} - \mathbf{At}).$$

Its projection in the second camera gives

$$\begin{aligned} s'_m \tilde{\mathbf{m}}' &= \mathbf{A}' [\mathbf{I} \ \mathbf{0}] \begin{bmatrix} \hat{\mathbf{M}}' \\ 1 \end{bmatrix} \\ &= \mathbf{A}'(\mathbf{AR})^{-1}(\tilde{\mathbf{m}} - \mathbf{At}) \\ &= \mathbf{A}'\mathbf{R}^{-1}\mathbf{A}^{-1}\tilde{\mathbf{m}} - \mathbf{A}'\mathbf{R}^{-1}\mathbf{t}. \end{aligned}$$

The epipolar line $\mathbf{l}'_{\mathbf{m}}$ is thus represented by

$$\begin{aligned}
\mathbf{l}'_{\mathbf{m}} &= s'_e s'_m \tilde{\mathbf{e}}' \times \tilde{\mathbf{m}}', & \mathbf{F} \tilde{\mathbf{e}}' = \mathbf{0} & \quad (33) \\
&= -(\mathbf{A}' \mathbf{R}^{-1} \mathbf{t}) \times (\mathbf{A}' \mathbf{R}^{-1} \mathbf{A}^{-1} \tilde{\mathbf{m}}) & \text{or} \\
&= -(\mathbf{A}' \mathbf{R}^{-1})^{-T} (\mathbf{t} \times \mathbf{A}^{-1} \tilde{\mathbf{m}}) \\
&= -\mathbf{A}'^{-T} \mathbf{R}^T [\mathbf{t}]_{\times} \mathbf{A}^{-1} \tilde{\mathbf{m}} \\
&= \mathbf{F}^T \tilde{\mathbf{m}}.
\end{aligned}$$

In the above, we have used the following properties:

- $(\mathbf{Ax}) \times (\mathbf{Ay}) = \det(\mathbf{A}) \mathbf{A}^{-T} (\mathbf{x} \times \mathbf{y})$, $\forall \mathbf{x}, \mathbf{y}$ if matrix \mathbf{A} is invertible.
- $(\mathbf{AB})^{-1} = \mathbf{B}^{-1} \mathbf{A}^{-1}$ if matrices \mathbf{A} and \mathbf{B} are invertible.
- $\mathbf{R}^T = \mathbf{R}^{-1}$ if \mathbf{R} is a rotation matrix.
- $[\mathbf{t}]_{\times}^T = -[\mathbf{t}]_{\times}$ if $[\mathbf{t}]_{\times}$ is an antisymmetric matrix.

It is thus clear that if \mathbf{F} describes epipolar lines in the first image for points given in the second image, then \mathbf{F}^T describes epipolar lines in the second image for points given in the first image. The two images play a symmetric role in the epipolar geometry.

We now compute the epipoles from a different point of view. By definition, all epipolar lines in the first image go through the epipole \mathbf{e} . This implies

$$\tilde{\mathbf{e}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0, \quad \forall \mathbf{m}',$$

or in vector equation form

$$\mathbf{F}^T \tilde{\mathbf{e}} = \mathbf{0}. \quad (32)$$

Plugging Eq. (28) into the above equation gives

$$\mathbf{A}'^{-T} \mathbf{R}^T [\mathbf{t}]_{\times} \mathbf{A}^{-1} \tilde{\mathbf{e}} = \mathbf{0}.$$

Because $[\mathbf{t}]_{\times} \mathbf{t} = \mathbf{0}$, up to a scale factor, we have $s_e \mathbf{A}^{-1} \tilde{\mathbf{e}} = \mathbf{t}$, and thus $s_e \tilde{\mathbf{e}} = \mathbf{At}$. This is exactly Eq. (30). Similarly, for the epipole \mathbf{e}' in the second image, we have

or

$$\mathbf{A}'^{-T} [\mathbf{t}]_{\times} \mathbf{R} \mathbf{A}'^{-1} \tilde{\mathbf{e}}' = \mathbf{0}.$$

This gives $s'_e \mathbf{R} \mathbf{A}'^{-1} \tilde{\mathbf{e}}' = -\mathbf{t}$, or $s'_e \tilde{\mathbf{e}}' = -\mathbf{A}' \mathbf{R}^{-1} \mathbf{t}$. This is exactly Eq. (31).

Working with Camera Perspective Projection Matrices

In several applications, for example, in the case of calibrated stereo, the camera perspective projection matrices are given, and we want to compute the epipolar geometry. Let \mathbf{P} and \mathbf{P}' be the projection matrices of the first and second camera. Furthermore, the 3×4 matrix \mathbf{P} is decomposed as the concatenation of a 3×3 submatrix \mathbf{B} and a three-vector \mathbf{b} , that is, $\mathbf{P} = [\mathbf{B} \ \mathbf{b}]$. Similarly, $\mathbf{P}' = [\mathbf{B}' \ \mathbf{b}']$.

From the pinhole model, we have

$$\begin{aligned}
s \tilde{\mathbf{m}} &= [\mathbf{B} \ \mathbf{b}] \begin{bmatrix} \mathbf{M}' \\ 1 \end{bmatrix} \\
s' \tilde{\mathbf{m}}' &= [\mathbf{B}' \ \mathbf{b}'] \begin{bmatrix} \mathbf{M}' \\ 1 \end{bmatrix}.
\end{aligned}$$

Assume that \mathbf{B} and \mathbf{B}' are invertible, we can compute \mathbf{M}' from each of the above equations:

$$\begin{aligned}
\mathbf{M}' &= s \mathbf{B}^{-1} \tilde{\mathbf{m}} - \mathbf{B}^{-1} \mathbf{b} \\
\mathbf{M}' &= s' \mathbf{B}'^{-1} \tilde{\mathbf{m}}' - \mathbf{B}'^{-1} \mathbf{b}'.
\end{aligned}$$

The right sides of the above equations must be equal, which gives

$$s \mathbf{B}^{-1} \tilde{\mathbf{m}} = s' \mathbf{B}'^{-1} \tilde{\mathbf{m}}' + \mathbf{B}'^{-1} \mathbf{b} - \mathbf{B}'^{-1} \mathbf{b}'.$$

Multiplying both sides by \mathbf{B} gives

$$s \tilde{\mathbf{m}} = s' \mathbf{B} \mathbf{B}'^{-1} \tilde{\mathbf{m}}' + \mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}'.$$

Performing a cross product with $\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}'$ yields

$$\begin{aligned} s \left(\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}' \right) \times \tilde{\mathbf{m}} \\ = s' \left(\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}' \right) \times \mathbf{B} \mathbf{B}'^{-1} \tilde{\mathbf{m}}'. \end{aligned}$$

Eliminating the arbitrary scalars s and s' by multiplying $\tilde{\mathbf{m}}^T$ from the left (i.e., dot product) gives

$$\tilde{\mathbf{m}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0, \quad (34)$$

where

$$\mathbf{F} = \left[\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}' \right]_{\times} \mathbf{B} \mathbf{B}'^{-1}. \quad (35)$$

We thus obtain the epipolar equation in terms of the perspective projection matrices. Again, it is clear that the roles of \mathbf{m} and \mathbf{m}' are symmetric, and we have $\tilde{\mathbf{m}}'^T \mathbf{F}^T \tilde{\mathbf{m}} = 0$.

Now let us show how to compute the epipoles. The epipole \mathbf{e} in the first image is the projection of the optical center C' of the second camera, and the optical center C is given by

$$C' = -\mathbf{B}'^{-1} \mathbf{b}'.$$

We thus have

$$s_e \tilde{\mathbf{e}} = \mathbf{P} \begin{bmatrix} C' \\ 1 \end{bmatrix} = \mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}', \quad (36)$$

where s_e is a scale factor. Thus, epipole \mathbf{e} is equal to $(\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}')$ divided by its third element. Similarly, the epipole in the second image, \mathbf{e}' , is equal to $(\mathbf{b}' - \mathbf{B}' \mathbf{B}'^{-1} \mathbf{b})$ divided by its third element.

Next, we show how, for a given point \mathbf{m}' in the second image, to compute the corresponding epipolar line $\mathbf{l}_{\mathbf{m}'}$ in the first image. The epipolar line must go through the epipole \mathbf{e} . We thus need another point to determine it. This point can be the projection of any point $\hat{\mathbf{M}}'$ on the optical ray $\langle C', \tilde{\mathbf{m}}' \rangle$. In particular, we can choose $\hat{\mathbf{M}}'$ such that

$$\tilde{\mathbf{m}}' = \mathbf{P}' \begin{bmatrix} \hat{\mathbf{M}}' \\ 1 \end{bmatrix} = \mathbf{B}' \hat{\mathbf{M}}' + \mathbf{b}',$$

that is, the scale factor is equal to 1. This gives $\hat{\mathbf{M}}' = \mathbf{B}'^{-1} (\tilde{\mathbf{m}}' - \mathbf{b}')$. According to the pinhole model, the image $\hat{\mathbf{m}}$ of this point is given by

$$s_m \tilde{\mathbf{m}} = \mathbf{P} \begin{bmatrix} \hat{\mathbf{M}}' \\ 1 \end{bmatrix} = \mathbf{B} \mathbf{B}'^{-1} \tilde{\mathbf{m}}' + (\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}'),$$

where s_m is the scale factor. As already described in Eq. (10) on page 241, a line can be represented by a three-vector defined *up to a scale factor*. According to Eq. (12), the epipolar line $\mathbf{l}_{\mathbf{m}'}$ is given by

$$\begin{aligned} \mathbf{l}_{\mathbf{m}'} &= s_e s_m \tilde{\mathbf{e}} \times \tilde{\mathbf{m}} \\ &= (\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}') \times [\mathbf{B} \mathbf{B}'^{-1} \tilde{\mathbf{m}}' + (\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}')] \\ &= (\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}') \times (\mathbf{B} \mathbf{B}'^{-1} \tilde{\mathbf{m}}'), \end{aligned}$$

or

$$\mathbf{l}_{\mathbf{m}'} = \mathbf{F} \tilde{\mathbf{m}}', \quad (37)$$

where \mathbf{F} is given by Eq. (35). Then any point \mathbf{m} on the epipolar line of \mathbf{m}' satisfies $\tilde{\mathbf{m}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0$, and this is exactly Eq. (34). Therefore, we obtain geometrically the same equation. Because of symmetry, for a given point \mathbf{m} in the first image, its corresponding epipolar line in the second image is represented by the vector $\mathbf{F}^T \tilde{\mathbf{m}}$.

Now, we show that if the images are calibrated, then the \mathbf{F} is reduced to the \mathbf{E} . Since the images are calibrated, the points \mathbf{m} can be expressed in normalized coordinates, that is, $\mathbf{m} = \mathbf{x}$. Without loss of generality, the world coordinate system is assumed to coincide with the second camera coordinate system. From the perspective projection model, we have the following camera projection matrices:

$$\mathbf{P} = [\mathbf{R} \ \mathbf{t}] \quad \text{and} \quad \mathbf{P}' = [\mathbf{I} \ \mathbf{0}].$$

This implies that $\mathbf{B} = \mathbf{R}$, $\mathbf{b} = \mathbf{t}$, $\mathbf{B}' = \mathbf{I}$, and $\mathbf{b}' = \mathbf{0}$. Plugging them into Eq. (35) gives $\mathbf{F} = [\mathbf{t}]_{\times} \mathbf{R}$, which is exactly the essential matrix Eq. (8).

In the above derivation of the fundamental matrix, a camera perspective projection matrix

\mathbf{P} is decomposed into a 3×3 matrix \mathbf{B} and a three-vector \mathbf{b} , and \mathbf{B} must be invertible. Later, we provide a more general derivation directly in terms of the camera projection matrices \mathbf{P} and \mathbf{P}' .

Fundamental Matrix and Epipolar Transformation

We examine the relationship between the fundamental matrix and the (i.e., the transformation of the epipoles and the epipolar lines between the two images).

For any point \mathbf{m}' in the second image, its epipolar line $\mathbf{l}'_{\mathbf{m}}$ in the first image is given by $\mathbf{l}'_{\mathbf{m}} = \mathbf{F}\tilde{\mathbf{m}}'$. It must go through the $\tilde{\mathbf{e}} = [e_1, e_2, e_3]^T$ and a point $\tilde{\mathbf{m}} = [u, v, s]^T$, that is, $\mathbf{l}'_{\mathbf{m}} = \tilde{\mathbf{e}} \times \tilde{\mathbf{m}} = \mathbf{F}\tilde{\mathbf{m}}'$. Here, we use the for the image points. Symmetrically, the epipolar line in the second image $\mathbf{l}'_{\mathbf{m}}$ of point \mathbf{m} is given by $\mathbf{l}'_{\mathbf{m}} = \mathbf{F}^T \tilde{\mathbf{m}}$ and must go through the epipole $\tilde{\mathbf{e}}' = [e'_1, e'_2, e'_3]^T$ and a point $\tilde{\mathbf{m}}' = [u', v', s']^T$, that is, $\mathbf{l}'_{\mathbf{m}} = \tilde{\mathbf{e}}' \times \tilde{\mathbf{m}}' = \mathbf{F}^T \tilde{\mathbf{m}}$. In other words, the epipole $\tilde{\mathbf{e}}'$ is on the epipolar line $\mathbf{l}'_{\mathbf{m}}$ for any point \mathbf{m} ; that is,

$$\tilde{\mathbf{e}}'^T \mathbf{l}'_{\mathbf{m}} = \tilde{\mathbf{e}}'^T \mathbf{F}^T \tilde{\mathbf{m}} = 0 \quad \forall \mathbf{m},$$

which yields

$$\mathbf{F}\tilde{\mathbf{e}}' = \mathbf{0}. \quad (38)$$

Let \mathbf{c}_1 , \mathbf{c}_2 , and \mathbf{c}_3 be the column vectors of \mathbf{F} , and we have $e_1^T \mathbf{c}_1 + e_2^T \mathbf{c}_2 + e_3^T \mathbf{c}_3 = \mathbf{0}$; thus the rank of \mathbf{F} is at most two. The solution to the epipole $\tilde{\mathbf{e}}'$ is given by

$$\begin{aligned} e'_1 &= F_{23}F_{12} - F_{22}F_{13} \\ e'_2 &= F_{13}F_{21} - F_{11}F_{23} \\ e'_3 &= F_{22}F_{11} - F_{21}F_{12}, \end{aligned} \quad (39)$$

up to, of course, a scale factor. Similarly, for the epipole in the first image, we have

$$\mathbf{F}^T \tilde{\mathbf{e}}' = \mathbf{0}, \quad (40)$$

which gives

$$\begin{aligned} e_1 &= F_{32}F_{21} - F_{22}F_{31} \\ e_2 &= F_{13}F_{21} - F_{11}F_{32} \\ e_3 &= F_{22}F_{11} - F_{21}F_{12}, \end{aligned} \quad (41)$$

also up to a scale factor.

Now let us examine the relationship between the epipolar lines. Once the epipole is known, an epipolar line can be parameterized by its direction vector. Consider $\mathbf{l}'_{\mathbf{m}} = \tilde{\mathbf{e}}' \times \tilde{\mathbf{m}}'$; its direction vector \mathbf{u}' can be parameterized by one parameter τ' such that $\mathbf{u}' = [1, \tau', 0]^T$. A particular point on $\mathbf{l}'_{\mathbf{m}}$ is then given by $\tilde{\mathbf{m}}' = \tilde{\mathbf{e}}' + \lambda' \mathbf{u}'$, where λ' is a scalar. Its epipolar line in the first image is given by

$$\begin{aligned} \mathbf{l}_{\mathbf{m}} &= \mathbf{F}\tilde{\mathbf{m}}' = \mathbf{F}\tilde{\mathbf{e}}' + \lambda' \mathbf{F}\mathbf{u}' = \lambda' \mathbf{F}\mathbf{u}' \\ &= \lambda' \begin{bmatrix} F_{11} + F_{12}\tau' \\ F_{21} + F_{22}\tau' \\ F_{31} + F_{32}\tau' \end{bmatrix}. \end{aligned} \quad (42)$$

This line can also be parameterized by its direction vector $\mathbf{u} = [1, \tau, 0]^T$ in the first image, which implies that

$$\begin{aligned} \mathbf{l}_{\mathbf{m}} &\cong \tilde{\mathbf{e}} \times (\tilde{\mathbf{e}} + \lambda \mathbf{u}) = \lambda \tilde{\mathbf{e}} \times \mathbf{u} \\ &= \lambda \begin{bmatrix} - (F_{11}F_{22} - F_{21}F_{12})\tau \\ F_{11}F_{22} - F_{21}F_{12} \\ (F_{32}F_{21} - F_{22}F_{31})\tau - F_{31}F_{12} + F_{11}F_{32} \end{bmatrix}, \end{aligned} \quad (43)$$

where \cong means “equal” up to a scale factor and λ is a scalar. By requiring that Eq. (42) and Eq. (43) represent the same line, we have

$$\tau = \frac{a\tau' + b}{c\tau' + d}, \quad (44)$$

where

$$\begin{aligned} a &= F_{12} \\ b &= F_{11} \\ c &= -F_{22} \\ d &= -F_{21}. \end{aligned} \quad (45)$$

Writing in matrix form gives

$$\rho \begin{bmatrix} \tau \\ 1 \end{bmatrix} = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} \tau' \\ 1 \end{bmatrix},$$

where ρ is a scale factor. This relation is known as the *homography* between τ and τ' , and we say that *there is a homography between the epipolar lines in the first image and those in the second image*. The above is, of course, only valid for the epipolar lines having the nonzero first element in the direction vector. If the first element is equal to zero, we should parameterize the direction vector as $[\tau, 1, 0]^T$, and similar results can be obtained.

At this point, we can see that the epipolar transformation is defined by the coordinates $\tilde{\mathbf{e}} = [e_1, e_2, e_3]^T$ and $\tilde{\mathbf{e}}' = [e'_1, e'_2, e'_3]^T$ of the epipoles and the four parameters a, b, c , and d of the homography between the two pencils of the epipolar lines. The coordinates of each epipole are defined up to a scale factor, and the parameters of the homography, as can be seen in Eq. (44), are also defined up to a scale factor. Thus, we have in total seven free parameters. This is exactly the number of parameters of the fundamental matrix.

If we have identified the parameters of the epipolar transformation, that is, the coordinates of the two epipoles and the coefficients of the homography, then we can construct the fundamental matrix, from Eq. (39), (41), and (45), as

$$\begin{aligned} F_{11} &= be_3e'_3 \\ F_{12} &= ae_3e'_3 \\ F_{13} &= -(ae'_2 + be'_1)e_3 \\ F_{21} &= -de_3e'_3 \\ F_{22} &= -ce_3e'_3 \\ F_{23} &= (ce'_2 + de'_1)e_3 \\ F_{31} &= (de_2 - be_1)e'_3 \\ F_{32} &= (ce_2 - ae_1)e'_3 \\ F_{33} &= -(ce'_2 + de'_1)e_2 + (ae'_2 + be'_1)e_1. \end{aligned} \quad (46)$$

The determinant $ad - bc$ of the homography is equal to the determinant of the first 2×2

submatrix of \mathbf{F} , $F_{11} F_{22} - F_{12} F_{21}$, which is zero when the epipoles are at infinity.

General Form of Epipolar Equation for Any Projection Model

In this section, we will derive a which does not assume any particular projection model.

E

Intersecting Two Optical Rays

The projections for the first and second cameras are represented respectively as

$$s\tilde{\mathbf{m}} = \mathbf{P}\tilde{\mathbf{M}}, \quad (47)$$

and

$$s'\tilde{\mathbf{m}}' = \mathbf{P}'\tilde{\mathbf{M}}', \quad (48)$$

where $\tilde{\mathbf{m}}$ and $\tilde{\mathbf{m}}'$ are augmented image coordinates and $\tilde{\mathbf{M}}$ and $\tilde{\mathbf{M}}'$ are augmented space coordinates of a single point in the two camera coordinate systems. Here both projection matrices *do not include the extrinsic parameters*.

The same point in the two camera coordinate systems can be related by

$$\tilde{\mathbf{M}} = \mathbf{D}\tilde{\mathbf{M}}', \quad (49)$$

where

$$\mathbf{D} = \begin{bmatrix} \mathbf{R} & \mathbf{t} \\ \mathbf{0}_3^T & 1 \end{bmatrix}$$

is the Euclidean transformation matrix compactly representing both rotation and translation. Now substituting Eq. (49) for (47), we have

$$s\tilde{\mathbf{m}} = \mathbf{P}\mathbf{D}\tilde{\mathbf{M}}'. \quad (50)$$

For an image point $\tilde{\mathbf{m}}'$, Eq. (48) actually defines an optical ray on which every space point $\tilde{\mathbf{M}}'$ projects onto the second image at $\tilde{\mathbf{m}}'$. This optical ray can be written in parametric form as

$$\tilde{\mathbf{M}}' = s'\mathbf{P}'^+\tilde{\mathbf{m}}' + \mathbf{p}'^\perp, \quad (51)$$

where \mathbf{P}'^+ is the pseudoinverse matrix of \mathbf{P}' :

$$\mathbf{P}'^+ = \mathbf{P}'^T \left(\mathbf{P}' \mathbf{P}'^T \right)^{-1}, \quad (52)$$

and \mathbf{p}'^\perp is a four-vector that is perpendicular to all the row vectors of \mathbf{P}' , that is,

$$\mathbf{P}' \mathbf{p}'^\perp = \mathbf{0}. \quad (53)$$

There are an infinite number of matrices that satisfy $\mathbf{P}' \mathbf{P}'^+ = \mathbf{I}$. Thus, \mathbf{P}'^+ is not unique. See [5, 6] for how to derive this particular pseudoinverse matrix.

It remains to determine \mathbf{p}'^\perp . First note that such a vector does exist because the difference between the row dimension and column dimension is one, and the row vectors are generally independent of each other. Actually, one way to obtain \mathbf{p}'^\perp is

$$\mathbf{p}'^\perp = (\mathbf{I} - \mathbf{P}'^+ \mathbf{P}') \boldsymbol{\omega}, \quad (54)$$

where $\boldsymbol{\omega}$ is an arbitrary four-vector. To show that it is perpendicular to every row vector of \mathbf{P}' , we multiply \mathbf{P}' and \mathbf{p}'^\perp :

$$\mathbf{P}' (\mathbf{I} - \mathbf{P}'^+ \mathbf{P}') \boldsymbol{\omega} = \left(\mathbf{P}' - \mathbf{P}' \mathbf{P}'^T \left(\mathbf{P}' \mathbf{P}'^T \right)^{-1} \mathbf{P}' \right) \boldsymbol{\omega} = \mathbf{0}$$

which is indeed a zero vector.

Actually, the following equation always stands, as long as the of the 3×4 matrix \mathbf{P}' is 3:

$$\mathbf{I} - \mathbf{P}'^+ \mathbf{P}' = \mathbf{I} - \mathbf{P}'^T \left(\mathbf{P}' \mathbf{P}'^T \right)^{-1} \mathbf{P}' = \frac{\mathbf{p}'^\perp | \mathbf{p}'^{\perp T} |}{\| \mathbf{p}'^\perp \|^2}. \quad (55)$$

The effect of matrix $\mathbf{I} - \mathbf{P}'^+ \mathbf{P}'$ is to transform an arbitrary vector to a vector that is perpendicular to every row vector of \mathbf{P}' . If \mathbf{P}' is of rank 3 (which is usually the case), then \mathbf{p}'^\perp is unique up to a scale factor.

Equation (51) is easily justified by projecting $\tilde{\mathbf{M}}'$ onto the image using Eq. (48), which indeed gives $\tilde{\mathbf{m}}'$. If we look closely at the equation, we can find that \mathbf{p}'^\perp actually defines the optical

center, which always projects onto the origin, and $\mathbf{P}'^+ \tilde{\mathbf{m}}'$ defines the direction of the optical ray corresponding to image point $\tilde{\mathbf{m}}'$. For a particular value s' , Eq. (51) corresponds to a point on the optical ray defined by \mathbf{m}' .

Similarly, an image point $\tilde{\mathbf{m}}$ in the first image also defines an optical ray. Requiring the two rays to intersect in space means that a point $\tilde{\mathbf{M}}'$ corresponding to a particular s' in Eq. (51) must project onto the first image at $\tilde{\mathbf{m}}$. That is,

$$s \tilde{\mathbf{m}} = s' \mathbf{P} \mathbf{D} \mathbf{P}'^+ \tilde{\mathbf{m}}' + \mathbf{P} \mathbf{D} \mathbf{p}'^\perp, \quad (56)$$

where $\mathbf{P} \mathbf{D} \mathbf{p}'^\perp$ is the \mathbf{e} in the first image.

Performing a cross product with $\mathbf{P} \mathbf{D} \mathbf{p}'^\perp$ yields

$$s (\mathbf{P} \mathbf{D} \mathbf{p}'^\perp) \times \tilde{\mathbf{m}} = (\mathbf{P} \mathbf{D} \mathbf{p}'^\perp) \times (s' \mathbf{P} \mathbf{D} \mathbf{P}'^+ \tilde{\mathbf{m}}').$$

Eliminating s and s' by multiplying $\tilde{\mathbf{m}}^T$ from the left (equivalent to an inner product), we have

$$\tilde{\mathbf{m}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0, \quad (57)$$

where

$$\mathbf{F} = \left[\mathbf{P} \mathbf{D} \mathbf{p}'^\perp \right]_{\times} \mathbf{P} \mathbf{D} \mathbf{P}'^+ \quad (58)$$

is the general form of fundamental matrix. It is evident that the roles that the two images play are symmetrical.

Note that Eq. (58) will be the essential matrix \mathbf{E} if \mathbf{P} and \mathbf{P}' do not include the intrinsic parameters, that is, if we work with normalized cameras.

We can also include all the intrinsic and extrinsic parameters in the two projection matrices \mathbf{P} and \mathbf{P}' , so that for a 3D point $\tilde{\mathbf{M}}'$ in a world coordinate system, we have

$$s \tilde{\mathbf{m}} = \mathbf{P} \tilde{\mathbf{M}}', \quad (59)$$

$$s' \tilde{\mathbf{m}}' = \mathbf{P}' \tilde{\mathbf{M}}'. \quad (60)$$

Similarly we get

$$s \tilde{\mathbf{m}} = s' \mathbf{P} \mathbf{P}'^+ \tilde{\mathbf{m}}' + \mathbf{P} \mathbf{p}'^\perp, \quad (61)$$

The same line of reasoning will lead to the general form of epipolar equation

$$\tilde{\mathbf{m}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0,$$

where

$$\mathbf{F} = [\mathbf{P} \mathbf{p}'^\perp]_\times \mathbf{P} \mathbf{P}'^+. \quad (62)$$

It can also be shown that this expression is equivalent to Eq. (35) for the full perspective projection (see next subsection), but it is more general. Indeed, Eq. (35) assumes that the 3×3 matrix \mathbf{B}' is invertible, which is the case for full perspective projection but not for affine cameras, while Eq. (62) makes use of the pseudoinverse of the projection matrix, which is valid for both full perspective projection as well as affine cameras. Therefore the equation does not depend on any specific knowledge of projection model. Replacing the projection matrix in the equation by specific projection matrix for each specific projection model produces the epipolar equation for that specific projection model.

The Full Perspective Projection Case

Here we work with normalized cameras. Under the full perspective projection, the projection matrices for the two cameras are the same:

$$\mathbf{P}_p = \mathbf{P}'_p = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \quad (63)$$

It is not difficult to obtain

$$\mathbf{P}'_p^+ = \mathbf{P}_p^T,$$

and

$$\mathbf{p}'_p^\perp = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}.$$

Now substituting the above equations for Eq. (58), we have obtained the essential matrix

$$\mathbf{E}_p = [\mathbf{P}_p \mathbf{D} \mathbf{p}'_p^\perp]_\times \mathbf{P}_p \mathbf{D} \mathbf{p}'_p^\perp = [\mathbf{t}]_\times \mathbf{R}, \quad (64)$$

which is exactly the same as what we derived in the last section.

For the full perspective projection, we can prove that Eq. (62) is equivalent to Eq. (35). From definitions, we have

$$\begin{aligned} [\mathbf{B}' \mathbf{b}'] \mathbf{p}'_p^\perp &= \mathbf{0}, \\ [\mathbf{B}' \mathbf{b}'] \mathbf{P}'_p^+ &= \mathbf{I}. \end{aligned}$$

It is easy to show

$$\begin{aligned} \mathbf{P}'_p^\perp &= \lambda (\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}'), \\ \mathbf{P}'_p^+ &= \begin{bmatrix} \mathbf{B}'^{-1} - \mathbf{B}'^{-1} \mathbf{b}' \mathbf{q}^T \\ \mathbf{q}^T \end{bmatrix}, \end{aligned}$$

where λ is a nonzero scalar and \mathbf{q} is a nonzero arbitrary three vector. Substituting them for Eq. (62) yields

$$\begin{aligned} \mathbf{F} &= \lambda [\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}']_\times \\ &\quad (\mathbf{B} \mathbf{B}'^{-1} - (\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}') \mathbf{q}^T) \\ &= \lambda [\mathbf{b} - \mathbf{B} \mathbf{B}'^{-1} \mathbf{b}']_\times \mathbf{B} \mathbf{B}'^{-1}, \end{aligned} \quad (65)$$

which completes the proof as \mathbf{F} is defined up to a scale factor.

The reader is referred to [5, 6] for the epipolar geometry between affine cameras and for a general expression of the fundamental matrix for both perspective and affine cameras. The reader is referred to [7, 8] for various algorithms of determining essential matrix and fundamental matrix from point correspondences. The reader is referred to [9, 10] for a general treatment of geometry across multiple cameras.

Essential Matrix

Zhengyou Zhang

Tencent AI Lab & Robotics X, Shenzhen, China

Related Concepts

- [Epipolar Geometry](#)
- [Fundamental Matrix](#)

Definition

Essential matrix is a special 3×3 matrix which captures the geometric relationship between two calibrated cameras or between two locations of a single moving camera.

Background

See entry ► “[Epipolar Geometry](#)” for details.

Theory

Because the cameras are calibrated, we use the normalized image coordinates. The two images of a space point $\mathbf{X} = [X, Y, Z]^T$ are $[x, y, 1]^T$ and $[x', y', 1]^T$ in the first and second images and are denoted by \tilde{x} and \tilde{x}' . Assume that the second camera is brought from the position of the first camera through a rotation \mathbf{R} followed by a translation \mathbf{t} . From the epipolar geometry, we have the following equation

$$\tilde{x}^T \mathbf{E} \tilde{x}' = 0, \quad (1)$$

where

$$\mathbf{E} = [\mathbf{t}]_{\times} \mathbf{R}. \quad (2)$$

And $[\mathbf{t}]_{\times}$ is a 3×3 antisymmetric matrix defined by vector \mathbf{t} . This equation is called the

epipolar equation, and matrix \mathbf{E} is known as the *essential matrix*.

Essential matrix has a number of properties, including:

1. $\det \mathbf{E} = 0$, because $[\mathbf{t}]_\times$ is an antisymmetric matrix.
2. $\mathbf{E}^T \mathbf{t} = \mathbf{0}$, because $([\mathbf{t}]_\times \mathbf{R})^T \mathbf{t} = \mathbf{R}^T [\mathbf{t}]_\times^T \mathbf{t} = -\mathbf{R}^T (\mathbf{t} \times \mathbf{t}) = \mathbf{0}$.
3. $\mathbf{E}\mathbf{E}^T = (\mathbf{t}'\mathbf{t})\mathbf{I} - \mathbf{t}\mathbf{t}^T$, because $\mathbf{E}\mathbf{E}^T = ([\mathbf{t}]_\times \mathbf{R})([\mathbf{t}]_\times \mathbf{R})^T = [\mathbf{t}]_\times \mathbf{R} \mathbf{R}^T [\mathbf{t}]_\times^T = -[\mathbf{t}]_\times^2$.
4. $\|\mathbf{E}\|^2 = 2 \|\mathbf{t}\|^2$. Here, $\|\mathbf{E}\|^2$ is the Frobenius norm of matrix \mathbf{E} , i.e., $\|\mathbf{E}\|^2 = \sum_{i,j} E_{ij}^2$.

It can be shown that a real 3×3 matrix can be decomposed into the multiplication of an antisymmetric matrix \mathbf{T} and a rotation matrix \mathbf{R} if and only if one of \mathbf{E} 's singular values is 0 while the other two are equal.

Definition

Euclidean geometry deals with properties of geometric configurations that are preserved under isometric (or *length preserving*) transformations. Alternatively, it may be characterized as a mathematical theory based on an axiom system (that can be traced back to Euclid) expressing, in modern terminology, incidence, order, congruence, continuity, and parallelity. Euclidean geometry is today a special case of many geometric theories

(projective, affine, and Riemannian geometries, Hilbert spaces ...).

Historical Background

Euclidean geometry has a long and glorious history (cf. [1, 2, 3]), having lived at the core of the development of science and culture since antiquity. It is today not an area of research per se, but still plays an important role in many contexts.

Euclidean geometry is one of the oldest manifestations of humans in science. The latter part of the word *geometry* originates from the Greek word *metri'a* for *measure*, and the subject developed in the antiquity as an empirical science for surveying. It was given a scientific formulation by the Greek mathematician Euclid in Alexandria, about 300 B.C. Starting from a small set of intuitively appealing *axioms*, in his monumental treatise, the *Elements*, he deduced a large number of *propositions* about geometrical figures (cf. [8]). In the Elements, plane geometry was presented in essentially the way it is today taught in secondary school. Also the solid geometry of three dimensions was addressed. Two other big contributors to ancient geometry, both active in the third century B.C., were Archimedes, with equations for, e.g., the circumference of the circle and the area of the sphere, and Apollonius, with investigations of conic sections.

For over 2,000 years, the attribute *Euclidean* was unnecessary, because no other kind of geometry was conceived of. Early, however, the fifth of Euclid's axioms, the *parallel axiom*, was met with challenge, and many unsuccessful efforts were made to deduce it from the other axioms. However, it took until the nineteenth-century before its independence was settled by the construction of consistent geometric models with other parallelity concepts. Some contributors to such non-Euclidean geometries were Gauss, Bolyai, and Lobachevsky.

By today's standard of rigor, the treatment of Euclid is not without objections, using some assumptions and concepts not explicitly accounted for. Beginning in the

nineteenth-century, several categorical axiom systems were presented, e.g., by Hilbert in 1899 (cf. [9, 6]).

Also other geometric systems were discovered and developed, like affine geometry, beginning with Euler in the eighteenth-century, and projective geometry, through Poncelet, von Staudt, a.o. in the nineteenth-century. While in affine geometry, parallelity plays a prominent role; in projective geometry, the concept does not exist, in that every pair of lines intersect.

In contrast to the then prevalent *synthetic* approach to geometry, based on geometric constructions, in the seventeenth century, Descartes introduced coordinate systems and founded the *analytic geometry*. Also de Moivre made significant contributions. The use of coordinates enabled the study of geometry by means of algebra and calculus. In this formalism, in a natural way, Euclidean geometry can be generalized to higher dimensions, by means of the notion of Euclidean space; see below.

From a more modern mathematical point of view, geometry in some space is the study of properties of configurations that are preserved under some group of one-to-one transformations of the space in question (cf. [1, 2, 3]). This viewpoint was first formulated by Klein 1872 in the so-called Erlanger program, cf. [6]. It has been the key to a fruitful interplay between geometry, algebra, analysis, and topology. For Euclidean geometry, the characterizing transformation group is the group of isometric transformations, reflecting, e.g., the crucial property of congruence, that two triangles are congruent if one of them can be moved rigidly onto the other one.

Theory and Applications

The topic of Euclidean geometry today has branched out in many directions. Below, we focus on a few of relevance to computer vision.

Synthetic Euclidean Geometry

The synthetic approach to Euclidean geometry (the one used by Euclid) starts from the basic concepts of *point, line, and surface*. The rules

for interaction between these are described by *axioms*. Euclid used five axioms (cf. [8]):

1. Through any two points, there is exactly one line.
2. A finite line segment can be extended to a line.
3. A circle can be drawn with any center point and any radius.
4. All right angles are equal to another.
5. The parallel postulate: If a straight line falling on two straight lines make the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which are the angles less than the two right angles.

For a rigorous exposition of Euclidean geometry, see [9], built on Hilbert's system of 20 axioms in five main groups: combination, order, parallelity, congruence, and continuity.

From the beginning, Euclidean geometry mostly dealt with squares and rectangles, right-angled triangles, trapezia, and circles. Some well-known examples of results from Euclidean geometry are the theorem of Pythagoras, the theorem stating that the sum of angles in a triangle equals two right angles, and the theorem stating that the periphery angle corresponding to an arch of a circle equals half the angle at the center.

The proofs in this tradition were constructive. Questions were raised about the possibility of generally solving geometric problems by ruler and compass. Using advances in algebra, the inherent impossibility of such constructions for some famed problems was proved, e.g., the trisectioning of an angle, the doubling of the cube, and the squaring of a circle.

Analytic Geometry: The Space \mathbf{R}^n

In the analytic geometry, as learned at school, points in the plane are represented by coordinates as (x_1, x_2) , and points in space as (x_1, x_2, x_3) . This inspires to consider n -tuples of real numbers (x_1, x_2, \dots, x_n) , which together build up \mathbf{R}^n . This space forms the scene for geometry, not only in 1, 2, and 3 dimensions, but also

in higher dimensions. The elements are called points $X : (x_1, x_2, \dots, x_n)$.

The set \mathbf{R}^n can be provided with different structures:

Linear Space. Equip \mathbf{R}^n with the operations of addition, $x + y = (x_1, \dots, x_n) + (y_1, \dots, y_n) = (x_1 + y_1, \dots, x_n + y_n)$, and multiplication with a scalar $\lambda x = (\lambda x_1, \dots, \lambda x_n)$. Then, in a way known from introductory courses in linear algebra, the notion of linear space is introduced. The elements of \mathbf{R}^n are called *vectors*. The notion of *dimension* is defined, giving \mathbf{R}^n the dimension n .

Affine Space. Combining the *point* and vector interpretations of \mathbf{R}^n , affine spaces are defined in a way such that, loosely speaking, it is possible to subtract points to get vectors and add a vector to a point to get another point. (On the contrary, it is not possible to add points.) For a thorough presentation, see [1]. For affine spaces, the notation A^n will be used below.

Euclidean Space. Known from *linear* algebra is also the notion of *scalar product* on \mathbf{R}^n , being a function $\mathbf{x} \cdot \mathbf{y}$ such that for all vectors \mathbf{x}, \mathbf{y} , and all scalars λ :

- $\mathbf{x} \cdot \mathbf{y} = \mathbf{y} \cdot \mathbf{x}$.
- $\mathbf{x} \cdot (\lambda_1 \mathbf{y}_1 + \lambda_2 \mathbf{y}_2) = \lambda_1 \mathbf{x} \cdot \mathbf{y}_1 + \lambda_2 \mathbf{x} \cdot \mathbf{y}_2$.
- $\mathbf{x} \cdot \mathbf{x} \geq 0$ with equality if and only if $\mathbf{x} = 0$.

Given a scalar product, a *norm* on the linear space \mathbf{R}^n is defined by $\|\mathbf{x}\| = \sqrt{\mathbf{x} \cdot \mathbf{x}}$. Two vectors x and y are orthogonal if $\mathbf{x} \cdot \mathbf{y} = 0$. An orthonormal basis e_1, \dots, e_n is characterized by $e_i \cdot e_j = 0$ for $i \neq j$ and $= 1$ for $i = j$.

Having a scalar product, the affine space A^n can be provided with a *metric*, by which the distance between points is given by $d(X, Y) = \|\mathbf{u}\|$ where \mathbf{u} is the vector from X to Y . In particular, in an orthonormal basis, the distance between the points $X : (x_1, \dots, x_n)$ and $Y = (y_1, \dots, y_n)$ is

$$- |XY| = ((x_1 - y_1)^2 + \dots + (x_n - y_n)^2)^{1/2}$$

(in agreement with the theorem of Pythagoras in the planar case).

The scalar product also makes it possible to define the *angle* θ between two vectors x and y as

$$\mathbf{x} \cdot \mathbf{y} = \|\mathbf{x}\| \|\mathbf{y}\| \cos \theta.$$

Provided with a scalar product for vectors, A^n becomes a Euclidean space, below denoted E^n .

Euclidean Geometry and Transformation Groups

Given a set S , consider the group $\text{Bij}(S)$ consisting of all one-to-one transformations $f : S \rightarrow S$. According to the view of the Erlanger program, to impose a geometry on S is the same as to specify a subgroup G of $\text{Bij}(S)$ and to say that two subsets A, B of S are equivalent if there is an $f \in G$ such that $fA = B$. See [1, 2, 3].

Two important such transformation groups on \mathbb{R}^n are $\text{GL}(n)$, consisting of all non-singular $n \times n$ -matrices, and $\text{O}(n)$, consisting of all orthogonal $n \times n$ -matrices.

For planar Euclidean geometry, S is the affine space A^2 and G is the group of all *isometric transformations*, i.e., transformations such that for any points $X, Y \in \mathbb{R}^2$, $d(TX, TY) = d(X, Y)$. In fact, it can be proven that every mapping T with this property can be written as

$$T : X \rightarrow QX + b, \text{ with } Q \in \text{O}(n).$$

In particular, T is an affine map, mapping lines onto lines. Thus, it also maps triangles onto triangles, after which the isometric property guarantees congruence. In higher dimensions holds the analogous formula for T .

In Euclidean geometry, also the notion of *similarity* plays a prominent role, which could motivate the use of similarity transformations above (where Q is replaced by cQ , $c \neq 0$). Note that the isometric transformations form a subgroup of the similarity transformations.

The example of planar Euclidean geometry is so crucial that it is worthwhile to comment further on the structure of its transformation group. The formula above shows that an isometric transformation is composed by a rotation around the origin (expressed by Q), followed by a translation (by b). Furthermore, it is possible to prove that

any such transformation is equal to either the identity, or a translation, or a rotation (around some point), or a reflection in some line, or a so-called glide reflection (a translation followed by a reflection in a line parallel to the translation). Also in \mathbb{R}^3 , it is possible to make an analogous characterization, where a type screw (composition of a rotation and a translation) is added. Note in particular that in this way, isometries on \mathbb{R}^2 and \mathbb{R}^3 are characterized by geometric constructions only, without use of any particular coordinate system.

On the Stratum of Euclidean, Affine and Projective Geometry

Euclidean geometry is one of the layers in a hierarchy of structures that can be imposed on \mathbb{R}^n and which are of high relevance to computer vision. With a term introduced by Faugeras [5], these form a *geometric stratum*. For more details on the respective geometries, see [1, 2, 3, 10].

Affine Geometry. For the linear space \mathbf{R}^n , a particular role is played by linear subspaces of the form $a_1 x_1 + \dots + a_n x_n = 0$, called *hyperplanes* (always passing through the origin). As a linear space, its dimension is $n - 1$. Analogously, in the affine space A^n , one considers *affine hyperplanes* $a_1 x_1 + \dots + a_n x_n = a$ (which for $a \neq 0$ do not pass through the origin). In the case $n = 2$, one talks about *lines* instead of hyperplanes.

For affine geometry on \mathbf{R}^n , the characterizing transformations are

$$T : X \rightarrow AX + b, \text{ with } A \in \text{GL}(n).$$

By such transformations, affine hyperplanes are mapped onto affine hyperplanes. Two non-intersecting hyperplanes are mapped onto two nonintersecting hyperplanes. Hence, the property of parallelity is preserved and is thus a concept within affine geometry. On the contrary, distance is not preserved and is an alien concept for affine geometry. However, it is possible to compare distances along a line (e.g., saying that M is the midpoint of a line segment PQ), but it is not possible to measure and compare distances on

nonparallel lines. Neither does the concept of angle live in affine geometry, in lack of a scalar product.

Also affine geometry can be built up from axioms. Compared to Euclidean geometry, one way of doing this is by replacing the parallel axiom by an axiom “for any point P and any line ℓ , not through P , there is at least one line through P which does not meet ℓ ,” plus another one, involving seven-point configurations, named after Desargues.

Projective Geometry. By a point in the so-called projective space \mathbb{P}^n is meant a line through the origin in \mathbb{R}^{n+1} . In other words, a point is represented by any of the vectors $\lambda(x_1, x_2, \dots, x_{n+1})$, $\lambda \neq 0$. This is called *homogeneous coordinates* for the point in \mathbb{P}^n . By a *projective transformation* T is meant a mapping represented by $\text{GL}(n+1)$ in homogeneous coordinates, i.e., $y = \lambda Tx$ for some λ .

Looking in particular at plane projective geometry, where points are represented by lines through the origin in \mathbb{R}^3 , a *projective line* is represented by a plane through the origin in \mathbb{R}^3 . Since every pair of such planes intersect in a line through the origin, i.e., a point in \mathbb{P}^2 , the notion of parallelity does not exist in projective geometry.

The projective space \mathbb{P}^n , embedded in \mathbb{R}^{n+1} , can also be visualized by means of an affine hyperplane in \mathbb{R}^{n+1} , e.g., $\Pi : x_{n+1} = 1$. Every line not parallel to Π intersects Π in a unique point. Besides these, \mathbb{P}^n contains points corresponding to lines parallel to Π . The latter points of \mathbb{P}^n are called *points at infinity* and may be identified with directions in Π . The set of points at infinity is called the *line at infinity*. To sum up, the projective space \mathbb{P}^n can be visualized by a model formed by an n -dimensional affine space extended with points at infinity.

Perspective Transformations: Multiple View Geometry

For computer vision, *perspective transformations* play a crucial role. Specializing to three dimensions, consider two affine 3-dimensional hyperplanes Π and Π' in \mathbb{R}^4 . If C is a point outside Π

and Π' , a mapping $P : \Pi \rightarrow \Pi'$ is defined by considering the intersections of lines through C with Π and Π' . Then C is called the *focal point* of the *perspective transformation* P . In particular, one notes that if Π and Π' are nonparallel, then point at infinity of Π is mapped onto *ordinary* points of Π' and vice versa. If Π and Π' are parallel, then points at infinity are mapped onto points at infinity, and the perspective transformation is an affine transformation.

To sum up, Euclidean geometry is a special case of affine geometry, as follows from the fact that the group of isometries is a subgroup of the affine group. Affine geometry is a special case of projective geometry, since the affine transformations form a subgroup of the projective ones, characterized by leaving the line at infinite invariant.

Of particular importance to computer vision is the case of perspective transformations from three dimensions to two. These are singular, i.e., not one to one, contrary to the ones discussed above. They may be visualized by letting C tend to the plane Π' , which in the limit gives a mapping $\Pi \rightarrow \Pi \cap \Pi'$, from three to two dimensions. Moreover, the ambient space \mathbb{R}^4 becomes superfluous and can be replaced by the three-dimensional affine space Π .

Multiple view geometry deals with the situation where a number of such two-dimensional perspective images are known of a common three-dimensional object (cf. [4, 7]). With no further information, reconstruction is possible up to projective transformations. Having more geometric structure available, e.g., Euclidean information on the image planes and focal points, more structure can be obtained for the reconstruction, ideally making it Euclidean. This situation is termed *camera calibration*; see [7].

Some Other Geometries Embracing Euclidean Geometry

Algebraic Geometry. Besides hyperplanes, crucial roles in the study of Euclidean (as well as projective and affine) geometry are played by *conics*. While hyperplanes have equations

involving first-order polynomials, conics are described by second-order polynomials. In two dimensions, this leads to the analytic geometry of conic sections, representing ellipses, hyperbolas, and parabolas. Algebraic geometry is the generalization of this to higher dimensions and higher-order polynomials, where Euclidean geometry thus falls out as a special case.

Riemannian geometry. Riemann geometry lives on a so-called Riemannian manifold, which, loosely speaking, is a space constructed by deforming and patching together Euclidean spaces according to certain rules, guaranteeing, e.g., *smoothness*. Such a space enjoys notions of distance and angle but behaves in a curved, non-Euclidean manner. The simplest Riemannian manifold consists of \mathbb{R}^n with a constant scalar product, leading to classical Euclidean geometry. Riemannian geometry plays a prominent role in general relativity.

Hilbert Spaces. Considering infinite sequences (x_1, x_2, \dots) instead of finite ones, (x_1, x_2, \dots, x_n) , will lead to convergence problems whenever forming sums. Restricting oneself to sequences with $\sum_1^\infty x_i^2$ finite, a prototype of so-called Hilbert spaces is obtained. In a natural way, a scalar product is defined, leading to a distance measure, by means of which it is possible to prove, e.g., the infinite-dimensional analogue of the theorem of Pythagoras and many other theorems of Euclidean geometry.

Evolution of Robotic Heads

Michael Jenkin

Department of Electrical Engineering and Computer Science, Lassonde School of Engineering, York University, Toronto, ON, Canada

Related Concepts

- Active Sensor (Eye) Movement Control
- Active Stereo Vision

Definition

Robotic heads are actively controlled camera platforms, typically designed to mimic the head and camera (eye) motions associated with humans. Early designs were typically built to study the role of eye and head motion in active vision systems [1]. Later designs are also used in the study of human-robot interaction.

Background

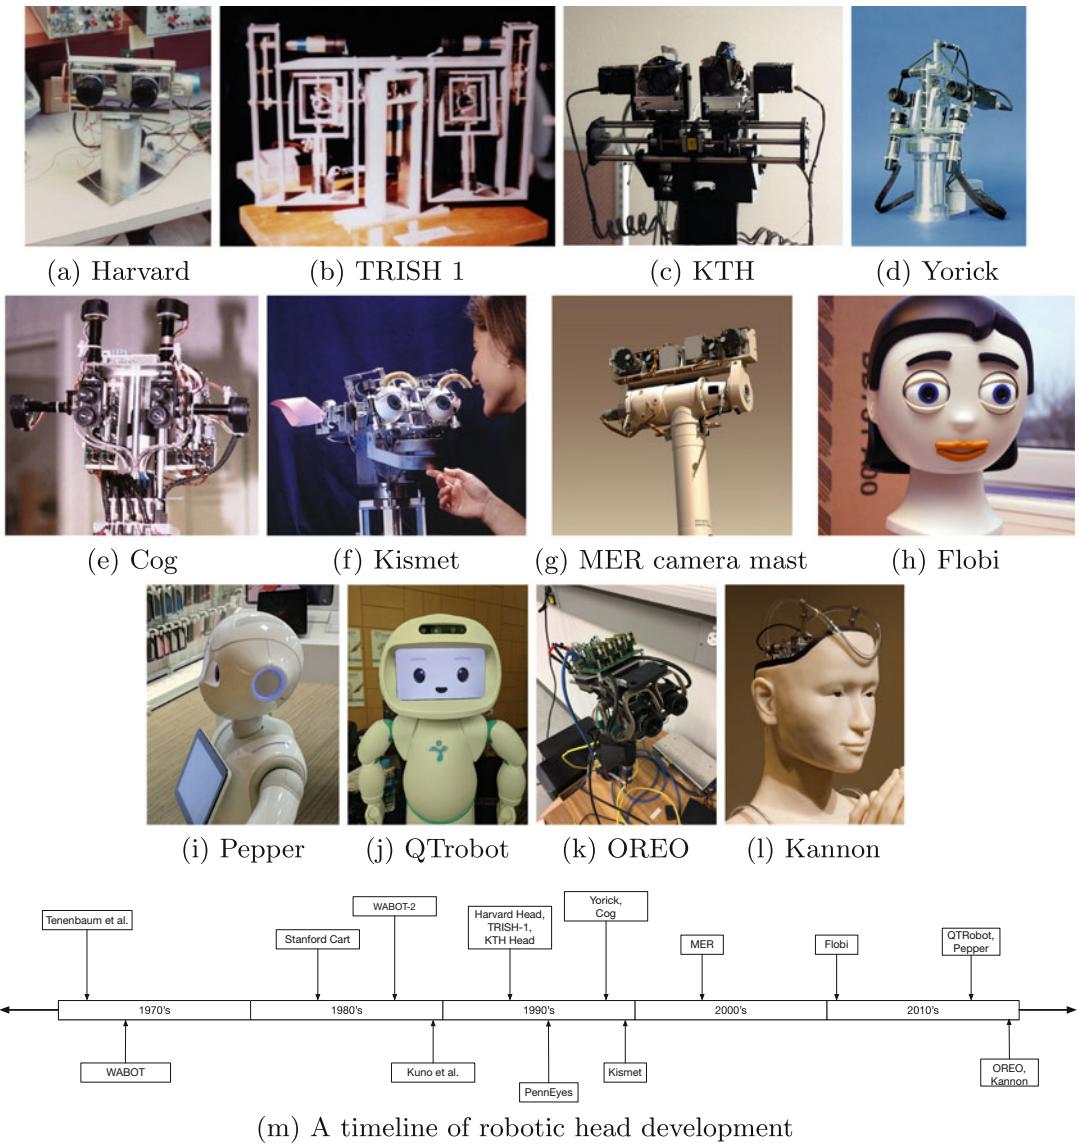

Cameras have a finite field of view and thus must be actively controlled in order to bring out of view portions of the scene into view and to track dynamic scene events. The need for active control of camera geometry becomes even more critical when multiple cameras are involved as changes in relative camera geometry can simplify stereo image processing and can be used to bring specific scene features within the tuning range of multiple camera scene reconstruction algorithms.

The development of single camera robotic heads can be traced back to the 1970s [2], the Stanford Cart [3], and the robot musician “WABOT-2” [4]. Binocular systems began to appear in the mid-1970s, and a number of designs appear in the late 1980s and early 1990s (e.g., [5–12]). By the late 1990s, head designs were beginning to be driven by research interest in human-robot interaction (e.g., [13, 14]). Current head designs are typically designed to be anthropomorphic (e.g., [15]) or to meet specific requirements of the sensors or the application (e.g., [16]) (see Fig. 1 for examples).

Theory

Although there is a wide range of different head designs, stereo robotic heads are perhaps the most common. Either such systems have fixed relative geometry between the two cameras or the relative geometry is controllable. Individual cameras may also be equipped with controllable intrinsic camera settings. Heads are typically mounted on pan and tilt “necks” that drive the entire head to look at different portions of the scene. Controllable parameters can include:

- *Head pan*. Pan angle introduced by a robotic neck.
- *Head tilt*. Tilt angle introduced by a robotic neck.

(m) A timeline of robotic head development

Evolution of Robotic Heads, Fig. 1 The evolution of robotic heads. (a) Appears with the kind permission of J. Clark. (b), (c), (i), (j) and (l) appear courtesy of M. Jenkin. (d) Appears with the kind permission of P.

Sharkey. (e) Appears courtesy NAS/JPL-Caltech. (h) Appears with the kind permission of Bielefeld University. (k) Appears with the kind permission of B. Tripp.

- *Baseline*. The displacement between the left and right cameras.
- *Fixation point*. The point at which the optical axes of the left and right cameras intersect. The fixation point can be defined in various ways including the individual pan directions

of the left and right cameras and the vergence/version angles.

- *Cyclotorsion*. The roll of each camera about its optical axis.
- *Zoom/focus/aperture*. Intrinsic settings of each camera.

Being able to control the relative pose of the two cameras provides the sensor the ability to bring different portions of space into alignment so that objects appear at the same position in both cameras. As stereo image processing is typically performed only over a limited range of disparities (image differences), changing the relative geometry between the cameras leads to the camera system attending to different regions of space. The region of space that is brought into alignment is known as the horopter (see [17] for a review of the geometry). Typically stereo heads are developed with common camera tilt and utilize camera pan to select a binocular fixation point. Cyclotorsion (see [18, 19]) warps the zero disparity surface so that it tilts away from or toward the robotic head – a useful property if surfaces such as the ground plane is to be imaged. For robotic heads designed to be used for human-robot interaction, it is common to provide some level of simulated facial animation in order to simulate emotional states (see [20]).

Early designs were strongly constrained by the mass of available camera housings and especially the mass of controllable focus/zoom lenses. This is particularly evident in the early designs shown in Fig. 1. More recent designs have taken advantage of the decreased size and mass of camera systems. Figure 1m places these heads and others in a timeline. Recent advances in 3D printing have simplified the construction of robot heads, and it is now possible to “roll your own” without the need of a dedicated research machine shop (see [21]).

Many modern robotic heads have been developed to help study aspects of human-robot interaction. Such “social robots” are designed to not only use multiple sensors to reconstruct 3D environments, but they often also provide a range of actuators to simulate human facial responses. For example, the android Kannon shown in Fig. 1 uses a range of realistic facial and body motions to help communicate the teachings of Buddha.

► Maximum Likelihood Estimation

Definition

The expectation-maximization algorithm iteratively maximizes the likelihood of a training sample with respect to unknown parameters of a probability model under the condition of missing information. The training sample is assumed to represent a set of independent realizations of a random variable defined on the underlying probability space.

Background

One of the main paradigms of statistical pattern recognition and Bayesian inference is to model the relation between the observable features $x \in \mathcal{X}$ of an object and its hidden state $y \in \mathcal{Y}$ by a joint probability measure $p(x, y)$. This probability measure is, however, often known only up to some parameters $\theta \in \Theta$. It is thus necessary to estimate these parameters from a training sample, which is assumed to represent a sequence of independent realizations of a random variable. If, ideally, these are realizations of pairs (x, y) , then the corresponding estimation methods are addressed as *supervised* learning. It is, however, quite common that some of those variables describing the hidden state are latent and never observed in the training data. It is therefore necessary to marginalize over them in order to estimate the unknown parameters θ . Corresponding estimation methods are known as *unsupervised* learning. Moreover, especially in computer vision, the observation x and the hidden state y both may have a complex structure. The latter can be, e.g., a segmentation, a depth map, or a similar object. Consequently, it is often not feasible to provide the complete information y for the realizations in the sample. This means to estimate the parameters in the situation of missing information. The EM algorithm is a method searching for maximum likelihood estimates of the unknown parameters under such conditions.

Theory

All the situations described in the previous section can be treated in a uniform way by assuming the training sample as a set of independent realizations of a random variable.

Let Ω be a finite sample space, \mathcal{F} be its power set, and $p_\theta: \mathcal{F} \rightarrow \mathbb{R}_+$ be a probability measure defined up to unknown parameters $\theta \in \Theta$. Let $X: \Omega \rightarrow \mathcal{X}$ be a random variable and $T = \{x_i \mid i = 1, 2, \dots, n\}$ be a sample of independent realizations of X (see, e.g., [1, 2] for a formal definition of independent realizations). The maximum likelihood estimator provides estimates of

the unknown parameters θ by maximizing the probability of T

$$\theta^* = \operatorname{argmax}_{\theta} \prod_{i=1}^n p_{\theta}(\Omega_i), \quad (1)$$

where Ω_i denotes the pre-image $\{\omega \in \Omega \mid X(\omega) = x_i\}$. Taking the logarithm, the task reads

$$\begin{aligned} \theta^* &= \operatorname{argmax}_{\theta} L(T, \theta) \\ &= \operatorname{argmax}_{\theta} \sum_{i=1}^n \log \sum_{\omega \in \Omega_i} p_{\theta}(\omega). \end{aligned} \quad (2)$$

Remark 1 It is often assumed that Ω is a Cartesian product $\Omega = \mathcal{X} \times \mathcal{Y}$ and that X simply projects onto the first component $X(x, y) = x$. Then the probability $p_{\theta}(\Omega_i) = p_{\theta}(x_i) = \sum_{y \in \mathcal{Y}} p_{\theta}(x_i, y)$ is nothing but the marginalization over all possible y . This special case will be considered in the example below. \square

The optimization task (2) is often complicated and hardly solvable by standard optimization methods – either because the objective function is not concave or because θ represents a set of parameters of different natures. Suppose, however, that the task of parameter estimation is feasible if complete information, i.e., a set of realizations of $\omega \in \Omega$, is available. This applies in particular if the corresponding simpler objective function $\sum_i \log p_{\theta}(\omega_i)$ is concave with respect to θ or if the task decomposes into simpler, independent optimization tasks with respect to individual components of a parameter collection.

The key idea of the expectation-maximization algorithm is to exploit this circumstance and to solve the optimization task (2) by iterating the following two feasible tasks:

- (1) given a current estimate of θ , determine the missing information, i.e., $p_{\theta}(\omega|\Omega_i)$ for each element $x_i \in T$ and
- (2) given the complete information, solve the corresponding estimation task, resulting in an improved estimate of θ .

To further substantiate this idea of “iterative splitting” of the task (2), it is convenient to introduce nonnegative auxiliary variables $\alpha_i(\omega)$, $\omega \in \Omega_i$, for each element x_i of the learning sample T such that they fulfill

$$\sum_{\omega \in \Omega_i} \alpha_i(\omega) = 1, \forall i = 1, 2, \dots, n. \quad (3)$$

These variables α_i can be seen as (so far arbitrary) posterior probabilities $p(\omega|\Omega_i)$ for $\omega \in \Omega_i$, given a realization x_i . The log-likelihood of a realization x_i can be written by their use as

$$\begin{aligned} \log p_{\theta}(\Omega_i) &= \sum_{\omega \in \Omega_i} \alpha_i(\omega) \log p_{\theta}(\Omega_i) = \\ &= \sum_{\omega \in \Omega_i} \alpha_i(\omega) \log p_{\theta}(\omega) \\ &\quad - \sum_{\omega \in \Omega_i} \alpha_i(\omega) \log \frac{p_{\theta}(\omega)}{p_{\theta}(\Omega_i)}, \end{aligned} \quad (4)$$

where the first equality follows directly from (3). The log-likelihood of the training sample can be therefore expressed equivalently as

$$\begin{aligned} L(T, \theta) &= \sum_{i=1}^n \sum_{\omega \in \Omega_i} \alpha_i(\omega) \log p_{\theta}(\omega) \\ &\quad - \sum_{i=1}^n \sum_{\omega \in \Omega_i} \alpha_i(\omega) \log p_{\theta}(\omega|\Omega_i). \end{aligned} \quad (5)$$

The expression as a whole does not depend on the specific choice of the auxiliary variables α , whereas the minuend and subtrahend do. Moreover, note that the minuend is nothing but the likelihood of a sample of complete data, if the α are interpreted as the missing information, i.e., posterior probabilities for $\omega \in \Omega_i$ given the observation x_i .

Starting with some reasonable choice for the initial $\theta^{(0)}$, the likelihood is iteratively increased by alternating the following two steps. The (E)xpectation step calculates new α such that $\theta^{(t)}$ becomes a maximizer of the subtrahend. Changing θ subsequently can thus only decrease its value. The (M)aximization step relies on this

and maximizes the minuend only, avoiding to deal with the subtrahend.

$$\text{E-step} \quad \alpha_i^{(t)}(\omega) = \overline{p_{\theta^{(t)}}(\omega | \Omega_i)} \quad (6)$$

$$\text{M-step} \quad \theta^{(t+1)} = \underset{\theta}{\operatorname{argmax}} \sum_{i=1}^n \sum_{\omega \in \Omega_i} \alpha_i^{(t)}(\omega) \log p_{\theta}(\omega). \quad (7)$$

From the conceptual point of view, the E-step can be seen as inference – it calculates the missing data, i.e., the posterior probabilities $p_{\theta^{(t)}}(\omega | \Omega_i)$ for each element x_i in the training sample. The M-step utilizes these posterior probabilities for a supervised learning step. The names themselves stem from a rather formal view: the E-step calculates the α and therefore the objective function in (7) which has the form of an expectation of $\log p_{\theta}(\omega)$. The computation of this objective function is sometimes considered to be a part of the E-step. The name for the M-step is obvious.

It is easy to see that the likelihood is monotonically increasing: The choice (6) for α guarantees that the subtrahend in (5) can only decrease whatever new θ will be chosen in the subsequent M-step. This follows from the inequality

$$\begin{aligned} & \sum_{\omega \in \Omega_i} p_{\theta}(\omega | \Omega_i) \log \frac{p_{\theta}(\omega | \Omega_i)}{p_{\theta'}(\omega | \Omega_i)} \\ &= D_{KL}(p_{\theta}(\omega | \Omega_i) \| p_{\theta'}(\omega | \Omega_i)) \geq 0, \end{aligned} \quad (8)$$

where D_{KL} denotes the Kullback-Leibler divergence. Since the M-step chooses the new θ so as to maximize the minuend, the likelihood can only increase (or stay constant). Another convenient way to prove monotonicity of the EM algorithm can be found in [3, 4]. These tutorials consider the EM algorithm as the maximization of a lower bound of the likelihood. It is obtained from (4) by adding and subtracting the entropy of the distribution $\alpha_i(\omega)$, which gives

$$\begin{aligned} \log p_{\theta}(\Omega_i) &= \sum_{\omega \in \Omega_i} \alpha_i(\omega) \log \frac{p_{\theta}(\omega)}{\alpha_i(\omega)} \\ &\quad - D_{KL}(\alpha_i(\omega) \| p_{\theta}(\omega | \Omega_i)). \end{aligned} \quad (9)$$

The first term is thus a lower bound of the likelihood, which becomes tight if the KL divergence vanishes. This lower bound (summed over the training data) is then maximized by block coordinate ascent, resulting in the same algorithm as described by (6), (7).

It remains unclear whether the global optimum of the likelihood is reached in a fixed point of the algorithm. Moreover, it happens quite often that the M-step is infeasible for complex models p_{θ} . Then a weaker form of the EM algorithm is used by choosing $\theta^{(t+1)}$ so as to guarantee an increase of the objective function of the M-step.

The derivation of the concept of the EM algorithm was given here for a discrete probability spaces and discrete random variables. It can be however generalized to uncountable probability spaces and random variables X with continuous probability densities.

Example 1 The EM algorithm is often considered for the following special case. The sampling space Ω is a Cartesian product $\Omega = \mathcal{X} \times \mathcal{Y}$, and the random variable X simply projects onto the first component $X(x, y) = x$. The parameters $\theta \in \Theta$ of the probability $p_{\theta}(x, y)$ are to be estimated given a sequence of independent realizations of x . In this special case, the log-likelihood has the

$$L = \sum_{i=1}^n \log \sum_{y \in \mathcal{Y}} p_{\theta}(x_i, y). \quad (10)$$

Its decomposition (5) is

$$\begin{aligned} L &= \sum_{i=1}^n \sum_{y \in \mathcal{Y}} \alpha_i(y) \log p_{\theta}(x_i, y) \\ &\quad - \sum_{i=1}^n \sum_{y \in \mathcal{Y}} \alpha_i(y) \log p_{\theta}(y | x_i). \end{aligned} \quad (11)$$

The EM algorithm itself then reads

$$\text{E-step} \quad \alpha_i^{(t)}(y) = p_{\theta^{(t)}}(y|x_i) \quad (12)$$

$$\text{M-step} \quad \theta^{(t+1)} = \underset{\theta}{\operatorname{argmax}} \sum_{i=1}^n \sum_{y \in \mathcal{Y}} \alpha_i^{(t)}(y) \log p_{\theta}(x_i, y). \quad (13)$$

History and Applications

The classic paper [5] is often cited as the first one introducing the EM algorithm in its general form. It should be noted, however, that the method was introduced and analyzed substantially earlier for a broad class of pattern recognition tasks in [6] and for exponential families in [7].

A comprehensive discussion of the EM algorithm can be found in [8] and in the context of pattern recognition in [9] and [10]. Standard application examples are parameter estimation for mixtures of Gaussians [8] and the mean shift algorithm [11]. Another important application is parameter estimation for hidden Markov models. This model class is extensively used for automated speech recognition. The corresponding EM algorithm is known as Baum-Welch algorithm in this context [12]. Rather complex applications of the EM algorithm arise in the context of parameter estimation for Markov random fields [13].

Definition

Exploration refers to gathering data about an environment through sensors in order to discover its structure. A fundamental technique for exploration of an unknown environment is Simultaneous Localization and Mapping (SLAM). SLAM is a technique that supports the incremental building of a 3-D map representation of an environment while also using the same incremental map to accurately localize the observer in order to minimize errors in the map building. SLAM techniques can be implemented with laser range finders, monocular vision, stereo vision, and RGB-D cameras.

Background

An accurate representation of an environment is highly useful for autonomous and human assistive applications. Such a representation can be a high level minimalistic map derived from a sparse set of landmarks or a detailed dense 3-D model (e.g., Fig. 1). An accurate map can be used to perform useful tasks such as answering the question, “Where am I ?” and enables navigation and guiding tasks such as “How to get there?.” When dealing with unknown environments, the map representation must be acquired through an exploration phase. With SLAM the map can be built through a data gathering or map building phase, by either online or off-line methods. In online methods, the map is incrementally built, and location within the map is simultaneously calculated. With off-line methods the data is collected and then post-processed to yield an accurate map representation.

The key process of SLAM is an optimization algorithm. Noisy observations are made about the landmarks from different viewpoints (poses), and the task is to solve the optimization problem of estimating the position of each landmark and

E

Exploration: Simultaneous Localization and Mapping (SLAM), Fig. 1 A 3-D map generated by RGB-D Mapping by Henry et al. [1]. (Copyright 2012 SAGE. Reprinted by Permission of SAGE)

the set of camera viewpoints which best explain the observations. In off-line mapping this is a global optimization problem where all observations are available (e.g., Bundle Adjustment (BA) [2] applied to a full image dataset). In online mapping this is performed sequentially, using observations available up to and including the current observation. Thus, in online mapping, an incremental version of the map is available as the map is being constructed.

Two different methods are used in online mapping, namely, filtering-based and keyframe-based methods. Filtering-based methods are based on the following nature of sequential mapping. As camera observations/measurements are noisy, there is induced error in the newly identified landmarks. Later when one localizes with respect to the current map, again there is induced error in this new pose estimate due to error in observation and error in these new landmarks. So in subsequent new landmark additions to the map, there will be error in landmarks due to both measurement errors and the camera viewpoint estimation error. Due to the common error associated with camera viewpoint, estimates of the landmarks are all necessarily correlated with each other [3]. Therefore

a consistent full solution to the combined localization and mapping problem requires a joint state composed of the camera pose and every landmark position, to be updated following each landmark observation and hence the name Simultaneous Localization And Mapping.

In contrast keyframe-based methods do not propagate a probability distribution over time but employ a subset of image frames, called keyframes, in the map to perform efficient global optimization of the map and keyframe poses within a practical time limit. Although non keyframes are discarded in the optimization, it permits a large number of image observations per keyframe to be efficiently processed.

Visual SLAM is possible with both monocular and stereo cameras, and these systems are termed monoSLAM and stereoSLAM, respectively. In addition, RGB-D Mapping [1] which generates a dense 3-D map with RGB-D cameras has recently been introduced. It should be noted that, despite the computational effort, the use of cameras provides several unique advantages over other sensor types such as laser rangefinders and sonars. They are inexpensive, low power, compact, and capture scene information up to very large distances.

Theory

A complete SLAM system performs following operations in a cycle. First a set of new landmarks are identified in the environment, initialized (*new landmark/feature initialization*), and inserted into the map. Upon moving to a new location, *observations* are made and matched with the map landmarks, and this is referred to as *data association*. Here, *relocalization* methods are used to recover from possible tracking failures. Next, a prior estimate of the observer motion is obtained (*motion estimation*). Then the estimates of landmark positions and sensor pose that best explains the data are sought (*optimization*). If reobserving a previously mapped portion of the environment, care should be taken to ensure correct closure of the trajectory loop and consistency of the map (*loop closure*). Algorithm 1 illustrates this process (Note that as online mapping is an

Algorithm 1 SLAM operation

 (6) Loop closure correction
 (7) New landmark initialization

incremental process, Algorithm 1 assumes for generality some initial map is available. This may be the result of a single observation and new landmark initialization from the starting position).

An example situation is illustrated by Fig. 2. At time k , the true state of the observer is given by \mathbf{x}_k . The observer makes observations $\mathbf{z}_{k,i}$, $\mathbf{z}_{k,j}$, $\mathbf{z}_{k,p}$ of static landmarks whose true states are given by \mathbf{m}_i , \mathbf{m}_j , and \mathbf{m}_p , respectively. In the landmark selection process, it also discovers a new landmark whose true state is given by \mathbf{m}_q . Based on the corresponding measurement $\mathbf{z}_{k,q}$, the state of this new landmark is then initialized and inserted into the map. At time $k+1$, the observer has moved to a state \mathbf{x}_{k+1} under the control input \mathbf{u}_{k+1} . The observer has been able to reobserve two existing landmarks in the map, namely, \mathbf{m}_p and \mathbf{m}_q . Both the corresponding measurements $\mathbf{z}_{k+1,p}$, $\mathbf{z}_{k+1,q}$ and control input \mathbf{u}_{k+1} can be utilized to obtain a prior estimate of the incremental motion of the observer between time k and $k+1$.

At time $k+n$, the observer has travelled along a long trajectory loop and is revisiting a previously mapped part of the environment, namely, landmarks \mathbf{m}_i and \mathbf{m}_j . However, as can be seen from Fig. 2, the estimated state of the observer might not show a closed loop. Loop closure methods detect this situation and correct the state of the observer and the states of landmarks in the map.

The following subsections details the key stages of the SLAM system operation as given in Algorithm 1.

Exploration: Simultaneous Localization and Mapping (SLAM), Fig. 2 SLAM problem

Observation

A new image frame is fetched from the camera and features (e.g., interest points, lines) which can be potential landmarks are extracted.

Data Association

Data association refers to finding correspondences between observations and landmarks. There are a number of methods in this regard. The active search/covariance-driven gating approach projects individual covariance predictions of landmarks into the observation image and limits the observation area based on suitable Mahalanobis distance. The Joint Compatibility Branch and Bound (JCBB) method [4] uses the fact that observation prediction errors

are correlated with each other and hence calculates the joint probability of any set of correspondences. Active matching [5], on the other hand, considers the joint distribution and uses information theory to guide which landmarks to measure and when to measure them.

Relocalization

In case of rapid (unmodelled) motion, blur, and occlusion, camera pose tracking can fail and will result in subsequent corruption of the map. Relocalization refers to automatically detecting and recovering from such tracking failures to preserve the integrity of the map. Tracking failure can be

detected by considering the percentage of unsuccessful observations and large uncertainty in the camera pose. The pose of the camera is recovered by establishing correspondence between the image and the map and solving the resulting perspective pose estimation problem [6].

Motion Estimation

The observer's movement can be predicted based on odometry information or by making smooth motion assumptions (e.g., a constant velocity motion model). This information stands as a prior estimate of the observer state and covariance which is used later in the optimization stage. An example of such observer-state covariance computation is given by 5.

Optimization: Filtering-Based SLAM

Probabilistically the SLAM problem requires the computation of the joint posterior density of the landmark locations and observer (camera) state at time k , given the available observations and control inputs up to and including time k , together with the initial state of the observer [7–9].

This probability distribution can be stated as $P(\mathbf{x}_k, \mathbf{m} | \mathbf{Z}_{0:k}, \mathbf{U}_{0:k}, \mathbf{x}_0)$ where the quantities are defined as below (see Fig. 2).

\mathbf{x}_k = observer state vector

\mathbf{m} = vector describing the set of all landmark locations, i.e., landmark states \mathbf{m}_i

$\mathbf{Z}_{0:k}$ = set of all landmark observations \mathbf{Z}_i, k

$\mathbf{U}_{0:k}$ = history of control inputs \mathbf{u}_k

Given an estimate for the problem at time $k - 1$ (i.e., $P(\mathbf{x}_{k-1}, \mathbf{m} | \mathbf{Z}_{0:k-1}, \mathbf{U}_{0:k-1})$) a recursive solution to the problem can be obtained by employing a state transition model and an observation model which characterize the effect of the control input and observation, respectively.

Motion model: $P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{u}_k)$

Observation model: $P(\mathbf{z}_k | \mathbf{x}_k, \mathbf{m})$

Therefore, the SLAM algorithm can now be expressed as a standard two-step recursive prediction (time update) correction (measurement update) form as below:

Time Update

$$\begin{aligned} P(\mathbf{x}_k, \mathbf{m} | \mathbf{Z}_{0:k-1}, \mathbf{U}_{0:k}, \mathbf{x}_0) &= \int P(\mathbf{x}_k | \mathbf{x}_{k-1}, \mathbf{u}_k) \\ &\times P(\mathbf{x}_{k-1}, \mathbf{m} | \mathbf{Z}_{0:k-1}, \mathbf{U}_{0:k-1}, \mathbf{x}_0) d \mathbf{x}_{k-1} \end{aligned} \quad (1)$$

Measurement Update

$$\begin{aligned} P(\mathbf{x}_k, \mathbf{m} | \mathbf{Z}_{0:k}, \mathbf{U}_{0:k}, \mathbf{x}_0) &= \frac{P(\mathbf{z}_k | \mathbf{x}_k, \mathbf{m}) P(\mathbf{x}_k, \mathbf{m} | \mathbf{Z}_{0:k-1}, \mathbf{U}_{0:k}, \mathbf{x}_0)}{P(\mathbf{z}_k | \mathbf{Z}_{0:k-1}, \mathbf{U}_{0:k})} \end{aligned} \quad (2)$$

Two main solution methods to the probabilistic SLAM problem include Extended Kalman Filter (EKF)-based SLAM [3] and Rao-Blackwellized Filter (RBF)-based SLAM [10, 11].

Extended Kalman Filter (EKF)-Based SLAM

As noted, the solution to the SLAM problem requires a joint state composed of the observer state and the state of every landmark, to be updated following each landmark observation. This motivates to use the Kalman filter which provides a recursive solution to the discrete data linear filtering problem. When the motion model and measurement errors/noise are independent white Gaussian, the Kalman filter computes an optimal gain which minimizes mean-square error of the posterior estimate of the system. The Gaussian distribution is completely characterized by its mean and covariance. Here correlations between observer state and different landmarks can be properly represented in the total system covariance matrix of the Kalman filter. As the system would generally be nonlinear, the Extended Kalman Filter (EKF) is used.

Propagation of Uncertainty A fundamental problem in estimating covariance matrices is how to propagate uncertainty through a function. Consider a nonlinear function f which acts on the vector \mathbf{a} of input variables to produce the output vector \mathbf{b} :

$$\mathbf{b} = f(\mathbf{a}) \quad (3)$$

Under affine approximation, the error covariance of the output vector $P_{\mathbf{bb}}$ is obtained in terms of the error covariance of the input vector $P_{\mathbf{aa}}$ by 4 (The covariance between two arbitrary vectors \mathbf{a} and \mathbf{b} is defined as $P_{\mathbf{ab}} = E[(\mathbf{a} - E[\mathbf{a}])(\mathbf{b} - E[\mathbf{b}])^T]$):

$$P_{\mathbf{bb}} = \frac{\partial f}{\partial \mathbf{a}} P_{\mathbf{aa}} = \frac{\partial f^T}{\partial \mathbf{a}} \quad (4)$$

State Prediction The general form of the EKF prediction steps can be customized for SLAM to yield faster computation. Note that there is no need to perform a time update for landmark states $\mathbf{m}_i : i = 1 \dots n$ if the landmarks are stationary. Hence, only the observer's state, \mathbf{x}_k , is predicted ahead. The new error covariance of the observer's predicted state should also be computed. In addition, though there is no change in error covariance of landmarks, there will be change in error covariance between each landmark and observer state (since observer state changed). Given below are the new time update equations for the covariance items that require an update.

Notation:

$\{\cdot\}^-$ = time update (prior) estimate

\mathbf{n} = observer motion model noise

$P_{\mathbf{nn}}$ = observer motion model noise covariance

f_v = observer state transfer function $\mathbf{x}_{k+1}^- = f_v(\mathbf{x}_k, \mathbf{n})$ such that $\mathbf{x}_{k+1}^- = f_v(\mathbf{x}_k, \mathbf{0})$

$$P_{\mathbf{x}_{k+1}^- \mathbf{x}_{k+1}^-}^- = \frac{\partial f_v}{\partial \mathbf{x}_k} P_{\mathbf{x}_k \mathbf{x}_k}^- \frac{\partial f_v^T}{\partial \mathbf{x}_k} + \frac{\partial f_v}{\partial \mathbf{n}} P_{\mathbf{nn}} \frac{\partial f_v^T}{\partial \mathbf{n}} \quad (5)$$

$$P_{\mathbf{x}_{k+1}^- \mathbf{m}_i}^- = \frac{\partial f_v}{\partial \mathbf{x}_k} P_{\mathbf{x}_k \mathbf{m}_i} \quad (6)$$

The computational complexity of the EKF-SLAM solution grows quadratically with the number of landmarks. This is due to the calculations involved in the EKF update steps.

Rao-Blackwellized Filter (RBF)-Based SLAM

Rao-Blackwellized filter based SLAM methods include FastSLAM [10] and FastSLAM 2 [11] algorithms. The algorithms utilize a key point in

SLAM, i.e., given the observer path/trajectory (if the observer path is assumed correct), different landmark measurements are independent of each other. So a particle filter is used to estimate the observer's path and for each particle a map is maintained. Since landmarks within this map are independent/uncorrelated, they can be represented with separate low-dimensional EKFs. Therefore, it has linear complexity rather than the quadratic complexity of EKF-SLAM.

Landmark Representation As noted, probabilistic SLAM (EKF/RBF SLAM) requires the uncertainty of landmarks to be modelled. A landmark's uncertainty modelling depends upon the parameterization used to represent its state. The simplest way to parametrize a landmark is by the common three-dimensional Cartesian coordinates $\mathbf{m}_i^{car} = (X_i, Y_i, Z_i)^T$. This is applicable in stereo camera SLAM systems where the landmark state can be obtained by triangulation, and the uncertainty follows the common Gaussian assumption. However, in single camera SLAM systems, in which it is not possible to estimate a landmark's state from a single measurement, there is large uncertainty in the depth direction which cannot be modelled as Gaussian. Therefore, alternative parameterizations are proposed to alleviate this issue.

Civera et al. [12] represent a feature using inverse depth parameterization as

$$\mathbf{m}_i^{i\ dp} = (x_i, y_i, z_i, \theta_i, \phi_i, \rho_i)^T, \quad (7)$$

where x_i, y_i, z_i represent the camera position from which the feature was first observed, θ_i, ϕ_i represent the azimuth and elevation of the corresponding ray, and ρ_i represents the inverse depth to the landmark along this ray. The relationship of $\mathbf{m}_i^{i\ dp}$ to \mathbf{m}_i^{car} is as follows:

$$\begin{aligned} \mathbf{m}_i^{car} &= \begin{pmatrix} X_i \\ Y_i \\ Z_i \end{pmatrix} \\ &= \begin{pmatrix} x_i \\ y_i \\ z_i \end{pmatrix} + \frac{1}{\rho_i} \begin{pmatrix} \cos \phi_i & \sin \phi_i \\ -\sin \phi_i & \cos \phi_i \\ \cos \theta_i & \sin \theta_i \end{pmatrix}. \end{aligned} \quad (8)$$

Marzorati et al. [13] use the homogenous coordinates

$$\mathbf{m}_i^{i\ sp} = (x_i, y_i, z_i, \omega_i)^T, \quad (9)$$

which relates with \mathbf{m}_i^{car} as

$$\mathbf{m}_i^{car} = \begin{pmatrix} X_i \\ Y_i \\ Z_i \end{pmatrix} = \frac{1}{\omega_i} \begin{pmatrix} x_i \\ y_i \\ z_i \end{pmatrix} \quad (10)$$

where ω_i is the inverse scale.

Although the number of parameters per landmark has increased from three of the minimal representation (\mathbf{m}_i^{car}), $\mathbf{m}_i^{i\ dp}$ and $\mathbf{m}_i^{i\ sp}$ are able to represent the landmark uncertainty as Gaussian and make the measurement equation more linear.

Optimization: Keyframe-Based SLAM

Keyframe-based SLAM splits camera pose tracking and mapping into separate processes. The accuracy of camera pose estimation is increased by using measurements from large numbers of landmarks per image frame. The map is usually estimated by performing bundle adjustment/optimization over only a set of frames (keyframes) since measurements from nearby image frames provides redundant and therefore less information for a given computational budget [14]. Here a new keyframe can be selected and inserted to the map based on a sliding window of most recent camera poses or by ensuring a minimum distance to the pose of the nearest keyframe already in the map.

Loop Closure

Ideally when a SLAM system reobserves a previously mapped region of an environment, it should correctly recognize the corresponding landmarks in the map. However, particularly in long trajectory loops, landmark states in two such regions of the map can be incompatible given their uncertainty estimates. Therefore, loop closure methods are utilized to align such regions and make the map globally coherent. These include image-to-image matching [15], image-to-map matching [16], and hybrid methods [17].

New Landmark Initialization

Significant and distinguishable parts of the environment are selected as landmarks/features. In visual SLAM, these typically include interest points and edges/lines in the observed image. Upon selecting suitable landmarks, their position states and covariances are initialized and inserted into the map. Adding a new landmark \mathbf{m}_{new} to the map is a function of observer pose \mathbf{x}_k and new landmark observation \mathbf{z} which is given by $\mathbf{m}_{new} = f_{new}(\mathbf{x}_k, \mathbf{z})$. To add a new landmark, one needs to know the error covariance of the new landmark with other landmarks \mathbf{m}_{oth} and the observer \mathbf{x}_k . This can be calculated using the system uncertainty at that time as below:

$$P_{\mathbf{m}_{new} \mathbf{m}_{new}} = \frac{\partial f_{new}}{\partial \mathbf{x}_k} P_{\mathbf{x}_k \mathbf{x}_k} \frac{\partial f_{new}}{\partial \mathbf{x}_k}^T + \frac{\partial f_{new}}{\partial \mathbf{z}} R \frac{\partial f_{new}}{\partial \mathbf{z}}^T \quad (11)$$

$$P_{\mathbf{x}_k \mathbf{m}_{new}} = P_{\mathbf{x}_k \mathbf{x}_k} \frac{\partial f_{new}}{\partial \mathbf{x}_k}^T \quad (12)$$

$$P_{\mathbf{m}_{oth} \mathbf{m}_{new}} = P_{\mathbf{m}_{oth} \mathbf{x}_k} \frac{\partial f_{new}}{\partial \mathbf{x}_k}^T \quad (13)$$

Note R denotes the error covariance of the observation \mathbf{z} .

Application

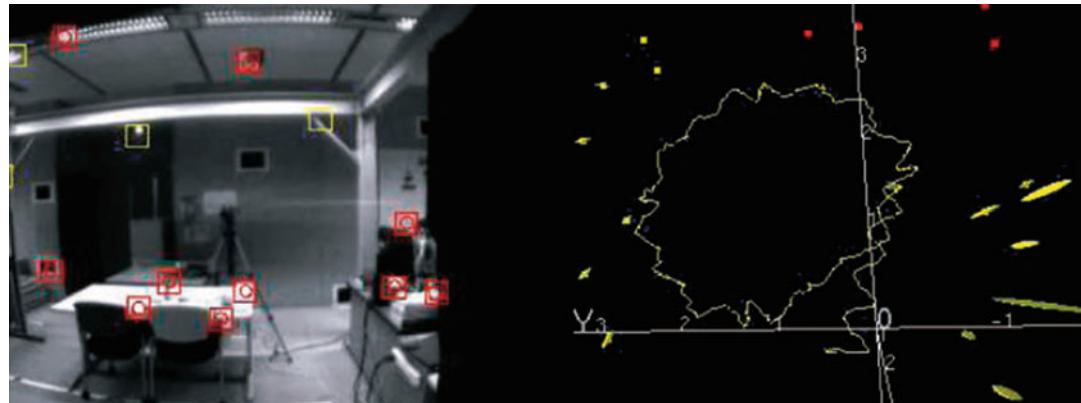

Visual SLAM approaches have been successfully used in large scale outdoor environment mappings, and due to the human-like visual sensing of the camera, it has found applications in augmented reality applications [18] (see Fig. 3).

Open Problems

Despite recent work [19], the performance of visual SLAM is not sufficiently robust in dynamic environments where multiple moving objects are present in the scene. This is similar to the motion segmentation problem in computer vision. In

Definition

The extended Gaussian image (EGI) of a 3-D object is a function defined on a unit sphere. The value of the EGI at a point on the unit sphere is the inverse of the curvature at the corresponding point on the object – where the corresponding point is the one that has the same surface orientation. In the case of a polyhedral object, the value on the sphere is zero except for impulses at points on the sphere corresponding to faces of the polyhedron. The “size” or volume of each impulse is equal to the area of the corresponding face. The mapping from a 3-D polyhedron to the EGI is illustrated in Fig. 1. Figure 2 shows the mapping for a 3-D piecewise smooth object.

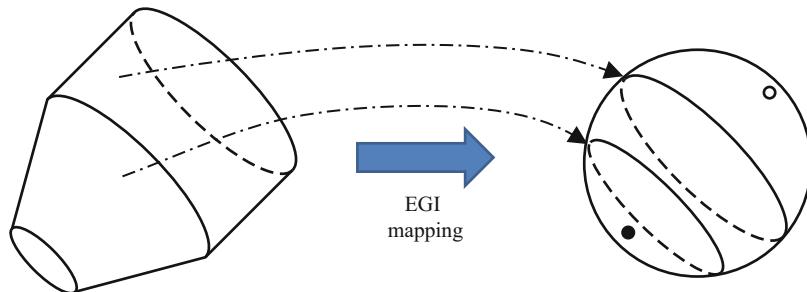

Background

Object recognition and determination of object pose (orientation and translation) are two fundamental, interlinked tasks in 3-D computer vision and robotics. The shape of an object can be measured directly using, for example, a rangefinder or binocular stereo techniques or indirectly using, say, photometric stereo. A representation for that

shape is needed that makes recognition and attitude determination relatively easy. One requirement is that the representation transforms in a simple way when the object is rotated.

each face at a point on the sphere with the same surface orientation as the face.

More specifically, the Gaussian image of an object is obtained by mapping from a point on the surface of the object to the point on the unit sphere that has the same surface normal. In the case of a convex object, this mapping is invertible – only one point on the object's surface corresponds to a point on the unit sphere. This mapping extends in a natural way to curves and surface patches. The Gaussian curvature is the limit of the ratio of the (signed) area of a patch on the unit sphere to the area of the corresponding patch on the surface of the object, as the size of the patches becomes smaller and smaller. The Gaussian curvature is everywhere nonnegative in the case of a convex object. The extended Gaussian image (EGI) associates a value with a point on the unit sphere equal to the inverse of the Gaussian curvature at the corresponding point on the object.

Theory

EGIs can be used to represent both smoothly curved objects as well as polyhedra. For ease of explanation, the convex polyhedra are discussed first. Minkowski [11] showed in 1897 that a convex polyhedron is fully specified (up to translation) by the areas and orientations of its faces (see also [10, 14]). The area and orientation of faces can be represented conveniently by point masses (i.e., impulses of mass density) on a sphere. The extended Gaussian image of a polyhedron is obtained by placing a mass equal to the area of

A.D. Alexandrov showed that a smoothly curved convex object is fully specified by curvature given as a function of surface orientation [1]. So the EGI representation is unique for both smoothly curved convex objects and convex polyhedra. Note, however, that neither of the proofs is constructive and thus they do not provide a basis for reconstructing an object from its EGI. Importantly, reconstruction is *not* required for recognition and orientation determination.

The discrete and continuous versions of the EGI can be related as follows: An object with planar faces can be thought of as the limit of an object with patches of spherical surfaces as the radius of the curvature of the patches get larger and larger. A spherical patch of radius R contributes a constant value R^2 (its Gaussian curvature) to an area of the unit sphere corresponding to all of the surface orientations at points in that patch. As the radius tends to infinity, the value increases, at the same time that the area on the sphere shrinks. So the EGI of a polyhedron consists of a set of impulses, each of which has “volume” equal to the area of the corresponding face. It is convenient to treat these impulses as weights (or arrows of varying length) placed on the unit sphere. This is the discrete EGI. Conversely, the continuous EGI can be viewed as the limit of point mass density on the sphere as an approximation of a smoothly curved surface using a tessellation consisting of planar facets is made finer and finer.

The EGI has the following properties:

- *Translation invariance.* The EGI is not affected by object translation.
- *Rotation tracking.* Rotation of the object induces an equal rotation of the EGI since the unit surface normals rotate with the object.
- *Total mass equals total surface area.* Follows directly from the definition.
- *Center of mass at origin.* If the object is closed and bounded, the center of mass of the EGI is at the center of the Gaussian sphere.
- *Uniqueness.* There is only one closed convex object that corresponds to a particular EGI [1, 15].

If the object is not convex, more than one point on the object will contribute to a given point on the Gaussian sphere. One way of extending the definition of the EGI in the non-convex case is to use the sum of the inverses of the absolute values of the Gaussian curvature of all points on the surface that have the same orientation. While still useful in recognition and orientation determination, multiple non-convex objects may have the same EGI. For example, the EGI of all tori with the same surface area ($4\pi^2 R\rho$) and axis orientation is $2R\rho \sec \eta$, while there is but one *convex* object with that EGI. (Here R and ρ are the major axis and minor axis, respectively, while η is the angle between the surface normal and the plane perpendicular to the axis of the torus.)

In generating an EGI from an object, explicit information on shapes of faces and their adjacency relationships is not kept. Interestingly, a convex polyhedron can be recovered from its EGI [6, 9] as well as face adjacency and edge length information [12]. For a much more detailed treatment on EGIs, see [4]. The EGI has also been examined more broadly in the context of orientation-based representations [8].

The original version of the EGI is translation invariant. While it allows orientation to be extracted without regard to translation, a separate step is required to compute the translation. A variant of the EGI, the Complex EGI [7], uses complex mass to represent area (magnitude) and distance (phase). This decouples translation from rotation, allowing rotation to be determined in the usual fashion using the magnitudes while phase is subsequently used to compute translation. A support-function-based representation described in [13] encodes descriptors that are both local (tangent plane) and global (position and orientation of tangent plane).

Other extensions of the EGI address another inherent feature of not explicitly coding structural information. For example, the CSG-EESI (Constructive Solid Geometry-Enhanced Extended Spherical Image) [17] has two levels. The higher level contains the CSG tree which describes who the various subparts form the body, while the lower level describes the subparts

using enhanced spherical images similar to that of [15]. Another tree-like representation is that of Hierarchical Extended Gaussian Image (HEGI) [18]. An HEGI description can be constructed as a tree where each leaf node corresponds to an Extended Gaussian Image (EGI) description of a convex part resulting from the recursive convex hull decomposition of an object. The COSMOS system described in [3] uses support functions based on Gaussian curvature and mean curvedness; connectivity information is maintained as a list.

Application

The EGI has been used for recognition and bin-picking of topmost objects (e.g., [2, 5, 6, 19]). It has also been used for symmetry detection [16] (for both reflectional and rotational symmetries).

In practice, the continuous EGI of a smoothly curved object is numerically approximated. The surface of the object may be divided into many patches, each of which is approximated by a planar facet of known area and orientation. The unit sphere may also be tessellated into cells, in each of which a total is accumulated of the areas of facets that have orientations falling within the range of orientations of that cell. Regular and semiregular tessellations of the sphere can be obtained by projecting regular polyhedra (Platonic solids) or semiregular polyhedra (Archimedean solids). Unfortunately there are only 5 regular solids, with the icosahedron having 20 facets, which is not a fine enough tessellation. There are 13 semiregular solids, but again there are relatively few faces in these tessellations, the truncated icosahedron, for example, having only 32 faces. Finer, but less regular, tessellations can be obtained by subdividing faces of the regular and semiregular tessellations.

In typical practical applications, the object is only partially observed. Assuming the object is not occluded by other objects, the EGI of an observed convex object has information on at most one hemisphere. For a non-convex object, there is the issue of self-occlusion, so that the weight distribution for a set of tracked surface

normal may change with object orientation. The most obvious solution is that of brute force search through the space of possible discrete orientations (e.g., as was done in [7]), but this is computationally expensive. Ikeuchi [6] reduces the search space by computing the ratio of the surface area to the projected area and constraining the freedom of rotation (since this ratio is independent of planar rotation for a given line of sight).

Face Alignment

Amit Kumar¹ and Rama Chellappa²

USA

²Departments of Electrical and Computer
Engineering and Biomedical Engineering
(School of Medicine), Johns Hopkins University,
Baltimore, MD, USA

Definition

Face alignment refers to transforming a given face image to a canonical coordinate system. This is done by automatically detecting facial fiducial points also called facial landmarks or keypoints and then using standard transformation methods such as affine/similarity transformation. These fiducial points are predefined points on the face image which are mainly located or centered around facial parts such as the eyes, nose, chin, and mouth corners as shown in Fig. 1.

Background

While face detection (localizing faces in a given image) is regarded as the starting point for any face analysis task, face alignment is

an essential intermediary step for solving tasks such as expression recognition, face recognition, face modeling, etc. In recent years, facial landmark extraction, subsequently used for aligning the face images, has received significant interest from the research community. Methods developed using convolution neural networks have been able to localize facial landmarks with great precision even in unconstrained settings, which in turn have set new benchmarks in face recognition, identification, and emotion recognition tasks. A brief description of the evolution of facial landmark localization methods is presented in section “[Theory and Applications](#).”

A large number of approaches have been proposed to tackle the problem of face alignment of 2D images with varying degrees of success. From an overall perspective, face alignment can be formulated as searching over the face image for the pre-defined facial points (also called facial landmarks, fiducial, keypoints, or face shape). Most of the methods in literature start from an initial estimate and proceed to refine the estimate incrementally. Typically, two different sources of information are used: local appearance features and shape constraint. The shape constraints exploit the relationships among different landmark points to ensure that the estimated facial landmark points forms a valid shape.

Face Alignment, Fig. 1 Sample results for facial landmark localization task. First image shows the landmarks when all the facial components are visible. (Image taken from iBug dataset [1]). Second image taken from COFW

dataset [2] shows the landmarks when face parts are invisible due to occlusion. Third image from AFW dataset [3] shows typical keypoints used for face alignment after localization. All results generated using Kumar et al. [4]

Theory and Applications

Existing methods for facial landmark extraction are categorized into two prominent categories: **generative** and **discriminative**.

- **Generative methods:** These methods build a generative model for face shape and appearance. They typically formulate face alignment as an optimization problem to find face shape and appearance parameters that generate the appearance model that best fits the test face. The appearance model can be characterized by the whole face or local patches.
- **Discriminative methods:** These methods directly infer the target location of keypoints from facial appearance. This is done by learning local descriptors or a set of regressors for each facial point or a global shape model which implicitly enforces the shape constraints. Many recent works including the works based on convolution neural networks fall into this category.

Generative Methods

Typically, faces are modeled as deformable objects which can vary in terms of shape and appearance. Generative face alignment develops parametric models for both face shape and appearance and seeks to find the best model parameters that can reconstruct the test face well, during testing. Active Appearance Models

(AAMs) proposed by Cootes et al. [5], which are linear statistical models of both the shape and appearance, are arguably the most well-known family of generative methods and have been used and studied extensively over the last 20 years. Generative models in general are defined by three components, i.e., *shape model*, *appearance model*, and *motion model*. The shape model is built from a set of manually annotated N facial points $\mathbf{s} = (\mathbf{x}_1^T \dots \mathbf{x}_N^T)^T$ describing the face shape, where $\mathbf{x}_i = (x_i, y_i)$ is the 2-D location of the i th point. Then the shape model can be mathematically expressed as:

$$\mathbf{s}(\mathbf{p}) = \mathbf{s}_0 + \mathbf{S}\mathbf{p} \quad (1)$$

where $\mathbf{s}_0 \in \mathbb{R}^{(2N,1)}$ is the mean shape and $\mathbf{S} \in \mathbb{R}^{(2N,n)}$ and $\mathbf{p} \in \mathbb{R}^n$ are the shape eigenvectors and parameters. Similarly, the texture model is defined as follows:

$$\mathbf{A}(\mathbf{c}) = \mathbf{a}_0 + \mathbf{A}\mathbf{c} \quad (2)$$

where $\mathbf{a}_0 \in \mathbb{R}^{(F,1)}$ is the mean appearance and $\mathbf{A} \in \mathbb{R}^{(F,m)}$ and $\mathbf{c} \in \mathbb{R}^m$ are the appearance eigenvectors and parameters. Given a test image \mathbf{I} , the goal is to find the optimal parameters \mathbf{p} and \mathbf{c} . Formally, let $\mathbf{I}[\mathbf{p}] = \mathbf{I}(W(\mathbf{p}))$ denote the vectorized version of the warped image, warped using W , defining how given a shape, the image should be warped into a canonical frame of reference. The optimization problem can then

be formulated as:

$$\operatorname{argmin}_{\mathbf{p}, \mathbf{c}} \|\mathbf{I}[\mathbf{p}] - \mathbf{a}_0 - \mathbf{A}\mathbf{c}\|^2 \quad (3)$$

This optimization problem is solved using an iterative process that updates the model parameters in each update. Subsequently, significant developments have been made in solving the aforementioned problem, by using nonlinear regressor or the Gauss-Newton method.

Part-based generative models build generative appearance models for facial parts constrained by a generic face model governing the deformations. A notable example is the well-known original Active Shape Models (AAM) [6] that combine the generative appearance model for each facial part and a global shape model. A second approach is to simultaneously construct generative models for all facial parts as in Gauss Newton Deformable Part Models (GN-DPM) [7].

Discriminative Methods

Discriminative models seek to learn discriminative functions that directly map the facial appearance to the target facial points. One of the early methods used for discriminative fitting is Constrained Local Models (CLMs) which aim to learn independent local detectors for each facial part and a shape model to impose the shape constraint. The task of the local detectors is to estimate pseudo-probability that the target point occurs at a particular position. In the literature, different types of classifiers have been studied: logistic regression [8], support vector machines [9], and local neural fields [10]. Exemplar-based model fitting proposed by Belhumeur et al. [11] can also be interpreted under the conventional CLM framework. Tree structure models are a natural choice to model deformable objects, and one can find optimal solutions using efficient dynamic programming algorithms. The main drawback that a single tree structure model is insufficient to capture various face shapes has been addressed in the seminal work of Ramanan et al. [3] by designing different part models for faces in different poses.

Cascade Regression

Several methods based on the discriminative approach exist in the literature. One such approach is the method of cascade regression. The motivation behind this being that performing regression from image features to face shape in one step is challenging and, hence, the regression process is divided into stages, by learning a cascade of regressors. Formally, given an image \mathbf{I} and an initial shape \mathbf{s}_0 , the face shape \mathbf{s} is progressively refined by estimating a shape increment $\Delta\mathbf{s}$ stage by stage. In a generic form, a shape increment $\Delta\mathbf{s}$ at stage t is regressed as:

$$\Delta\mathbf{s}_t = \mathcal{R}_t(\Phi_t(\mathbf{I}, \mathbf{s}_{t-1})) \quad (4)$$

where \mathbf{s}_{t-1} is the shape estimated in the previous stage, Φ_t is the feature mapping function, and \mathcal{R}_t is the stage regressor. Note that $\Phi_t(\mathbf{I}, \mathbf{s}_{t-1})$ is referred to as the shape-indexed feature [12] that depends on the current shape estimate and can be either designed by hand [13, 14] using Local Binary Patterns [15] or SIFT [16] or by learning [17–20]. In the training phase, the stage regressors ($\mathcal{R}_1, \mathcal{R}_2, \dots, \mathcal{R}_t$) are sequentially learned to reduce the alignment errors on the training set, during which geometric constraints among points are implicitly encoded.

Convolution Neural Networks

Deep neural networks, especially deep convolution neural networks, have dramatically improved the performance of landmark localization methods both in terms of precision and speed. Many cascade neural regression-based methods have been adopted to incorporate deep features to learn the local detectors. Multistage methods such as [17, 19, 21] directly model the keypoint locations. However, single-stage methods based on encoder-decoder architecture such as [4, 22] have proven to be efficient in terms of speed and localization error. These models learn the inherent relationships among the different landmark points so as to maintain the shape constraints. Some methods such as [23, 24] also make use of the 3D structure of the face to model large pose variations and occlusion, whereas methods such

as the ones in [4] model large pose variations implicitly through modified loss functions.

Open Problems

Under constrained or laboratory settings, the problem of landmark detection has been well addressed [7–9], and in many cases methods achieve close to human performance. However, real-life scenarios cast a new set of challenges, due to large facial appearance variability caused either by intrinsic dynamic features of the facial components such as the eyes, mouth, and chin or by ambient environmental changes. In general, the following factors could significantly influence the local and global facial features:

- **Pose:** The appearance features vary greatly between different camera poses, for example, some facial components can be completely occluded in a profile face image.
- **Occlusion:** In unconstrained settings, occlusion due to external circumstances happens quite often and brings great challenges to landmark extraction and hence face alignment. For instance, eyes may be occluded by hair or sunglasses.
- **Illumination:** In the age of mobile devices, images are taken in varying lighting conditions (outdoors in sunny or cloudy conditions or indoors under fluorescent light), which significantly alter the appearance of whole face and make the detailed textures of the components missing.
- **Expression:** Some facial features such as the eyes and mouth are sensitive to varying expressions. For example, laughing may cause the eyes to shut completely.
- **Low Resolution:** Low resolution causes facial details to get obscured, and hence methods which rely on local appearance face great difficulty in localizing the keypoints with precision.

Definition

Face detection refers to the detection of face instances in an image.

F

Background

Face detection is a fundamental step to all facial analysis algorithms, including face alignment, face parsing, and face recognition. Given an arbitrary image, the goal of face detection is to determine the presence of faces in the image and, if present, return the location and extent of each face in an image.

As in object detection, early work in face detection took a sliding window paradigm, in which a classifier is applied on a dense image grid. Following this paradigm, early progress in face detection is closely related to the combined use of handcrafted features and classifiers, e.g., Haar-like features with boosting [1,2], Histogram of Oriented Gradients (HOG) with Support Vector Machine (SVM) [3,4], and multiple channel features with boosting [5]. Most early detectors perform well in constrained scenarios where near frontal faces are assumed but encounter problems in dealing with images in the wild due to large appearance variations.

Contemporary face detectors are based on deep Convolutional Neural Network (CNN), in which the feature extractor and classifier are jointly trained in an end-to-end manner. These detectors perform much better than approaches based on handcrafted features due to the capability of deep CNNs in extracting discriminative representation from data. Modern face detectors based on deep CNNs can easily detect faces under moderate variations in pose, scale, facial expression, occlusion, and lighting condition. Consequently, deep learning-based face detectors are now widely used in a myriad

of consumer products, e.g., video surveillance systems, digital cameras, and social networks.

Current research efforts are devoted to solving extreme cases such as finding tiny faces in crowded scenes, coping with wide range of face scales more efficiently and effectively, and handling intricate factors such as extreme pose, exaggerated expressions, and large portion of occlusion.

Theory and Applications

Face detection [6, 7] has seen significant progress after the seminal work by Viola and Jones [1, 2], who popularize the framework of boosted cascade with simple Haar-like features represented as integral images. The simple nature of such features allows efficient evaluation of large number of window candidates, while the boosted cascade permits fast detection with low false-positive rates. Many studies thereafter follow the boosted cascade framework with more advanced features [8–11], boosting algorithms [12, 13], and cascade structures [14, 15].

Deformable Part Model (DPM) [16] has also been widely applied for face detection [4]. In general, a DPM represents the appearance of parts as well as the connections between them in a pictorial structure. Methods have been proposed to improve the vanilla DPM by training tree-structured DPM by treating every facial landmark as a part [17, 18] or using a multi-scale model with elaborated features like integral channel features [4, 19]. Some variants were proposed to reduce the computational complexity of DPM-based methods [20, 21].

Some of the earlier work on face detection employed neural networks [22–24], but they were soon replaced by boosted cascade and DPM-based approaches. A new wave of interests of applying Convolutional Neural Networks (CNN) for face detection [25–33] is sparked by the success of deep learning in ImageNet Large Scale Visual Recognition Challenge 2012. There are various design variations in the literature. Recent face detection methods typically follow the paradigm of a two-stage detector, e.g., Faster

R-CNN [34], or a single-stage detector like Single Shot MultiBox Detector (SSD) [35] and You Only Look Once (YOLO) [36]. Different variants are developed with the aim to improve the performance in detecting faces of a wide range of scales and the efficiency of the aforementioned networks for face detection.

Detection across scales A major challenge in face detection is to detect faces of a wide range of scales. This issue remains despite the use of deep CNNs. Detection across scales cannot be fully resolved by just using deeper networks. On one hand, more convolution layers are required to learn highly representative features that can distinguish faces with large appearance variations, i.e., pose, expression, and occlusion from clutter background. On the other hand, by going deeper, the spatial information, which is essential to finding tiny faces, would lose through pooling or convolution operations. The aforementioned problem can be partially alleviated by using a dilation operation [37] and reducing the number of pooling operations. However, the computation will dramatically increase with high spatial resolution of feature maps in the network, making it difficult to meet practical runtime speed.

Existing studies perform detection across scales by either performing image pyramid prediction using a single-scale detector or building different detectors for different face scales. It is possible to make use of both coarse image pyramid together with multiple scale-specific detectors too [25]. To reduce the computational cost introduced by using multiple scale-specific detectors, one can divide a network into a few specialized subnetworks/layers, each of which has their depth, spatial pooling, or anchors (regression references to predict proposals for two-stage detectors) carefully designed to optimize the detection of faces that fall onto a particular range of size. This technique has been shown effective on two-stage detectors [31] and single-stage detector [33, 38].

Contextual information plays an important role in face detection, especially in the detection of small faces. One can make use of additional local context around faces to improve the

detection performance [25, 38, 39], either by enlarging the window around the candidate proposals or using larger filters to increase the receptive field.

Cascading In many applications it is important to have swift face detection while still maintaining the detection performance. Cascading is a common technique to reduce the computational time of face detection. The common practice is to combine a few successively more complex classifiers in a cascade structure so that early-stage classifiers can quickly eliminate easy background regions while detecting almost all positive instances, and subsequent classifiers focus on evaluation of a small number of challenging candidates.

The first cascading classifier for face detection was proposed by Viola and Jones [1]. Stages in the cascade are constructed by training classifiers using AdaBoost [40] and then adjusting the threshold to minimize false negatives. The notion of cascading can also be applied on deep CNN-based face detectors [27, 32]. Specifically, a cascade is usually constructed such that in early stages candidate windows are quickly produced through a shallow CNN with low-resolution images; the subsequent stages refine the windows by rejecting a large number of non-face windows through more complex CNNs. There exist alternative ways of constructing cascaded networks, for instance, by using a face attribute recognition network in the first stage to generate high-quality proposals by face responses and using a multitask network for face classification and bounding box regression in the second stage [30].

Loss functions The typical loss used for training a deep network-based face detector is ℓ_2 loss, measuring the localization error between the coordinates of a bounding box's corners and the ground truth coordinates. Some studies have proposed alternative losses to train a detector. For instance, Smooth ℓ_1 loss [33] is used so that the training is less sensitive to outliers. Intersection over Union (IoU) Loss [41] aims at regressing the four corners of a predicted box as a whole

unit. Unlike ℓ_2 loss, this loss considers the correlation of object boundaries. Multitask learning introduces auxiliary losses to further improve the performance of a face detector. For instance, training a face detector jointly with facial landmark detection is shown to considerably improve the face detection performance [32].

Hard example mining It is always desirable to perform hard example mining during the training to improve the robustness of a face detector. Traditional face detection methods select hard examples in an off-line manner, i.e., the identification of hard examples (samples that are misclassified) and retraining are conducted in an alternate manner. Due to the nature of deep learning which requires hundreds of thousands of stochastic gradient descent (SGD) steps on millions of examples, hard example mining is shifted to an online paradigm [31, 32, 42]. For instance, this can be done by sorting the samples in each mini batch by their losses during the forward propagation and select those with the highest loss as hard samples. Only gradients of hard samples are back-propagated [32].

Other considerations Other techniques that have shown effective on general object detection, e.g., Deformable Convolution [43], Guided Anchoring [44], and Feature Pyramids [45], can also be used to improve the performance of a face detector. Data augmentation such as random crops, horizontal flip, and color jitter is found useful to enrich the data for training a deep network for face detection.

Benchmark Databases and Evaluation Metrics

Benchmark databases In the past decades, many benchmark databases have been constructed to evaluate the performance of face detection. Some of the popular ones include FDDB [46], AFW [18], PASCAL FACE [17], and IJB-A [47]. These databases have contributed to spurring interest and progress in face detection

Face Detection, Fig. 1 Example images and annotations from the WIDER FACE dataset [48]

research. However, as algorithm performance improves, more challenging datasets are needed to catalyze new approaches. These face detection datasets typically contain a few thousand faces, with limited variations in pose, scale, facial expression, occlusion, and background clutter. The assessment results of a detector on these datasets are typically far from its real-world performance. In 2016, a new large-scale face detection dataset called WIDER FACE [48] was presented. It consists of 32,203 images with 393,703 labeled faces, which is 10 times larger than the IJB-A dataset [47]. As shown in Fig. 1, the faces in WIDER FACE vary largely in appearance, pose, and scale, making the dataset a good platform for developing and testing face detection algorithms.

Evaluation metrics The quality of a face detector is generally measured by its recall, false-positive rate, and speed (which is typically measured in frame per second, FPS). To measure recall and false-positive rate, an object is considered detected if the IoU between the predicted bounding box and ground truth bounding box is no less than 0.5. The overall performance of a face detector is characterized by the receiver operating characteristic (ROC) curve, which is widely used to evaluate the recall against the false-positive rate of a face detection system at various threshold settings. Average precision (AP) is also typically used for characterizing the performance of a face detector. The mean value of AP is obtained by averaging over multiple IoU

values. Averaging over IoUs rewards detectors with better localization [28].

Definition

Face modeling usually refers to the problem of recovering 3D face geometries from one or more images, though the recovery of lighting and skin reflectance is sometimes considered as face modeling as well.

Background

Because the face is a special type of object which people are all familiar with, there have been tremendous interests among researchers in the problem of 3D face reconstruction. The most reliable and accurate way to obtain face geometries is by using active sensors such as laser scanners and structured light systems. So far, laser scanners are the most commonly used and most accurate active sensors. Structured light systems are becoming more popular because they are capable of capturing continuous motions. Some structured light systems use visible light sources, while others use invisible light sources such as infrared lights. Visible light systems give better signals, but they are intrusive.

The disadvantage of active sensors is that they are usually expensive and not widely available. Recently, Microsoft released a depth camera, called Kinect, which uses active sensors. The device works with both game consoles and PCs and has popularized the use of depth cameras in many applications including face modeling.

Given that cameras are everywhere, it is not surprising that researchers have been fascinated by the problem of 3D face reconstruction from images. This can be thought of as a special case of the classical computer vision problem of 3D structure recovery from images. One could directly apply a generic 3D reconstruction technique to face images. It usually does not work very well because face skins are usually smooth making it difficult to find accurate matchings across images. Since all human faces are similar in terms of their rough shape and topology, a lot of the research has been devoted to developing techniques that leverage the prior knowledge on faces. For example, one can start from a generic face mesh and try to adjust the vertex positions of the mesh to fit the image observations. To reduce the number of degrees of freedoms involved in the fitting process, people have proposed to use a linear space of face geometries to constrain the parameter space. One can use a set of pre-captured or hand-designed face geometries as the examples. Any face is assumed to be a linear combination of the example faces.

Theory

Face modeling techniques can be divided into two categories based on whether the illumination effects are modeled or not. The methods that belong to the first category do not model illumination effects [1–4]. They have origins from structure from motion or stereovision. The methods in the second category takes illumination into account [5–8]. In fact, they leverage the shading information for the geometry reconstruction. These techniques can be traced to shape from shading. For a more detailed and systematic descriptions of face modeling techniques and applications, the readers are referred to the book [9].

Regardless of which method is used, the first question is how to represent a face. As mentioned earlier, linear space representation has been shown to be an effective way to constrain the parameter space. There are two different ways to construct a linear space representation.

The first, called a morphable model, was proposed by Blanz and Vetter in their seminar paper [5]. They used a set of existing face meshes obtained by laser scanners. These meshes must be aligned so that there is a correspondence between the vertices of different meshes.

Let $\mathbf{V}_i = (X_i, Y_i, Z_i)^T$, $i = 1, \dots, n$, denote the vertices of a face mesh. Its geometry is represented by a vector:

$$\begin{aligned} \mathcal{S} &= (\mathbf{V}_1^T, \dots, \mathbf{V}_n^T)^T \\ &= (X_1, Y_1, Z_1, \dots, X_n, Y_n, Z_n)^T. \end{aligned} \quad (1)$$

Suppose there are $m + 1$ face meshes which are obtained by using laser scanner or some other means. Let \mathcal{S}^j denote the geometry of the j th mesh, $j = 1, \dots, m + 1$. These faces generate a linear space of face geometries:

$$F = \left\{ \sum_{j=1}^{m+1} \alpha_j \mathcal{S}^j : \sum_{j=1}^{m+1} \alpha_j = 1 \right\}. \quad (2)$$

Let \mathcal{S}^0 denote the average face geometry, that is: $\mathcal{S}^0 = \frac{1}{m+1} \sum_{j=1}^{m+1} \mathcal{S}^j$. Denote $\delta\mathcal{S}^j = \mathcal{S}^j - \mathcal{S}^0$, $j = 1, \dots, m + 1$. Note that these vectors are linearly dependent. Principal component analysis can be performed on the vectors $\delta\mathcal{S}^1, \dots, \delta\mathcal{S}^{m+1}$. Let $\sigma_1^2, \dots, \sigma_m^2$ denote the eigenvalues with $\sigma_1^2 \geq \sigma_2^2 \geq \dots \geq \sigma_m^2$. Let $\mathcal{M}^1, \dots, \mathcal{M}^m$ denote the corresponding eigenvectors. Then any face $\mathcal{S} \in F$ can be represented as the average face \mathcal{S}^0 plus a linear combination of the eigenvectors, that is:

$$\mathcal{S} = \mathcal{S}^0 + \sum_{j=1}^m c_j \mathcal{M}^j. \quad (3)$$

c_j are the geometry coefficients. The prior probability for geometry coefficients c_1, \dots, c_m is given by:

$$Pr(c_1, \dots, c_m) = e^{-\frac{1}{2} \sum_{j=1}^m \frac{c_j^2}{\sigma_j^2}}. \quad (4)$$

The second approach is to manually design the average mesh \mathcal{S}^0 and a set of deformation vectors which act as $\delta\mathcal{S}^j$ as proposed in [2, 10]. Each deformation vector corresponds to an intuitive way of deforming the face. For face modeling purpose, the deformation vectors are used in almost the same way as the eigenvectors. The only difference is that for eigenvectors, there is a prior probability for the geometry coefficients (see (4)). For deformation vectors, one can pre-define a valid range for each model coefficient.

Given the face representation as shown in (3), the problem of face reconstruction becomes searching for the model coefficients c_j . As mentioned earlier, the method of solving for the model coefficients can be divided into two categories depending on whether they model illumination effects or not.

The methods that belong to the first category typically assume there are two or more input images corresponding to different views of a face. If the camera motions corresponding to the views are not known, one can use structure-from-motion techniques to estimate the camera motion and obtain a set of 3D points, which are usually quite sparse and noisy. After that, one can solve

for the model coefficients and the head pose by minimizing the total distances of the 3D points to the model. Numerically, one can solve it through an iterative closest point (ICP) procedure. For details, the readers are referred to [2].

If the camera motions corresponding to the views are known such as in a stereo rig, one can perform dense stereo matching and obtain a depth map of the face. One such system was developed by Chen and Medioni [11]. The obtained depth map is usually quite noisy and has spikes. One could use a face model to fit the obtained depth map or inject a face model representation in the stereo reconstruction process in a way similar to the model-based bundle adjustment formulation in [12], but the camera motions are no longer variables anymore in this case.

Another approach is to use two orthogonal views [13–15]: one frontal view and one side view. The frontal view provides the information relative to the horizontal and vertical axis, while the side view provides depth information. Since the number of feature points that can be detected on the two views is usually quite small, one could use a linear space face representation to fit the detected feature points and obtain a complete face geometry.

The methods that belong to the second category only require a single view. Since the publication of Blanz and Vetter's paper [5] which assumed a single light source, researchers have extended their technique to handle more general lighting conditions. These techniques leverage shading information, and they typically recover the shape, reflectance, and lighting simultaneously. Most techniques assume the face skin is Lambertian. Similar to linear space representation for face geometry, the diffuse reflectance components (also called albedo or texture) can also be represented as a linear combination of example face albedos. In this way, the unknowns for the reflectance are the albedo (also called texture) coefficients. One effective tool to model the lighting is the spherical harmonics representation which was proposed by Ramamoorthi and Hanrahan [16] and Basri and Jacobs [17]. The basic idea is that the irradiance can be well approximated by using a linear combination of a

small number of spherical harmonic basis functions. They showed that with nine spherical harmonic basis functions, the average approximation error is no more than 1%. The coefficients of the spherical harmonic basis are called lighting coefficients. Given the pose, geometry model coefficients, albedo coefficients, and lighting coefficients, one can synthesize an image of the face. The objective is to solve for these parameters so that the synthesized image matches the input image. The optimization problem can be solved through an iterative procedure. For details, the readers are referred to [8].

In the past few years, there has been a lot of interests in using deep convolutional neural networks (CNN) for 3D face reconstruction [18–23]. Many of the deep learning-based approaches use the linear space representation where the model coefficients are regressed by CNNs [18, 20–23], while others have proposed direct reconstruction schemes without the linear space representation [19, 24].

Application

Face modeling has many applications. The techniques allow people to create personalized avatars which can be used in chatting rooms, e-mails, greeting cards, and games. Many human-machine dialog systems use realistic-looking avatars as visual representation of the computer agent that interacts with the human user [25–28]. Face models are useful for 3D head pose tracking and facial expression tracking. In teleconferencing, face modeling techniques can be used for eye-gaze correction to improve videoconferencing experience [29]. Face modeling techniques are useful for face recognition to handle pose variations [30] and lighting variations [31].

Definition

Face recognition is a biometric technique that identifies or verifies a person by comparing and analyzing the visual patterns from the person's facial image. Face recognition can be divided into two types of tasks, face verification and face identification.

Face verification aims to determine whether two given face images are from the same person or not. Face identification aims to determine the identity of a query face image from a number of registered persons. Usually, the query image is compared with the face images of all the registered persons to identify the similar ones. Face identification involves one-to-many matches, while face verification involves one-to-one matches. As the number of registered persons in the database increases, both the accuracy and the efficiency of face identification decrease. However, the performance of the face verification is not much affected by the size of the database.

Background

Face recognition is a fundamental yet important problem in computer vision with wide applications to surveillance, law enforcement, human-computer interaction, image and video search, and so on. Face recognition had been studied as early as the 1960s and has been receiving extensive research interests from the computer vision society. Face recognition is one of the most important biometric technologies. Compared with other biometric attributes, face images are easy to be captured in a nonintrusive way. Face identification has higher compatibility with other systems.

The challenge of face recognition may come from several aspects, including large intrapersonal variations, small interpersonal variations, high dimensionality of face images, and open set recognition problem. Face images of the same person may appear very differently because of variations of poses, illuminations, aging, occlusions, makeups, hairstyles, and expressions. On the other hand, the face images from different persons may look quite similar. It is critical for face recognition algorithms to effectively extract discriminative features which effectively capture the interpersonal variations and depress the intrapersonal variations. The input face images usually have a high dimension, while each person registered in the database only has a few face images for training. So one needs to address the curse of dimensionality in face recognition. In practice, face recognition is an open set recognition problem that, in the training phase, we don't have facial images from the persons who need to be recognized in test. Many face recognition system solves this problem by learn a model to extract features from any facial images and exploit a metric, e.g., cosine distance, to measure the similarity between facial images for identification and verification. Detailed surveys of face recognition methods can be found in [39].

Method and Application

Face Recognition with Handcrafted Features

Feature Extraction Geometric features, holistic features, local features, and semantic features are four types of handcrafted features widely used for face recognition. Geometric features measure the sizes of facial components and the distances between different components. However, geometric features are not always discriminative and difficult to calculate, which limit their application. Holistic features are extracted by the whole face regions. Holistic features are usually high-dimensional vectors (e.g., concatenation of all pixels) with redundancy. Local features are obtained by characterizing the texture patterns within local regions (a regular grid or the neighborhoods around detected landmarks). Among local features, Gabor responses [34] and local binary patterns (LBP) [1] are most widely used.

Gabor responses are obtained by the convolution of local face regions with a set of predefined Gabor kernels. Gabor kernels are characterized as localized, orientation selective, and frequency selective, and they are similar to the receptive field profiles in cortical simple cells. A Gabor kernel is the product of a Gaussian envelope and a plane wave:

$$\Psi_k(\mathbf{x}) = \frac{\|\mathbf{k}\|}{\sigma^2} \cdot e^{-\frac{\|\mathbf{k}\|^2 \|\mathbf{x}\|^2}{2\sigma^2}} \cdot [e^{i\mathbf{k} \cdot \mathbf{x}} - e^{-\frac{\sigma^2}{2}}]. \quad (1)$$

$\mathbf{x} = (x, y)$ is the variable in the spatial domain and \mathbf{k} is the frequency vector, which determines the scale. The orientation of the Gabor kernel is $\mathbf{k} = k_s e^{i\Phi_d}$, where $k_s = \frac{k_{\max}}{f^s}$, $f = 2, s = 0, \dots, L - 1$ and $\Phi_d = (\pi \cdot d)/8$, for $d = 0, \dots, M - 1$. There are totally $L \times M$ Gabor kernels at L different scales along M different orientations. The number of oscillations under the Gaussian envelope function is determined by $\delta = 2\pi$. The term $\exp(-\sigma^2)$ is subtracted to make the kernel DC-free, and thus, the Gabor responses are insensitive to illumination. Given

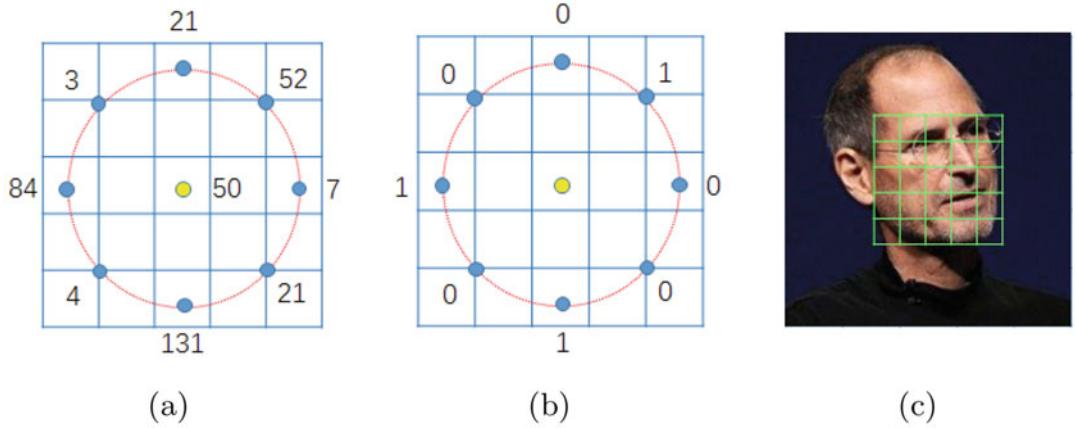

an image $I(\mathbf{x})$, the Gabor response at location x_0 is computed by convolution:

$$\Psi_k * I(x_0) = \int \Psi_k(\mathbf{x}_0 - \mathbf{x}) I(\mathbf{x}) d^2(\mathbf{x}). \quad (2)$$

Since the phases of Gabor responses change drastically with translation, usually only the magnitudes of the responses at landmarks or on a grid are used as local features for face identification. Gabor responses are robust to illumination variations and can tolerate the misalignment caused by variations of poses and expression to some extent.

LBP [21] is a powerful texture descriptor. As shown in Fig. 1a, it is calculated according to the neighborhood of a pixel p by uniformly sampling N pixels along the circle centered at p with radius R . The pixels in the neighborhood are assigned with binary numbers by thresholding against the value of pixel p , as shown in Fig. 1b. These binary numbers are converted to a decimal number, which indicates the local binary pattern of pixel p . A local binary pattern is called uniform if it contains at most two bitwise transitions from 0 to 1 or vice versa when the binary string is considered circular. For example, 00011110 is a uniform pattern and 00010100 is not. It is observed that uniform patterns appear much more frequently than nonuniform patterns. Both accuracy and computational efficiency of face identification can be improved if only uniform patterns are kept and all the nonuniform patterns are mapped to a single label.

Local binary patterns are treated as words of a codebook. The face region is divided into local regions by a grid as shown in Fig. 1c. The histograms of uniform patterns inside the local regions are used as LBP features for face recognition. LBP can characterize a large set of edges and has high discrimination power. If the values of centered pixels and their neighborhoods are under the same monotonous transformation, local binary patterns do not change. Therefore, LBP is robust to lighting variations. Since the histograms within local regions are used as features, they are robust to misalignment and pose variations.

Face Recognition, Fig. 1 LBP operator. (a), the neighborhood of a pixel. (b), the local binary pattern is labeled as $01001010 = 74$. (c) The face region is divided into local regions

Semantic features were proposed for face identification. Specially, two types of semantic features, attribute and simile, were proposed in [13]. To extract the attribute features, a set of binary classifiers are trained to recognize the presence or absence of describable aspects of visual appearance (e.g., does the face has double chin? and does the face have high cheekbones?). The output of each classifier is a score between 1 and -1 . The raw outputs of attribute classifiers are concatenated to form the feature vector for face identification. The simile features of a face image are the similarities between this face image and a set of reference people. Semantic features are high-level visual features. They are inspired by the process of face identification by human beings, since human beings often describe a face using some attribute terms or using its similarities with some known people. Semantic features are more insensitive to the variations of poses, illuminations, and expressions.

Classification Methods

The extracted features are usually in very high-dimensional spaces and include large intrapersonal variations and noise. It is inaccurate and inefficient to directly use them for face identification. They are typically projected into low-dimensional spaces or fed into trained classifiers in order to compare two face images. PCA [25] is widely used for dimension reduction. In face recognition, intrapersonal variations are the main

factor deteriorating the identification accuracy and may be larger than interpersonal variations. However, they cannot be depressed by PCA. Therefore, although PCA can improve the identification efficiency, it cannot effectively improve the accuracy.

Bayesian face recognition [20] effectively models the intrapersonal variations using the intrapersonal subspace, which is spanned by the eigenvectors $\{e_k\}$ and eigenvalues $\{\lambda_k\}$ of covariance matrix:

$$\Sigma = \sum_{\ell(x_i)=\ell(x_j)} (x_i - x_j)(x_i - x_j)^T, \quad (3)$$

where x_i is the feature vector and $\ell(x_i)$ is its identity. The distance between two feature vectors x and x' is computed as

$$d(x, x') = \sum (y_k^2 / \lambda_k), \quad (4)$$

where y_k is the projection of $x - x'$ on eigenvector e_k . Since the intrapersonal variations concentrate on the first few eigenvectors with the largest eigenvalues λ_k , they are effectively depressed by weighting the inverse of λ_i . Therefore, Bayesian face recognition can effectively improve the accuracy by reducing the intrapersonal variations. In Bayesian face recognition, the projection of the distance between a given face pair may reduce the separability. To alleviate this problem, Chen et al. [5] propose a joint Bayesian approach to

directly model the joint distribution of two faces with a prior face representation: each face is the summation of intrinsic variable for identity and intrapersonal variable for with-person variation.

LDA [2] is another widely used subspace method. LDA tries to find the subspace that best discriminates different face classes by maximizing the between-class scatter matrix S_b while minimizing the within-class scatter matrix S_w in the projective subspace. Suppose there are L persons in the training set and X_c is the set of feature vectors of person c . S_w and S_b are defined as

$$S_w = \sum_{c=1}^L \sum_{x_i \in X_c} (x_i - \mathbf{m}_c)(x_i - \mathbf{m}_c)^\top. \quad (5)$$

Here, $S_b = \sum_{c=1}^L n_c (\mathbf{m}_c - \mathbf{m})(\mathbf{m}_c - \mathbf{m})^\top$ and \mathbf{m}_c is the mean of vectors in X_c , n_c is the number of feature vectors in X_c , and \mathbf{m} denotes the mean of all the feature vectors in the training set. LDA subspace is spanned by a set of vectors W satisfying

$$W = \arg \max \left| \frac{W^\top S_b W}{W^\top S_w W} \right|. \quad (6)$$

Feature vectors are projected into the LDA subspace for calculating the distance between face images. W can be computed as the eigenvectors of $S_w^{-1} S_b$. However, because of the small sample size problem, S_w^{-1} is often singular and it is easy for W to overfit the training set. Many improvements of LDA, such as dual-space LDA [29], null-space LDA [3], and direct LDA [37], have been proposed to address this problem.

PCA and LDA are linear subspace methods and assume a Euclidean structure of the face space. Manifold learning [8] assumes that face images reside on a manifold structure and obtains a face subspace using locality preserving projections. It is used to reduce the variations of poses, expressions, and illuminations. Besides subspace methods, other classifiers such as SVM [9], boosting [31], and sparse representation [35] were also exploited for face identification. Using ℓ^1 regularization, sparse representation effectively handles errors due to occlusion and corruption by exploiting the fact that these errors

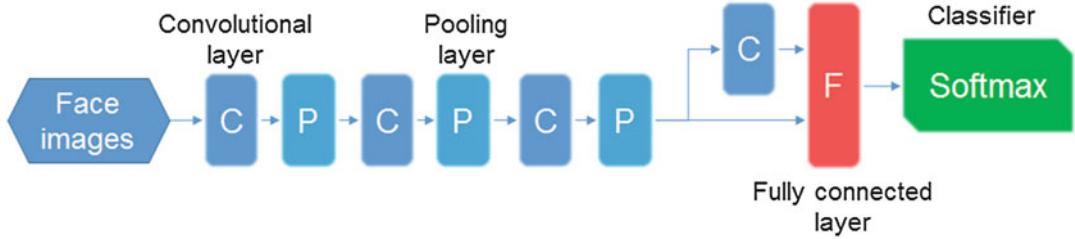

are often sparse. LDA was also extended to non-parametric discriminant analysis assuming that the distribution of face data is non-Gaussian [14].

Face Recognition with Deep Learning Models

Deep CNN integrates feature extraction and classification in a unified framework which can be trained end-to-end. For face recognition, deep CNNs can learn very discriminative features with much better performance than hand-crafted features [24, 36]. Network architectures, loss functions, and databases are three key parts which play key roles in training accurate deep face recognition models.

Deep Network Architectures Face images consist of parts such as the eye, nose, and mouth, with different local statistics. The weight-sharing scheme of classical CNNs may not be efficient for face recognition. Several works [24, 36] addressed this problem by adopting locally connected convolutional layers to learn a different set of filters for different face regions. Besides locally sharing scheme, DeepID [36] directly connects the output of convolutional layer to the last fully connected layer so that the latter can see multi-scale features and the possible information loss can be reduced. The of DeepID is shown in Fig. 2. DeepID [36] also adopts model ensemble strategy which integrates networks trained for different face regions to improve the performance. FaceNet [23] explored deeper architectures with inception modules and found that 128-dimensional face feature is proper for face recognition. Recent advanced deep CNNs, e.g., ResNet [7] and SENet [10], also yield effective architectures for face recognition.

Training Loss Functions Recent studies witnessed well-designed loss functions can improve the performance of deep face recognition [4, 15–17, 23, 26, 27, 38, 39]. Because face recognition is essentially an open set recognition problem where the testing identities are usually different from identities in training data, most deep learning-based face recognition approaches utilize CNNs to extract feature vectors from facial images and then adopt a metric to measure their

Face Recognition, Fig. 2 The architecture of DeepID [36]. “C” means convolutional layer, “P” means pooling layer, and “F” means fully connected layer

similarity between face pair during inference. Hence, there is a gap between training which uses softmax cross-entropy losses to separate the training identifiers and testing which uses similarity metric. To mitigate such gap between training and testing, many effective loss functions were proposed to reduce intra-identity variations and enlarge inter-identity variations.

Contrastive Loss and Triplet Loss DeepID [36] introduces the contrastive loss which takes two facial images as input and tries to minimize their distance in feature space if they are from the same identity and enlarge it if not. Later triplet loss was proposed in FaceNet [23]. Contrastive loss and triplet loss are usually used together with softmax to train deep face networks. Triplet loss utilizes triplets of matching and mismatching face images sampled using an online triplet mining method from the whole training dataset. In triplet loss, three samples, namely, anchor, positive, and negative, are input to calculate the loss. The anchor input is compared to the positive input and the negative input. The distance from the anchor input to the positive input is to be minimized, and the distance from the anchor input to the negative input is to be maximized. Suppose $\mathbf{x}_i \in \mathbb{R}^d$ is the deep feature representing a specified facial image and \mathbf{x}_i^a , \mathbf{x}_i^p , and \mathbf{x}_i^n are the anchor, positive, and negative inputs, respectively, the triplet loss is defined as

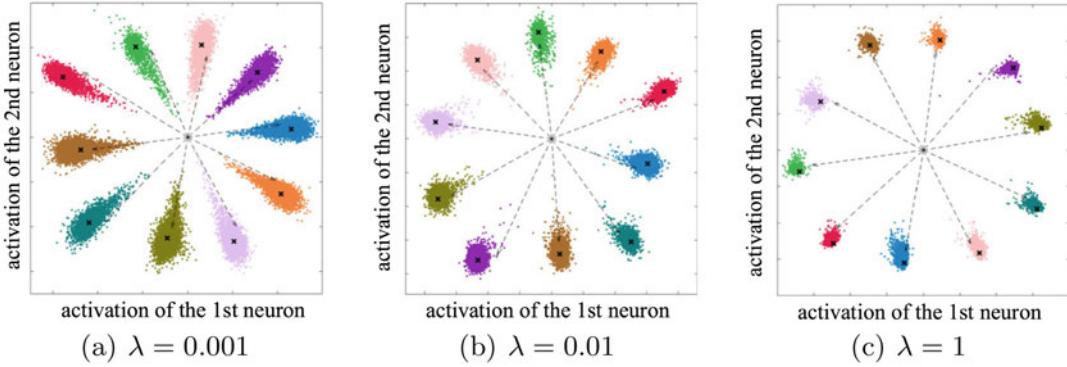

$$\mathcal{L}_T = \sum_i^N \max \left(\|\mathbf{x}_i^a - \mathbf{x}_i^p\|_2^2 - \|\mathbf{x}_i^a - \mathbf{x}_i^n\|_2^2 + \alpha, 0 \right), \quad (7)$$

where N is the number of triplets in the training set and α is a margin that is enforced between positive and negative pairs. Effective triplet selection is important to ensure fast convergence. For a given \mathbf{x}_i^a , triplet loss tends to select a hard-positive \mathbf{x}_i^p such that $\text{argmax}_{\mathbf{x}_i^p} \|\mathbf{x}_i^a - \mathbf{x}_i^p\|_2^2$ and hard-negative \mathbf{x}_i^n such that $\text{argmin}_{\mathbf{x}_i^n} \|\mathbf{x}_i^a - \mathbf{x}_i^n\|_2^2$. Since selecting such hard-positive and hard-negative is infeasible over the training set, triplet losses use an online triplet generation algorithm which computes the argmax and argmax within a mini-batch.

Center Loss Softmax loss does not explicitly encourage the intra-class compactness of the facial features. The resulting features are separable but not discriminative [33]. The discriminative power here characterizes features in both the inter-class separability and the intra-class compactness. To address this problem, center loss [32, 33] is proposed as

$$\mathcal{L}_C = \frac{1}{2n} \sum_{i=1}^n \|\mathbf{x}_i - \mathbf{c}_{y_i}\|_2^2, \quad (8)$$

where n is the sample size and vector $\mathbf{c}_{y_i} \in \mathbb{R}^d$ is the center for deep features \mathbf{x}_i of y_i th class. With the above formulation, center loss can effectively characterize the intra-class variations by penalizing the Euclidean distances between the deep features and their centers. Center loss is usually jointly used with softmax loss \mathcal{L}_S with total loss as $\mathcal{L} = \mathcal{L}_S + \lambda \mathcal{L}_C$. λ is the weight for balancing the two loss functions. Features learned by center Loss with different λ are visualized in

Face Recognition, Fig. 3 The feature distributions of the joint supervision of center loss and softmax loss. λ is the loss weight for center loss. Different sizes of λ s lead to

Fig. 3 [32, 33]. These figures show that different values of λ lead to different deep feature distributions. With proper λ , the learned features show clear intra-class compactness.

Cosine Distance-Based Softmax Loss In the testing phase of face recognition, cosine distance is a popular measure of similarities between facial images due to its good performance in practice. Therefore, directly adding cosine distances in loss function is an intuitive option in training deep face models. In [17] and [27], cosine softmax loss is proposed to apply cosine similarities in softmax cross-entropy loss. In general, the inputs of cosine softmax loss are cosine logits, while the inputs of conventional softmax loss are inner product logits. Suppose $f(\mathbf{x}_i, \mathbf{w}_j)$ is the logit between feature \mathbf{x}_i and class weight \mathbf{w}_j , inner product logits in softmax loss are $f(\mathbf{x}_i, \mathbf{w}_j) = \mathbf{w}_j^T \mathbf{x}_i$. In cosine softmax loss, feature \mathbf{x}_i and class weight \mathbf{w}_j are normalized by their norms, respectively, leading to cosine logit $f(\mathbf{x}_i, \mathbf{w}_j) = s \cdot \frac{\mathbf{w}_j}{\|\mathbf{w}_j\|_2} \cdot \frac{\mathbf{x}_i}{\|\mathbf{x}_i\|_2}$. The formulation of cosine distance-based softmax loss (Cosine loss) is presented as

$$\begin{aligned}\mathcal{L}_{\cos} &= -\frac{1}{n} \sum_{i=1}^n \log \frac{e^{f(\mathbf{x}_i, \mathbf{w}_{y_i})}}{\sum_{j=1}^c e^{f(\mathbf{x}_i, \mathbf{w}_j)}} \\ &= -\frac{1}{n} \sum_{i=1}^n \log \frac{e^{s \cdot \frac{\mathbf{w}_{y_i}^T}{\|\mathbf{w}_j\|_2} \cdot \frac{\mathbf{x}_i}{\|\mathbf{x}_i\|_2}}}{\sum_{j=1}^c e^{s \cdot \frac{\mathbf{w}_j^T}{\|\mathbf{w}_j\|_2} \cdot \frac{\mathbf{x}_i}{\|\mathbf{x}_i\|_2}}}\end{aligned}$$

different deep feature distributions (a) $\lambda = 0.001$. (b) $\lambda = 0.01$. (c) $\lambda = 1$

$$= -\frac{1}{n} \sum_{i=1}^n \log \frac{e^{s \cdot \cos \theta_{i,y_i}}}{\sum_{j=1}^c e^{s \cdot \cos \theta_{i,j}}}, \quad (9)$$

where $\cos \theta_{i,j}$ are the cosine distances between feature \mathbf{x}_i and all class weights \mathbf{w}_j and s is a scaling hyperparameter that can enlarge the range of cosine distance from $[-1, 1]$ to $[-s, s]$ to enhance the training efficiency. In cosine softmax loss, the cosine distance $\cos \theta_{i,y_i}$ between \mathbf{x}_i and its corresponding class weight \mathbf{w}_{y_i} is maximized, while $\{\cos \theta_{i,j}\}$ are minimized for $j \neq y_i$.

Margin-Based Softmax Loss Another effective way to enhance the discrimination ability of features is adding margin hyperparameters in softmax loss. Large margin softmax loss, aka L-softmax, was firstly proposed in [16]. Compared with conventional softmax loss, L-softmax sets the margin hyperparameter m as the factor of angles between feature \mathbf{x}_i and corresponding class weight \mathbf{w}_j . L-softmax is defined as follows:

$$\begin{aligned}\mathcal{L}_L &= -\frac{1}{n} \sum_{i=1}^n \log \\ &\left(\frac{e^{\|\mathbf{w}_{y_i}\| \|\mathbf{x}_i\| \psi(\theta_{i,y_i})}}{e^{\|\mathbf{w}_{y_i}\| \|\mathbf{x}_i\| \psi(\theta_{i,y_i})} + \sum_{j \neq y_i} e^{\|\mathbf{w}_j\| \|\mathbf{x}_i\| \cos \theta_{i,j}}} \right), \quad (10)\end{aligned}$$

where $\psi(\theta) = (-1)^k \cos(m\theta) - 2k, (\theta \in \left[\frac{k\pi}{m}, \frac{(k+1)\pi}{m} \right])$, m is an integer that makes the classification more harder, and $k \in [0, m-1]$ is

also an integer. $\psi(\theta)$ is smaller than $\cos \theta$ which leads to lower classification probabilities and makes the classification task harder.

Along this line, angular softmax [15], namely, A-softmax, adds margin in a normalized weight hypersphere (class weights are normalized to 1). Its formulation is presented as follows:

$$\mathcal{L}_A = -\frac{1}{n} \sum_{i=1}^n \log \left(\frac{e^{\|\mathbf{x}_i\| \psi(\theta_{i,y_i})}}{e^{\|\mathbf{x}_i\| \psi(\theta_{i,y_i})} + \sum_{j \neq y_i} e^{\|\mathbf{x}_i\| \cos \theta_{i,j}}} \right). \quad (11)$$

A-softmax maps all class weights w_j to a hypersphere in order to get rid of the effect of weight norms and learns discriminative deep features with angular margin factor.

The margin idea can also be integrated into cosine softmax. In CosFace [28] and AM-softmax [26], margin hyperparameter is added in cosine distances as follows:

$$\mathcal{L}_{AM} = -\frac{1}{n} \sum_{i=1}^n \log \left(\frac{e^{s \cdot (\cos \theta_{i,y_i} - m)}}{e^{s \cdot (\cos \theta_{i,y_i} - m)} + \sum_{j \neq y_i} e^{s \cdot \cos \theta_{i,j}}} \right). \quad (12)$$

Compared with L-softmax and A-softmax, there is one more scale hyperparameter s in the large margin cosine softmax loss (LMCL).

Another option is adding margin directly to angle θ_{i,y_i} as in ArcFace [4]. Because the embedding features are distributed around their corresponding class weights on the hypersphere, an additive angular margin penalty m is added between \mathbf{x}_i and w_{y_i} to simultaneously enhance the intra-class compactness and inter-class discrepancy. Therefore, ArcFace is defined as follows:

$$\begin{aligned} \mathcal{L}_{AF} &= -\frac{1}{n} \sum_{i=1}^n \log \left(\frac{e^{s \cdot \cos(\theta_{i,y_i} + m)}}{e^{s \cdot \cos(\theta_{i,y_i} + m)} + \sum_{j \neq y_i} e^{s \cdot \cos \theta_{i,j}}} \right). \end{aligned} \quad (13)$$

Range Loss

Large-scale face datasets collected from the Internet usually exhibit long-tail distribution, i.e.,

a small number of identities have large number face images while a large number of identities only have small number of samples. Range loss [38] is designed for the longtail problem.

Longtail distribution has negative effect in deep face models: with the increment of longtail data, the final recognition performance decreases. Analyzing features extracted by model trained with longtail data, the kurtosis of the intra-class features (the 4th order statistic) is significantly higher. Range loss is proposed to resist the increase of kurtosis and restrains the extension of inter-class distance. Range loss is defined as follows:

$$\mathcal{L}_R = \alpha \mathcal{L}_{R_{\text{intra}}} + \beta \mathcal{L}_{R_{\text{inter}}},$$

$$\mathcal{L}_{R_{\text{intra}}} = \sum_{i \subseteq I} \mathcal{L}_{R_{\text{intra}}}^i = \sum_{i \subseteq I} \frac{k}{\sum_{j=1}^k \frac{1}{D_j}}, \quad (14)$$

$$\mathcal{L}_{R_{\text{inter}}} = \max(M - D_{\text{Center}}, 0)$$

$$= \max(M - \|\bar{\mathbf{c}}_Q - \bar{\mathbf{c}}_R\|_2^2, 0),$$

where I denotes the complete set of identities in current mini-batch, D_j is the j th largest distance, D_{Center} is the shortest distance between the centers of two classes, and M is the max optimization margin of D_{Center} . Q and R are the two nearest classes within the current mini-batch, while $\bar{\mathbf{c}}_Q$ and $\bar{\mathbf{c}}_R$ represent their centers. α and β are two loss weights in range loss.

Benchmark Databases

Along with the successes of deep networks for face recognition, several large-scale face databases have been developed in the last years. More details are as follows:

Early benchmark databases include FRGC [22], multi-PIE [6], LFW [11], XM2VTS [19], and CUFS [30]. Among existing databases, FRGC [22] and multi-PIE [6] are in larger scales and are widely used. Face images in most early databases were collected in controlled

environments. In recent years, there has been an increasing interest in studying face recognition in uncontrolled environments. It was shown that the performance of many existing face recognition approaches dropped significantly in such uncontrolled environments. The LFW [11] database 13,233 face images of 1,040 from the Internet, and these face images were collected in uncontrolled environments. LFW has drawn a lot of attentions in the field of face recognition in recent years. Besides the 2D face photo images, some databases include other types of face data. For example, FRGC includes both 2D and 3D face data. XM2VTS [19] includes face video sequences for the evaluation of face identification using videos as queries. The CUFS database [30] includes face photos and face sketch drawings of 606 subjects and is used for the research of face sketch recognition.

MegaFace Challenge 1 MegaFace [12] Challenge 1 is released as a testing benchmark to evaluate the performance of face recognition algorithms at the million scale of distractors. The MegaFace identification dataset includes 1M images of 690K different individuals (from Flickr) as the distractor set and 100K photos of 530 unique individuals from FaceScrub as the probe set. The identification accuracy is evaluated with different size of distractors from 10^1 to 10^6 , and state-of-the-art performance has achieved over 99.9% on 10^6 distractors (<http://megaface.cs.washington.edu/results/facescrub.html>).

IARPA Janus Benchmark Dataset (IJB) IARPA Janus Benchmark [18] contains many unconstrained in-the-wild face images. The IJB-C distribution contains all three IJB challenges (including images and testing protocols), namely, IJB-A, IJB-B, and IJB-C. IJB testing protocols includes both 1:1 face verification and 1:N face identification. The biggest IJB-C dataset contains about 3,500 identities with a total of 31,334 still facial images and 117,542 unconstrained video frames. For face verification, there are 19,557 positive matches and 15,638,932 negative matches, which allow us to evaluate TARs at various FARs (e.g., 10^{-7}).

Face Recognition Vendor Test (FRVT) Face Recognition Vendor Test (FRVT) is an ongoing evaluation organized by the National Institute of Standards and Technology (NIST). Different from aforementioned benchmarks, FRVT only provides API documents for participants to build their own software, and then test the submission is under NIST's services. Therefore FRVT is much comprehensive. The latest FRVT 2018 includes both large-scale 1:1 verification and 1:N identification tasks (<https://www.nist.gov/programs-projects/face-recognition-vendor-test-frvt-ongoing>). The variations in FRVT evaluation are abundant, including wild photos, visa, mug shot, and lifetime photos. FRVT 1:1 verification includes comparisons like visa against visa, mug shot against mug shot, and wild photo against wild photo. In the comparisons of visa photos against visa photos, the number of genuine comparisons is on the order of 10^4 , while the number of impostor comparisons is on the order of 10^{10} . The comparisons between mug shot photos are on the order of 10^6 and 10^8 , respectively, and the comparisons between wild photos are on the order of 10^6 and 10^7 .

Facial Attribute Recognition: A Survey

Nathan Thom and Emily M. Hand
University of Nevada, Reno, NV, USA

Definition

We present a survey of attribute recognition research in the computer vision community over the past decade. Most of our attention is given to facial attributes, but attributes of objects, pedestrians, and actions are considered as well.

Background

Facial attributes – human-describable features of faces – were introduced to the computer vision community in 2008, with their first application being image search [1]. Kumar et al. identified a problem with the image search engines of the time, realizing that simple descriptive search terms would not produce expected face image

results. Attributes were then used for face recognition and verification as well as, again, for image search and retrieval [2–4] before attribute recognition itself became the focus of research. Facial attribute recognition is related to the problem of soft biometrics [5], which is focused on identification using these so-called soft traits rather than recognizing them for purely descriptive purposes.

Well before the introduction of facial attributes, recognition of gender and age from faces were well-established problems in the computer vision community [6–8]. One of the earliest works on gender recognition from faces utilized a neural network that predicted sex directly from image pixels [9]. This method, like many others, required the face images to be scaled, aligned, and cropped in order to perform well. In [10], the authors also took a holistic view of the face, creating so-called holons – reduced feature vectors learned via an auto-encoder – to perform identity, emotion, and gender recognition. Research has shown that both age and ethnicity play a big role in gender recognition. For example, gender recognition performance has been shown to degrade when models are trained on a mixture of ethnicities, rather than focused on a target ethnicity [11]. In addition, gender recognition performance significantly depends on age, with young males and older females posing challenges for the models [12, 13].

One of the earliest works on age recognition focused on craniofacial development theory, developing models to describe the changing shape of the face as it aged [14]. Focusing on texture as well as shape, active appearance models – statistical models – were developed for age recognition from face images [15]. Success was also found in age estimation by considering a collection of images from an individual in order to determine the aging pattern for that person [16]. Age estimation from face images remains a very challenging problem in the computer vision community because each person ages differently, and so it is a profoundly individual problem [17]. Adding to the challenge of age recognition problems, they can be considered a categorical

classification problem (e.g., to what age group does this face belong?) or a regression problem (e.g., what is the age of this face?), depending on the context and data available.

Attributes exist in domains other than faces, including pedestrians, objects, and actions. An attribute is simply a describable feature, and so it lends itself nicely to many problems in computer vision. Pedestrian attributes can include clothing, gender, hair color and length, as well as part visibility and pose [18]. Attributes of objects can include multiple categories: shape, color, texture, part, and material as well as global or local presence of the attributes [19, 20]. Attributes of actions include pedestrian attributes, object attributes, as well as action-specific attributes such as environment and motion [21].

The problem of attribute recognition has gained a lot of attention in the research community over the past decade, mostly due to the wide applicability of attribute prediction for real-world applications. Pedestrian attributes have been used in surveillance for re-identifying individuals and searching for suspects based on description of their visual attributes [50]. The application of attribute detection to surveillance is ultimately an image search problem where a query of attributes is provided and the most relevant results are returned. Thus, most image search techniques can directly correlate with surveillance, and many have utilized facial attributes [4, 22]. Applying attribute recognition to surveillance can lead to quicker identification and save a significant amount of human hours.

Another application of attribute recognition is in human computer interaction (HCI). Many applications that involve HCI benefit from knowledge of the user. For example, proper greetings rely on gender information (e.g., Mr., Ms.). A user’s expression can determine whether or not they are enjoying an application (e.g., smiling or frowning). More specifically, attributes have been used by companies such as Facebook in order to improve accessibility of their platform, providing image descriptions to those with visual impairments [23]. Other applications of facial attributes in HCI include active authentication, the process of continuously authenticating a user

on a device. Attributes have already been successfully deployed for this problem [24–26]. Being describable features by definition makes facial attributes widely applicable to many real-world problems.

Focus in attribute research has been dedicated to the general discovery of attributes for building datasets and vocabularies for preexisting data. Note that these approaches operate in a broader scope than just facial attribute recognition. Berg [20] made strides to automatically aggregate and label data from noisy internet sources. They cite work that uses gender, race, and other attributes to improve face verification and search. Expanding on this concept, the authors mine websites that have diverse images and automatically label the images based on captions. This allows for diverse vocabulary discovery and improved predictions across multiple object types. A similar approach, with the goal of learning attributes in large datasets, draws connections between semantically unrelated objects by looking at their visually describable attributes [27]. For example, zebras, beetles, and street crossings all share the stripes attribute. With the development of several large-scale-labeled datasets for the problem of facial attribute recognition, the field has grown significantly.

In the following sections, we detail the research in facial attribute recognition from images and videos. We will also present work in the general field of attribute recognition, when applicable. All the while we will be introducing datasets and discussing methods based on traditional machine learning and computer vision as well as those based on deep learning. Our survey will conclude with a discussion of open problems in the field.

Related Research

Attributes are not solely applicable to faces. They have been successfully applied to objects, pedestrians, and actions. Here we provide a brief history of each field, from early works to state of the art.

Objects

Attributes of objects include textures, colors, patterns, shapes, and many other describable features. Early methods for attribute recognition were focused on aiding object recognition. These initial works recognized basic patterns, textures, and colors [28–31]. As researchers became more active in the field, the focus shifted to describing objects, rather than simply naming them [19, 32]. Many researchers utilized object attributes for few and zero-shot learning as they provide a compact description of objects that a system may not have seen previously. In [33], Wang et al. focused on dependencies between objects and attributes, improving both attribute and object recognition. [34] identifies attributes (e.g., shape, color, material) of 3D objects with the goal of helping autonomous robots understand and interact with the world around them. In [35], the authors present a dataset (AirplanOID) and a method for understanding objects in fine-grain detail, using attributes. The dataset contains attributes such as *facing direction*, *is-airline*, *location*, etc. More recently, Wang et al. further explore attributes for object recognition [36]. Their approach utilizes attributes as additional information during model training, requiring no attribute labels at test time.

Actions

Attributes of actions include descriptive features such as environment, pose, objects involved, etc. that can be used to break an action down into its component parts. One of the first works in action attribute recognition modeled the human visual cortex. This was accomplished by applying motion-direction sensitive units to video inputs, thereby recognizing human body, head, hand, and general animal actions [37]. Liu et al. [21], Yao et al. [38], Sharma et al. [39] all focused on identifying action parts in still images. In [21], the authors used attributes of a scene to understand actions. Yao et al. used a combination of given action verbs (e.g., bending, squatting, riding, etc.) along with poselets and objects to predict actions from still images [38]. In [39], the authors presented a method which learns a template for a variety of actions in order to localize actions in a frame. Zhang et al. presented a multitask

learning method in which attributes and actions are learned simultaneously [40]. Tahmoush [41] and Cai et al. [42] focused on attributes for action recognition in 3D. State-of-the-art methods rely on supervised deep learning in order to recognize attributes of actions [43, 44].

Pedestrians

Attributes of pedestrians include whole-body attributes such as clothing, pose, as well as facial attributes. Identifying attributes in this context can be challenging due to viewpoint and extreme pose changes. With a focus on gait analysis, Zaki and Sayed [45] used K Nearest Neighbors and spectral clustering to identify attributes such as gender and age from gait information including speed, acceleration, rhythm, etc. In work done by Deng et al. support vector machines were trained on a large-scale dataset to recognize attributes of pedestrians [46, 47]. The authors collected the PETA dataset for these works, which is still a benchmark in the field [46]. In recent years, deep learning has become the standard for pedestrian attribute recognition, with the focus on convolutional and recurrent neural networks [48–52]. Convolutional neural networks are useful for localization of pedestrian attributes, while recurrent neural networks are successful in identifying attribute relationships. Automatic recognition of pedestrian attributes has applications in soft biometrics, surveillance, and autonomous vehicle guidance.

Theory and Application

We review work on facial attribute recognition from images and video and separate work into two categories: traditional methods and deep learning.

Attribute Recognition with Traditional Methods

Prior to the advent of deep learning in all aspects of computer vision, other traditional methods, such as support vector machines, were used for attribute recognition. In 2008, Kumar et al. built a face search engine that they called

FaceTracer [1]. This search engine operated on user queries involving one or more of the available attributes. For example, “smiling Asian men with glasses.” The search engine would then return images face images that exhibited the desired traits. The search engine was built on a set of attribute classifiers, capable of identifying binary facial attributes in an image. The attribute classifiers were built on four feature sets: face region, pixel data color space (e.g., RGB, HSV), normalization method, and data aggregation method. Support vector machines (SVMs) were then trained for every region, feature type, and parameter combination. Adaboost is then run on this set of “local SVMs” to generate a set of strong classifiers. Finally, a global SVM is trained by finding the union of the strong classifiers. Along with the FaceTracer search engine, Kumar et al. introduced a dataset by the same name. At the time of publication, the dataset consisted of over 3.1 million face images, 17,000 of which were manually labeled with 10 attributes: age, gender, race, hair color, eyewear, mustache, expression, blurry, lighting, and environment. Sample images from the FaceTracer dataset are shown in Fig. 1.

A year later, the same group shifted their research focus toward face verification using attributes [2]. Face verification aims to address the following question: given two images, do they belong to the same person? The authors developed two different methods to generate descriptions of faces, using attribute and simile classifiers. SVMs are used as attribute classifiers,

trained on a collection of low-level features, similar to the previous work [1]. They introduced additional low-level features such as edge magnitudes and gradient directions. As a part of this work, the authors introduced a new dataset, PubFig, for face verification. Sample images from the PubFig dataset are shown in Fig. 2. Additional data was collected in order to train facial attribute classifiers. 1000 images were labeled for each of 65 binary attributes using Amazon Mechanical Turk. Simile classifiers were used as well to identify the similarity of a face to a set of reference faces. For each reference individual, a classifier is trained on each region to distinguish that region from the same region on other faces. These simile classifiers allowed for comparisons between faces without requiring additional labels. The final face verification system utilized a hybrid of attribute and simile classifiers and achieved state-of-the-art accuracy. After the release of PubFig, the authors tested their attribute classifiers on all images in the dataset, providing 65 attribute scores for each image along with the image data. Some methods utilized these scores as labels in order to train attribute classifiers [24]. In 2011, the same group again used facial attributes for improved face verification and image search [3], extending the set of attributes to 73.

Several groups realized the potential of facial attributes to improve image search and retrieval with natural queries [1, 4, 22, 53]. With a focus on surveillance, Vaquero et al. utilized pedestrian attributes for search and retrieval in low-quality

Facial Attribute Recognition: A Survey, Fig. 1 Sample images from the FaceTracer dataset [1]

Facial Attribute Recognition: A Survey, Fig. 2 Sample images from the PubFig dataset [2]

F

video [53]. Others have explored different ways to perform multi-attribute search queries [4, 22]. [4] improved over previous ranking methods that required individual models for each search term. Instead they used correlations among attributes to provide additional information to the search query. Their Multi-Attribute Retrieval and Ranking (MARR) method benefited from the strong relationship among attributes. The authors labeled a subset of the Labeled Faces in the Wild (LFW) dataset [54] (9992 images) with 27 binary attributes (a subset from the work of [2]). A year later, [22] focused on developing a meaningful way to combine different attribute scores. They construct a normalized score space based on Extreme Value Theory. The authors aimed to convert raw SVM output scores to a normalized score that would be more consistent with human labeling as well as with the scores of other attributes. After converting the scores, they were able to fuse them to allow for multi-attribute queries in a shared score space. The authors use the method of [3] to extract attribute scores from face images.

All of the publicly available datasets up to this point considered facial attributes to have binary values, that is, the attribute is either present or not. This can be a very challenging way to view the problem when many attributes are subjective or exist on a gradient (e.g., some hair is more blond than others). Parikh et al. aimed to address this issue in [55], focusing on so-called relative attributes. The authors utilize the concept of relative attributes to generate a ranking function for each attribute allowing for a new type of

zero-shot learning in which they can describe unseen objects relative to previously seen ones. They propose a learning-to-rank formulation that learns a desired ordering of the training images. This learning framework resulted in a model that could better capture the strength of a particular attribute compared to a binary classification model. The authors utilized a subset of the PubFig dataset in order to learn their ranking functions.

Labeling attributes is a time-consuming process, with each image needing multiple (over 70 in the case of [3]) labels. This became a limiting factor in facial attribute research very quickly. In [56], the authors introduce a likeness measure as a way to utilize describable features without requiring an extensive labeling process. The goal of this work is to improve face verification performance. For each pair of subjects, the authors create a classifier that is capable of distinguishing between the two subjects. This process results in many likeness classifiers, or “Tom v. Pete” classifiers, as they call them. Face images are classified using this collection of “Tom v. Pete” classifiers giving a set of scores that indicate the person’s likeness to a particular subject in a pair classifier. This set of scores is then used as a subject’s feature vector which is in turn used for face verification. This work resulted in human-describable features of faces, in the form of their likeness to other individuals. That is, “this person looks more like subject 1 than subject 2, and more like subject 3 than subject 2,” etc. [56] built on the concept of automatically generated attributes as seen in the simile classifiers of [2].

Facial Attribute Recognition: A Survey, Fig. 3 Sample images from the CelebA dataset [57]

Attribute Recognition with Deep Learning

In 2015, Liu et al. introduced two large-scale benchmark datasets for the problem of facial attribute recognition in unconstrained images – CelebFaces Attributes (CelebA) and Labeled Faces in the Wild Attributes (LFWA) [57]. CelebA contains over 200,000 images each labeled with 40 binary attributes, which are a subset from those used in [3]. The CelebA dataset contains a wide range of images including full body and close cropped faces. The dataset includes these original images as well as cropped and aligned face images. Sample cropped and aligned images from CelebA are shown in Fig. 3. Along with CelebA, attribute labels were added to the popular face verification benchmark LFW, creating LFWA. LFWA contains roughly 13,000 images, labeled with the same 40 binary attributes from CelebA. Some sample images from LFW can be seen in Fig. 4. CelebA and LFWA were the first (and only to date) large-scale datasets introduced for the problem of facial attribute recognition from images. Prior to CelebA and LFWA, no dataset labeled with attributes was large enough to effectively train deep neural networks. With the introduction of this dataset, many deep learning methods were used for facial attribute recognition [25, 57–60].

Along with CelebA and LFWA, Liu et al. introduced a method for attribute recognition that involves two networks: LNet and ANet. LNet is a localization network that localizes the face with weak attribute supervision, and ANet uses

the localized face to predict facial attributes. LNet was built on the widely popular AlexNet [61] architecture trained on the ImageNet object recognition dataset [62]. After being pre-trained on the large-scale Imagenet dataset, LNet was fine-tuned on the original (full body, unaligned) CelebA images using weak attribute supervision. With the weak supervision from CelebA's facial attributes, LNet was able to accurately localize the face in a given image. Once the face was localized by LNet, ANet was trained from the cropped face image. ANet was also built on the AlexNet architecture, pre-trained on ImageNet, and fine-tuned on CelebA. This two-network scheme produced impressive results on CelebA and LFWA.

In 2016, Wang et al. introduced a method dubbed “Walk and Learn” in which they utilized face tracks as additional supervision for facial attribute recognition [59]. The authors collected additional data by attaching wearable cameras to their bodies and walking around different areas of New York City. They used face tracking to identify individuals in every frame and used face verification to pre-train their network. Their deep network was then fine-tuned on the CelebA dataset, producing improved results on some challenging attributes over [57].

Just a year after the release of CelebA and LFWA, many researchers began to notice some very serious label imbalance issues. In particular, [60] focused on adjusting the label imbalance during network training. The authors

Facial Attribute Recognition: A Survey, Fig. 4 Sample images from the LFW (also LFWA) dataset [54, 57]

F

introduced a Mixed Objective Optimization Network (MOON) capable of learning all attributes at once while at the same time adjusting for label imbalance. We note that prior to this work, individual models were learned for each attribute, including all of the methods previously discussed [1–3, 57, 59]. This was incredibly inefficient and did not take advantage of a shared representation for all attributes. MOON addressed both of these issues by utilizing the popular VGG-16 network architecture [63] and training from random initialization on CelebA. MOON was the first to combine attribute learning into one network, address dataset imbalance, and train on CelebA from scratch rather than fine-tune. MOON addressed label imbalance by calculating source and target distributions for each attribute and applying a weight to the backpropagation within a euclidean loss in order to adjust for the distribution discrepancies. The source distribution for an attribute was the distribution of positive and negative instances of the attribute in CelebA, and the target distribution could be set to any desired distribution, though the authors experimented with an even target distribution. MOON produced impressive results on CelebA and highlighted the severe imbalance issues associated with it.

Ehrlich et al. [64] also tackled the problem of multitask learning for facial attribute recognition, utilizing a Restricted Boltzmann Machine (RBM) rather than a CNN. Their model is trained with both the aligned face images from CelebA and facial landmark points as inputs. The authors extend RBMs to handle multiple tasks

and multiple inputs naming it the Multitask Multimodal RBM (MTM-RBM). The MTM-RBM compares favorably with [57]. To date this is the only method for facial attribute recognition that utilizes an RBM model.

With the introduction of deep learning in the facial attribute domain, many began to wonder how robust these models truly are. In [65] they aim to address this question by introducing an adversary. They develop a Fast Flipping Attribute (FFA) method that generates adversarial examples that cause classification errors. The FFA method identifies directions which can generate adversarial examples by inverting the classification score and calculating the gradient with respect to the inverted score. Searching along those gradient directions results in images that produce classification errors. The authors found that some attributes (e.g., *wavy hair* and *wearing necklace*) were more robust to adversarial attacks than others (e.g., *big nose* and *young*).

Several groups began to address the problem of facial alignment in attribute recognition. In [66], the authors introduce the Alignment-Free Facial Attribute Classification Technique (AFFACT), which performs data augmentation allowing a deep convolutional neural network to recognize attributes without first aligning the face images. The AFFACT method performs augmentation of the dataset through scaling, rotation, shifting, and blurring. Training ResNet [67] architectures, the authors applied AFFACT data augmentation to CelebA and were able to achieve state-of-the-art performance. Ding et al. [68] also aimed to address the problem of attribute

recognition from unaligned face images by utilizing a cascade network capable of identifying different regions of the face and recognizing attributes without alignment. Their face region localization network is capable of detecting face regions based on weakly supervised attribute data. Rather than performing data augmentation like [66], this work focused on part-based approach to attribute prediction.

Only 2 years after the introduction of CelebA and LFWA, performance on the benchmark datasets began to plateau. In [58], the authors aimed to improve attribute recognition accuracy by taking advantage of relationships among attributes both implicitly and explicitly. The authors introduce a new deep CNN architecture for attribute recognition: Multitask CNN (MCNN). MCNN had fewer than 16 million parameters compared to the 138 million parameters in the VGG-16 model used for MOON. MCNN took advantage of attribute relationships by learning a shared representation at the lower levels of the network and branching off into spatial attribute groupings at the higher levels of the network. Finally, attribute relationships were learned at the score level with an auxiliary network (AUX) that was attached to the trained MCNN. The combined network, MCNN-AUX utilizes attribute relationships in three different ways and produced state-of-the-art results on CelebA and LFWA.

Aiming to utilize localization cues to improve facial attribute prediction, [69] combined the problem of facial attribute recognition with that of semantic segmentation. Semantic segmentation requires predicting a label for every pixel in an image, producing a class map over the entire image. The authors aggregated face segments, provided as a part of the Helen Dataset [70], to create seven segments: background, hair, face skin, eyes, eyebrows, mouth, and nose. They utilize a gating mechanism to focus the attribute recognition network on regions of interest for a particular attribute. For example, they focus mouth-related attributes (e.g., smiling, mouth open) on the mouth segment provided by the segmentation method.

Along a similar vein, [71] uses generative adversarial networks (GANs) to generate abstraction images that are then used to improve facial attribute recognition through a multi-stream network acting on the abstraction and original images. The abstraction images produce a kind of facial segmentation with textual information, localizing parts and providing additional supervision to the facial attribute recognition task. The multi-stream abstraction image formulation for attribute recognition outperformed the recent work of segmentation for improved facial attribute recognition [69].

As a follow-up to MOON [60, 72] introduced a method called “selective learning” to perform balancing of multi-label datasets during training of a deep neural network in order to address the label imbalance in CelebA. The authors introduce a new CNN, Attribute CNN (AttCNN), which has roughly 6 million parameters, compared to the 16 from MCNN [58]. In MOON, the labels were balanced by considering an overall dataset source distribution for each attribute. In [72], the authors note that this does not fully address the problem as each batch that is used to train the CNN may be more or less balanced than the overall training set. The author’s solution was to perform label balancing at the batch level. Every attribute in each batch was balanced according to a desired target distribution by sampling from the over-represented class and weighting the underrepresented class. The selective learning method produced comparable results to MOON on CelebA and LFWA. The authors also introduced a new evaluation dataset: the University of Maryland Attribute Evaluation Dataset (UMD-AED). UMD-AED consists of roughly 3,000 images sparsely labeled with facial attributes. Some sample images from UMD-AED are shown in Fig. 5. Each of the 40 attributes in CelebA has 50 positive and 50 negative instances in UMD-AED, allowing for balanced testing of facial attribute recognition methods. Selective learning and AttCNN significantly outperformed MOON on UMD-AED.

Most research in facial attribute recognition focused on unconstrained images. Hand et al.

Facial Attribute Recognition: A Survey, Fig. 5 Sample images from the UMD-AED dataset [72]

F

shifted the focus to video in [73] using weakly labeled video to train attribute prediction models. The authors labeled four frames in every video of YouTube Faces [74] – a video dataset collected for face verification – with the 40 binary facial attributes from CelebA. They introduced several methods for utilizing weakly labeled frames to improve attribute prediction in video: motion attention and temporal coherence. Their motion attention mechanism focused attribute models on areas of motion in the video, reducing overfitting, and the temporal coherence constraint encouraged nearby frames to have similar network responses, relying on the fact that nearby frames in a video will likely have similar – but perhaps not the same – attributes. Combining motion attention and temporal coherence, the authors were able to train a deep CNN on unlabeled video frames from YouTube Faces, outperforming traditional fine-tuning methods. Hand et al. [73] was the first, and only to date, attempt to utilize video for facial attribute recognition.

We present the average accuracy over all attributes in CelebA for all state-of-the-art methods in Table 1. We can see that since the introduction of the dataset in [57], only a 4% gain in accuracy has been achieved on average. This emphasizes that there are many challenges that have yet to be addressed in the field of facial attribute recognition.

The field of facial attribute recognition is still a very young one, having been introduced just over a decade ago. Since its introduction, huge strides have been made, with current systems capable of recognizing facial attributes in unconstrained

Facial Attribute Recognition: A Survey, Table 1

Average attribute classification accuracy across all 40 attributes in CelebA for current state-of-the-art methods

| Method | Accuracy |
|-----------------------------------|----------|
| Liu et al. (LNet+ANet) [57] | 87.30% |
| Ehrlich et al. (MTM-RBM) [64] | 87.00% |
| Wang et al. (Walk and Learn) [59] | 88.00% |
| Rudd et al. (MOON) [60] | 90.94% |
| Gunther et al. (AFFACT) [66] | 91.97% |
| Hand et al. (MCNN-AUX) [58] | 91.30% |
| Kalayeh et al. [69] | 91.80% |
| Ding et al. [68] | 91.23% |
| Hand et al. (AttCNN) [72] | 91.05% |
| He et al. [71] | 91.81% |

images and video. There are many open research directions that will lead to significant improvements in the state-of-the-art in facial attribute prediction. With many applications relying heavily on the recognition of human-describable features, the field of facial attribute recognition will be of great interest for many years to come.

Open Problems

Addressing Bias

With the popularization of deep learning methods comes the inevitable question of bias. Most of the state-of-the-art deep learning models have tens of millions of parameters. Overfitting is a very common problem with such complex and deep architectures. For many problems, including attribute recognition, overfitting leads to learning

dataset biases and imbalances. Due to the large number of parameters in deep learning models, the cause of bias is also difficult to locate.

Even outside of deep learning, bias can be an issue for models that draw correlations between attributes that frequently exist together. Siddiquie et al. [4] proposes a method for image search and ranking for multi-attribute queries. Their method is to find interdependencies of queried attributes with attributes not mentioned. The danger of this approach is that without diverse data, potentially inaccurate or even inappropriate results can be returned. Hand et al. found this to be true in [58], when utilizing implicit and explicit attribute relationships to improve prediction. They found that many relationships were not indicative of the real world but rather were overfit to the CelebA dataset (e.g., *heavy makeup* and *arched eyebrows*).

Most of the methods for attribute prediction presented here simply consider accuracy as an evaluation metric. When we are dealing with severe class imbalance, precision and recall are more appropriate measures of good performance. Additionally, it is essential to account for age, race, and gender in attribute recognition research in order to truly learn a representation for an attribute across different groups. Ultimately, most bias stems from a lack of representation in the data or bias in the labeling of the data. Addressing these issues will improve attribute recognition research.

Noisy Data

There is a recent plateau in facial attribute recognition performance, which could be due to poor labeling of data. Many research groups rely on Amazon’s Mechanical Turk, as well as other paid services to provide manual labels on large datasets [2, 3, 22, 56]. While crowdsourcing such tasks can be very useful and result in large quantities of reasonably labeled data, there are some tasks which may be consistently labeled incorrectly – such as subjective tasks (e.g., *hair color*, *attractive*). Additionally, certain groups of people may find it challenging to label certain tasks. For example, men can have difficulty identifying makeup and lipstick in images of faces.

Mislabeled data is a very difficult challenge to overcome for most learning methods.

Mislabeled data is also known as noise. An open problem in facial attribute recognition – and many problems in computer vision and machine learning – is that of noise identification and removal. The difficulty here lies in removing noise while maintaining outliers – challenging, but correctly labeled, samples. It is essential to keep outliers in the dataset, as they represent samples that are outside of the average for a particular problem.

Identifying noise versus outliers is an especially challenging problem in the domain of facial attribute recognition. Many attributes are extremely subjective and exist on a gradient. Some examples of subjective attributes include *attractive*, *5 o’clock shadow*, *arched eyebrows*, *young*, etc. Due to this subjectivity, there is a need to consider the problem of facial attribute recognition as one of regression or real-value prediction. In this way, attributes can exist on a scale, and subjectivity will not pose as much of a problem as it does in the binary case. Parikh et al. introduced the concept of relative attributes in [55], and it has yet to be built upon. This is likely due to the significant amount of time that would be required to properly label a large dataset with relative attributes. However, it is undeniable that attributes as real-valued variables result in a more natural, rich description of faces. Relative attributes will help to alleviate the problem of poorly labeled data as well, since attributes will exist on a scale rather than in strict categories.

Attributes in Video

A relatively untouched and important problem in attribute recognition is attribute prediction in videos. There is a wealth of information that comes from video. Take, for example, the problem of classifying facial attributes depending on pose. In a video, various frames will contain the same attributes with a large variety of poses, expressions, angles, etc. Models trained on video data could be very robust in their ability to identify facial attributes. In addition to the large amount of data that can be used in videos to solve

current issues in attribute recognition, there are also new categories of attributes to be identified.

One such category is static versus dynamic attributes. Static attributes are the visual attributes that do not change with pose, expression, lighting, etc. These are features such as hair color, gender, age, facial hair, etc. Conversely, dynamic attributes include features such as smiling, narrow eyes, mouth open, etc. Accurate recognition of these attributes requires pose prediction, 3D processing, and semantic understanding of the data.

There are of course challenges associated with video processing. The main challenges of attribute recognition in videos, compared to images, are low resolution, poor lighting, severe poses, motion blur, and varying frame rate. Low resolution is a problem simply because lower-quality images contain less data. Videos commonly contain content with bad lighting, which can cause unwanted effects on a person's face leading to poor attribute recognition performance. Video also suffers from severe poses and motion blur. Recognizing visual features in still images usually only takes into account images of people in relatively normal positions or with common expressions. Videos contain many blurred frames, especially as frame rate increases.

Definition

Given arbitrary many images and 3D-points, the so-called *factorization* algorithm [1] is a

noniterative technique for simultaneously estimating 3D-structure along with orientations and positions of the cameras which observed the 3D-scene or object. It is based on the factorization of a matrix consisting of all measurements.

The original algorithm requires a particular affine camera. It was later extended to more general affine cameras and even to the full projective camera model. Other variants can handle lines, triangles, or ellipses instead of 2D-point correspondences. It can be further extended to nonrigid scenes or objects, not merely rigid ones. It can also minimize geometric error criteria instead of algebraic errors and even allow unknown entries in the measurement matrix.

Background

Let the 3×3 upper triangular matrix K_i denote the calibration of the i th camera, the 3×3 rotation matrix R_i its orientation and the 3-vector t_i its position, and X_j^H the j th 3D-feature in homogeneous coordinates. The perspective projection x_{ij} of X_j^H by the i th camera can be modeled by

$$x_{ij} \simeq K_i [R_i | t_i] X_j^H. \quad (1)$$

The symbol \simeq implies that every scalar multiple of the observed coordinates x_{ij} is a solution to this equation. Estimating all the camera parameters and the vectors X_j^H from the measurements x_{ij} at the same time is one of the oldest and most important problems in computer vision. The vectors X_j usually represent 3D-points in homogeneous coordinates, but they can also express lines, triangles, ellipses, or other features.

These days, the most widely used algorithm for structure-from-motion estimation, *bundle adjustment*, iteratively minimizes the reprojection error (The Euclidean distance between the projections of the estimated 3D-points X_j^H into the images and the measured 2D-points x_{ij}). It is regarded as the most accurate method, but it requires a good initialization and can handle only rigid scenes or rigid objects [2]. In this sense,

the factorization algorithm is more flexible and better suited to problems that do not demand so high accuracy.

Theory

If the nonhomogeneous 3D-vectors X_j are projected into the images by an affine camera (Any pinhole camera is reasonably approximated by an affine camera if the object is very far away from the camera. This implies that the depth variation within the scene is neglectable small compared with the distance between camera and scene), (Eq. 1) can be simplified to

$$x_{ij} = K_i [R_i | t_i] X_j^H = \underbrace{K_i R_i X_j}_{P_i} + K_i t_i. \quad (2)$$

As opposed to the case of a projective camera in (Eq. 1), matrix K_i is 2×3 in (Eq. 2).

The vectors x_{ij} are collected into a measurement matrix for all m images and the n 3D-features

$$\begin{aligned} W &= \begin{bmatrix} x_{11} & \dots & x_{1n} \\ \vdots & \ddots & \vdots \\ x_{m1} & \dots & x_{mn} \end{bmatrix} \\ &= \underbrace{\begin{bmatrix} P_1 \\ \vdots \\ P_m \end{bmatrix}}_P \underbrace{\begin{bmatrix} X_1 & \dots & X_n \end{bmatrix}}_X + \underbrace{\begin{bmatrix} K_1 t_1 \\ \vdots \\ K_m t_m \end{bmatrix}}_t \begin{bmatrix} 1 & \dots & 1 \end{bmatrix}. \end{aligned} \quad (3)$$

Since matrices P and X both have rank 3 in general (Matrix P only has three columns and X only three rows; cf. (Eq. 2).) and the matrix given by the product of t and $[1 \dots 1]$ has rank 1, W cannot have more than rank 4, because each column of W is a linear combination of the columns of P and t .

The world coordinate system can be arbitrarily defined, so let us place it in such a way that the centroid of all X_i is at the coordinate origin, i.e., $\sum_{j=1}^n X_j = 0$. Then, the translation $K_i t_i$ is the

centroid of all the observations of the i th image:

$$K_i t_i = \frac{1}{n} \sum_{j=1}^n X_{ij}, \quad (4)$$

Hence, if $K_i t_i$ is subtracted from x_{ij} to define

$$x'_{ij} = x_{ij} - K_i t_i, \quad (5)$$

the resulting measurement matrix is written as $W' = PX$, which has rank 3. The matrix W' can be factorized using the singular value decomposition in the form

$$W' = U \Sigma E^\top = U \left(\Sigma V^\top \right). \quad (6)$$

The original factorization algorithm in [1] decomposes W' in the form $(U \Sigma^{1/2})(\Sigma^{1/2} V^\top)$, but the decomposition in (Eq. 6) is preferred for numerical reasons and simplicity of notation. Due to the rank-3 constraint, only the first three singular values on the diagonal of the matrix Σ are nonzero in the absence of noise. It therefore suffices to take only the corresponding three vectors in U and V and truncate Σ accordingly. The matrices U and (ΣV^\top) define distorted camera parameters and a distorted 3D-structure, respectively, since singular value decomposition does not impose that each row-tuple of U are rows of a rotation matrix. Therefore, the computed camera parameters and the reconstructed 3D-structure are affinely distorted and need to be corrected in a subsequent step.

Since any nonsingular 3×3 matrix A may be inserted into the decomposition of W' ,

$$W' = U A A^{-1} \left(\Sigma V^\top \right), \quad (7)$$

without altering W' , matrix A can be determined as second step of the factorization algorithm. Denote by $I_{3 \times 3}$ the 3×3 identity matrix. As in the case of self-calibrating a perspective camera by means of the dual absolute quadric, matrix A is determined from (Eq. 2) such that the two rows U_i of U corresponding to image i equal $K_i R_i$

$$K_i R_i = U_i A$$

$$(K_i R_i)(K_i R_i)^\top = (U_i A)(U_i A)^\top \quad (8)$$

$$\underbrace{K_i R_i R_i^\top}_{I_{3 \times 3}} K_i^\top = U_i \underbrace{A A^\top}_{T} U_i^\top \quad (8)$$

$$K_i K_i^\top = U_i T U_i^\top.$$

F

For the simplest affine camera, the *orthographic* camera, the matrices K_i consist of the first two rows of a 3×3 identity matrix, i.e., $K_i K_i^\top$ equals the 2×2 identity matrix for all images. Hence, if u_{i1}^\top and u_{i2}^\top are the first and the second rows of U_i , respectively, the following three equations are obtained:

$$1 = u_{i1}^\top T u_{i1}, \quad (9)$$

$$1 = u_{i2}^\top T u_{i2}, \quad (10)$$

$$0 = u_{i1}^\top T u_{i2} = u_{i2}^\top T u_{i1}. \quad (11)$$

Equations 9–11 constitute three linear equations in the six unknown entries of the symmetric matrix T per image. If we define $t_6 = [T_{11} \ T_{22} \ T_{33} \ T_{12} \ T_{13} \ T_{23}]^\top$ where T_{ab} denotes the entry of T in the a th row and the b th column, and $H^{11} = u_{i1} \ u_{i1}^\top$, $H^{22} = u_{i2} \ u_{i2}^\top$, $H^{12} = u_{i1} \ u_{i2}^\top$, (Eq. 9)–(Eq. 11) can be written as

$$1 = [H_{11}^{11} \ H_{22}^{11} \ H_{33}^{11} \ 2H_{12}^{11} \ 2H_{13}^{11} \ 2H_{23}^{11}] t_6, \quad (12)$$

$$1 = [H_{11}^{22} \ H_{22}^{22} \ H_{33}^{22} \ 2H_{12}^{22} \ 2H_{13}^{22} \ 2H_{23}^{22}] t_6, \quad (13)$$

$$0 = \left[H_{11}^{12} \ H_{22}^{12} \ H_{33}^{12} \ (H_{12}^{12} + H_{21}^{12}) \ (H_{13}^{12} + H_{31}^{12}) \ (H_{23}^{12} + H_{32}^{12}) \right] t_6. \quad (14)$$

Here, H_{ab} denotes the (a, b) th entry of matrix H . For simplicity, the subscript i denoting the image is omitted.

After estimating t_6 from the three equations (Eq. 12)–(Eq. 14) per image using normal

equations, the correcting matrix A can be determined by eigenvalue decomposition $T = UDU^\top$ as $A = UD^{1/2}$. The matrix of camera parameters P can be taken as $P = UA$ and the 3D-structure as $X = A^{-1} \sum V^\top$.

Extensions

The original factorization algorithm was extended to more sophisticated affine camera models. For the projective camera model, noniterative [3] and iterative [4, 5] extensions exist. The latter alternate matrix decomposition with refinement of the *projective depths* λ_{ij} , scalar variables are chosen so that

$$\lambda_{ij}x_{ij} = K_i [R_i | t_i] X_j^H \quad (15)$$

holds true under perspective projection. In [6], a projective extension is proposed which minimizes the reprojection error to obtain projectively distorted estimates of shape and motion parameters. The reprojection error is a geometric error measure instead of the algebraic error which is minimized by factorization schemes. There also exist algorithms which can handle missing observations, i.e., not all observations x_{ij} need to be known.

A generalization of the affine factorization algorithm to the *kinematic chain* model was proposed in [7]. An algorithm for scenes or objects which generally deform nonrigidly was introduced in [8]. Using prior knowledge on the shape and pose variety of human bodies, a projective factorization algorithm was proposed in [9] which can also handle missing observations.

Open Problems

Many unsolved problems remain in all variants of the factorization scheme. One of the most prominent difficulties stems from the requirement that all observations of the measurement matrix must be known. For the affine factorization scheme, the matrix decomposition step can be solved by an alternating projection method [10], yet such

algorithms turn out to be unstable for the projective camera model and can therefore handle only small amounts of unknown observations. More robust algorithms combine different error metrics [11, 12] or use strong prior knowledge [9].

For iterative extensions, the problem of initialization reappears. If arbitrarily initialized, convergence to a reasonable local minimum is not guaranteed, so the resulting reconstructions can be strongly distorted.

Algorithms on nonrigid scenes or objects can handle small nonrigid deformations, unless restrictive prior knowledge is imposed. For the projective camera model without further prior knowledge, no successful 3D-reconstruction methods have been proposed which can reconstruct nonrigidly deforming scenes unless special devices, such as stereo cameras, are used or partially rigid scenes are assumed.

Lastly, the decomposition of matrix T is not possible if some eigenvalues are negative.

Synonyms

Dimensionality reduction; Feature reduction; Variable selection

Definition

Feature selection refers to a set of techniques for automatically extracting important features

from raw observations or reducing the set of dimensions from a given feature set, in a task-dependent manner.

Background

Feature selection refers to a large set of overlapping techniques, ranging from methods such as dimensionality reduction, subset selection, and more recently feature learning or representation learning. Since early works in pattern analysis [1], there has been an interest in extracting parsimonious and meaningful features from raw data for tasks such as recognition, compression, etc. Classically, features based on intuition or domain knowledge were considered popular; however, automatic methods for feature selection that can find optimal transformations of raw data are of contemporary interest. Toward this, linear and nonlinear methods for feature selection and learning have been suggested.

F

Theory

The basic intuition behind feature selection methods is to extract either lower-dimensional information from high-dimensional data such as images, videos, etc., in a domain-dependent or task-specific manner. Reducing the size of the feature set results in more parsimony and helps in beating the curse of dimensionality. Feature selection is approached by formulating a task-dependent criterion function that measures the “quality” of the obtained features, which is then optimized over the set of admissible feature selection operators.

Given a set of data points denoted by $\mathcal{X} = \{x_1, x_2, \dots, x_k\}$ where $x_i \in \mathbb{R}^n$, optionally along with lower-dimensional attributes or labels $l_i = \mathcal{L}(x_i)$ associated with each x_i , a set of admissible operators Φ , where for any $\phi \in \Phi$, $\phi : \mathbb{R}^n \rightarrow \mathbb{R}^d$, is a mapping from the raw data space to a feature space of dimension $d < n$, and a task-specific criterion function $\mathcal{E}(\mathcal{X}, \mathcal{L}, \phi)$, the goal of feature selection is to find a mapping $\phi \in \Phi$ such that the criterion function \mathcal{E} is optimized. In

computer vision, the x_i 's typically are images or other statistics of images, and the labels l_i 's can be discrete-valued such as names of objects, identities of people, etc. or continuous-valued such as the pose of an object, the age of a person, etc.

Linear methods restrict ϕ to the set of linear transforms, which can be represented as a matrix multiplication given by $y = \phi(x) = \mathbf{W}^T x$, where \mathbf{W} is a $n \times d$ matrix. Examples of linear feature selection methods include principal component analysis (PCA) [1], independent component analysis (ICA) [2], Fisher's linear discriminant analysis (FLDA) [3], support vector machines (SVM) [4], partial least squares (PLS) [5], boosting [6], etc. Nonlinear extensions of linear techniques are commonly achieved by means of the kernel method [7]. Subset selection methods consider ϕ to be a matrix with binary entries, typically only one non-zero element per row, which corresponds to choosing a subset of the dimensions available to us. In this case, feature selection results in a combinatorial search over all possible subsets, for which several approximate and greedy methods have been devised [8].

Examples

Principal Component Analysis In PCA, the goal is to obtain linear projections that allow optimal reconstruction of data as measured in terms of the reconstruction error. Thus, given a set of data points \mathcal{X} , the goal is to obtain a $n \times d$ orthonormal matrix \mathbf{W} , such that $\mathcal{E}(\mathcal{X}, \mathbf{W}) = \sum_{i=1}^k \|x_i - \mu - \mathbf{W}\mathbf{W}^T x_i\|^2$ is minimized, where μ is the mean of the set \mathcal{X} . For this case, the optimal \mathbf{W} has columns which are the top d eigenvectors of the data covariance matrix [9, 10].

Fisher's Linear Discriminant Analysis In FLDA, along with a set of points $\{x_i\}$, one is given a set of discrete class labels $l_i \in \{1, 2, \dots, c\}$. The goal is to obtain linear projections of the data so that separation between classes is increased with respect to the spread within each class. This is measured in terms of within-class and between-class scatter matrices. Denote $D_i =$

$\{x \in \mathcal{X} | \mathcal{L}(x) = i\}$, the subset of points belonging to the i th class, and m and m_i as the mean of the entire set \mathcal{X} and the i th class, respectively. The within-class scatter is defined as $S_W = \sum_{i=1}^c S_i$, where $S_i = \sum_{x \in D_i} (x - m_i)(x - m_i)^T$, and the between-class scatter is defined as $S_B = \sum_{i=1}^c n_i(m_i - m)(m_i - m)^T$, where n_i is the cardinality of D_i . Then, the criterion function to be maximized is $\mathcal{E}(\mathcal{X}, \mathcal{L}, \mathbf{W}) = \frac{|\mathbf{W}^T S_B \mathbf{W}|}{|\mathbf{W}^T S_W \mathbf{W}|}$. For this case, the optimal \mathbf{W} has columns which are the top d generalized eigenvectors of $S_B \mathbf{W}_i = \lambda_i S_W \mathbf{W}_i$ [10].

Projection Pursuit Projection pursuit is a broad class of techniques for exploratory data analysis where the goal is to find projections of data along interesting directions. This is typically stated as searching for directions of non-Gaussianity. Criterion functions to measure non-Gaussianity include entropy and higher-order moments such as the kurtosis. For the case of entropy, the Gaussian distribution has the largest entropy among the class of zero mean and unit variance densities. Thus, to maximize non-Gaussianity, the criterion function to be maximized is $E[f(\mathbf{W}^T x) \log f(\mathbf{W}^T x)]$ (the negative entropy), where f is the estimated probability density function of the projections [11].

Manifold Learning In many cases, it has been reasonably shown that high-dimensional data can be viewed as samples from an underlying manifold that is not known analytically. In this setting, a suite of techniques, broadly known as manifold learning techniques, have been developed. Examples include techniques such as LLE [12], Isomap [13], Laplacian eigenmaps [14], t-SNE [15], UMAP [16], etc. Manifold learning techniques aim to find an embedding of the manifold to a Euclidean space, where each method attempts to preserve different properties about the data. Once an acceptable embedding into a Euclidean space is found, feature selection can proceed using one of the existing algorithms mentioned before. However, the number and density of samples available on the manifold strongly affect the quality of features obtained.

Applications

Feature selection has found very wide applications in face recognition [17–19]. Kernelized versions of PCA, LDA [20], and SVMs [21] have been successful in face recognition. Similar applications have been proposed in numerous object recognition tasks. Recently, the method of partial least squares has found successful application in human detection and face recognition [22, 23].

Open Problems and Recent Trends

Feature Learning Classically, feature selection starts after an initial set of reasonable features has been established. This initial set of features was generally constructed with intuition or domain knowledge. In recent years, due to the resurgence of deep neural network architectures, one can now *learn* appropriate features directly from raw data, as well as implicitly include feature selection operations as layers within deep neural architectures. Examples of such approaches include auto-encoders [24] and newer development such as variational auto-encoders [25]. Feature learning can also be driven by end tasks such as classification [26] or generation tasks [27]. The fusion of feature learning with feature selection continues to be of current interest in machine learning.

Feature Selection and Differential Geometry The techniques for feature selection described above are implicitly designed to operate on Euclidean spaces. The definitions of various entities used – L_2 distortion measure, the mean, and covariances – are valid only for Euclidean spaces. In computer vision, there are several applications where the data space is a non-Euclidean manifold embedded in a larger ambient Euclidean space, which can be shown to have *differential* structures or *quotient* structures due to certain invariance requirements. This is different than manifold learning, where there is not much more information available

beyond discrete samples from an unknown manifold. Applications of such differentiable manifolds in vision include shape analysis [28], human detection and tracking [29], and activity analysis [30]. Often it is possible to extend feature selection concepts to manifolds by taking recourse to Riemannian geometry. The significant modification lies in redefining the notions of distances in terms of manifold geodesics and statistical quantities such as means and covariances in terms of intrinsic statistics [31, 32]. For example, the counterpart of PCA for manifolds is called principal geodesic analysis (PGA) [33]. However, these procedures are often approximations, and it is very hard in general to quantify their degree of accuracy. Feature selection on geometric spaces continues to be of interest in many diverse areas of computer vision and machine learning [34].

Feature Sensing There has been recent interest in designing sensors and cameras that can directly sense the required task-dependent features instead of sensing first and then performing feature selection. By directly sensing features, one can potentially reduce the load on the sensor without loss of performance in the given application. This is achieved in practice by modifying camera elements, such as by introducing a programmable micro-mirror array [35] or optical masks [36], in a way that the required transformations of the raw data are directly sensed. However, different designs are needed to preserve different properties of the images. In parallel, there has been recent interest in sensing “universal” features by random projections. The Johnson-Lindenstrauss lemma is used as motivation for using random projections directly for inference tasks [37]. Cameras to sense random projections of data have been designed using micro-mirror arrays [38]. High-level tasks, such as face and activity recognition and visual question answering, have been shown to be feasible [39–41] from directly sensed measurements. New architectures for sensing features continue to be of interest in the field of computational imaging and computational photography [42].

Definition

Few-shot learning refers to the machine learning problem of learning a model from very few examples (shots).

Background

Computer vision systems based on machine learning often require the collection of large datasets for their training. This is often a

challenging obstacle for their deployment. Moreover, there is evidence that humans are actually able to learn concepts from very few examples [1–3]. Few-shot learning methods aim to reduce this observed gap between human learning and machine learning. This is achieved by performing a form of transfer learning using data from many previously observed tasks toward new tasks with little data.

F

Theory and Application

In the 2000s, early research in computer vision on few-shot learning tackled the problem by using hand-designed feature representations and focusing on the exploration of learning and inference algorithms operating on that data representation [4–7]. A lot of that research focused on the one-shot learning setting, where a single example of a new object category is assumed to be available.

More recently, deep learning methods have become popular for computer vision, where we posit that it is more effective to include in the learning problem the training of the data representation. A simple approach to performing few-shot learning with deep learning is thus to train a representation on all the data of previously observed tasks/categories with regular supervised classification learning and post hoc use that representation (and potentially fine-tune it) on new tasks with little data. However, embracing fully the idea of end-to-end training behind deep learning, recent work in few-shot learning has been exploring the training of not just the representation but also the learning and inference mechanisms used by a few-shot learner of novel tasks/categories.

Meta-Learning Framework This problem has successfully been expressed in a meta-learning (or learning to learn) framework [8]. Formally, the problem we wish to solve is to produce, for a task with a small training set $\mathcal{D}_{\text{train}} = \{(\mathbf{x}_t, y_t)\}_{t=1}^L$ of image (\mathbf{x}_t) and object label (y_t) pairs, a predictor $f(\mathbf{x}^*)$ (usually taking the form of a deep neural network) of the task label y^* for new input images \mathbf{x}^* . In other words, we

want to discover a function $\mathcal{A}(\mathcal{D}_{\text{train}})$ (i.e., a learning algorithm) that can take in a labeled set for any task at hand and will output a predictor that solves that task as well as possible, on new inputs. In meta-learning, we solve this problem by assuming a parametrization for the function $\mathcal{A}(\mathcal{D}_{\text{train}})$ and (meta-)training it on many tasks. This is sometimes referred to as the *episodic approach* to few-shot learning, where an episode is an example pair of $\mathcal{D}_{\text{train}}$ (the training set for the task, also sometimes referred to as *support set*) and $\mathcal{D}_{\text{test}} = \{(\mathbf{x}_t^*, y_t^*)\}$ (the test set for the task, also sometimes referred to as the *query set*). The episodic approach is illustrated in Fig. 1.

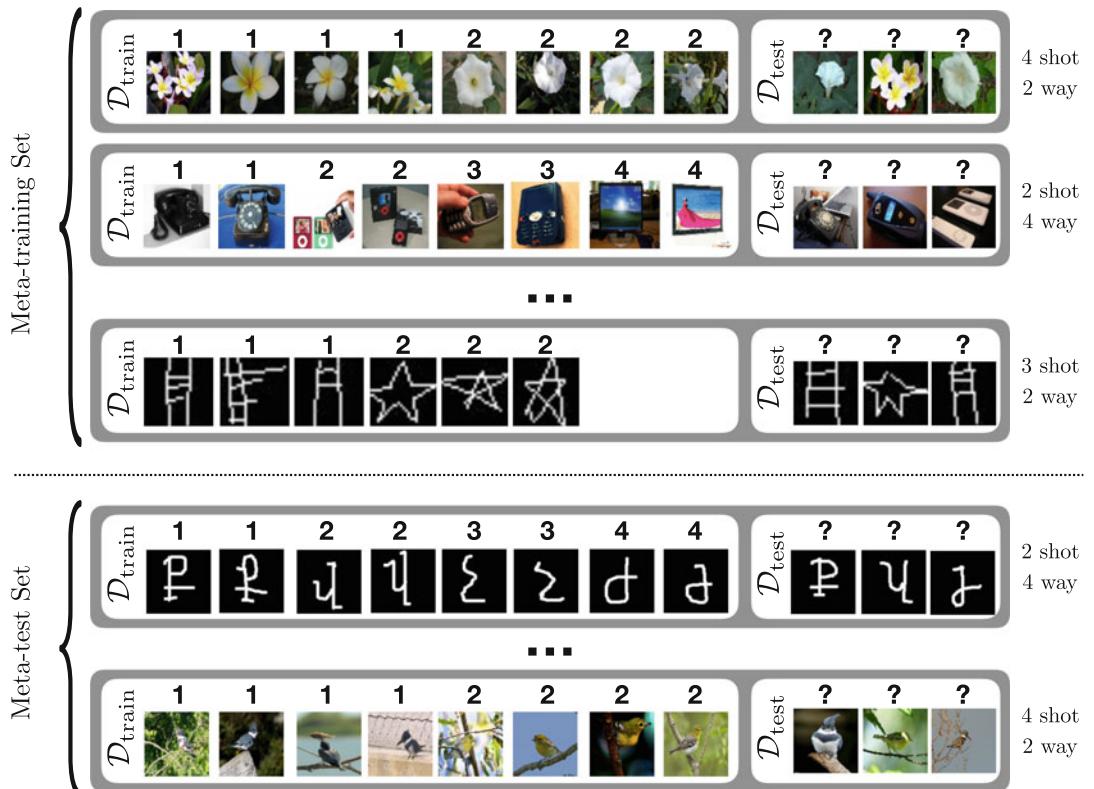

Approaches in parametrizing the learning algorithm function \mathcal{A} vary. One can distinguish two families of approaches.

A first family of methods are those that take direct inspiration from currently existing “hand-designed” learning algorithms and meta-train some of its free parameters. In other words, function \mathcal{A} will explicitly be running a familiar learning algorithm on $\mathcal{D}_{\text{train}}$, which is often referred to as the *inner loop*. Meta-learning \mathcal{A} (referred to as the *outer loop*) then requires back propagating gradients of a loss measured on $\mathcal{D}_{\text{test}}$ through the learning algorithm that produced $f(\mathbf{x}^*)$, iteratively for each episode. In Ravi and Larochelle [10], Finn et al. [11], $\mathcal{A}(\mathcal{D}_{\text{train}})$ corresponds to a gradient descent procedure in the inner loop that fits the weights of a neural network predictor on the data in $\mathcal{D}_{\text{train}}$. The meta-trained free parameters are the initialization of the neural network’s weights, as well as the parameters of the gradient descent optimizer (e.g., the learning rates). Some work has also looked at non-gradient-descent architectures for producing the weights of the neural network predictor $f(\mathbf{x}^*)$ [12]. Other methods have focused on learning an embedding space (represented by a deep neural network encoder) for the inputs in $\mathcal{D}_{\text{train}}$ such that a known learning algorithm in that space yields good generalization to $\mathcal{D}_{\text{test}}$. Snell et al. [13]’s prototypical networks can be seen as assuming a Gaussian classifier as the inner loop algorithm, Bertinetto et al. [14] uses a ridge regressor classifier, and Lee et al. [15] uses a linear SVM.

Finally, Vinyals et al. [16] instead learns a metric function that computes the similarity between training inputs \mathbf{x}_t in $\mathcal{D}_{\text{train}}$ and test inputs \mathbf{x}^* in $\mathcal{D}_{\text{test}}$, such that a soft-nearest-neighbor classifier using this metric performs well on $\mathcal{D}_{\text{test}}$.

A second family of methods corresponds to ignoring existing learning algorithms and instead embracing the end-to-end nature of meta-learning, to directly design a neural network architecture that ingests a set $\mathcal{D}_{\text{train}}$ and a test input \mathbf{x}^* and outputs a predictive distribution over the label y^* of \mathbf{x}^* . Hochreiter et al. [17] proposes such an approach by framing the meta-learning framework as a sequential labeling problem. There, examples in each episode are put in a sequence in some arbitrary order, with each time step corresponding to an input pair (\mathbf{x}_t, y_{t-1}) (i.e., the current input and the label of the previous input) and a predicted target y_t (i.e., the label of the current input). Santoro et al. [18] leveraged this framework to train an adapted version of a neural turing machine [19] for few-shot learning. Another approach, followed by Mishra et al. [20], is to convert episodes into sequences $[(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_T, y_T), (\mathbf{x}^*, 0)]$ where labels are aligned with inputs but where the last element is an input from $\mathcal{D}_{\text{test}}$ without its label and the neural network must predict that label y^* . You can then leverage any deep learning architecture appropriate for sequences such as (dilated) convolutions and attentional layers, to encode the provided sequence.

Evaluation and Benchmarks To benchmark few-shot learning methods in the episodic setting, a source dataset is leveraged to create the episodes. Most research in few-shot learning is focused on the problem of few-shot classification. Episodes are stochastically generated by first randomly choosing a small number of classes (e.g., 5 or 20) and then randomly picking without replacement examples from these classes to build the training (support) set and the test (query) set of the episode. The most popular benchmarks are based on the Omniglot dataset [21] and the ImageNet dataset [22] (specifically the mini-ImageNet benchmark [10, 16], which leverages only 100 classes from the original ImageNet dataset). Recent research has also proposed

Few-Shot Learning, Fig. 1 Illustration of the episodic approach of the meta-learning framework. Each episode is a pair of a training (or support) set $\mathcal{D}_{\text{train}}$ and test (or query) set $\mathcal{D}_{\text{test}}$, corresponding to an N -way/ K -shot image classification task. Meta-training is performed on a

set of episodes corresponding to classification tasks over different concepts/categories than those used for meta-testing. The episodes illustrated here were derived from the Meta-Dataset benchmark [9]

merging many source datasets to benchmark few-shot learning methods [9].

To measure generalization performance (i.e., meta-test performance), it is important to use episodes that are created from classes never seen during meta-training, to reflect the fact that \mathcal{A} is expected to be used on classification tasks that it has never seen before. However, it is sometimes more realistic to also include classes seen during meta-training (referred to as base classes) in the evaluation and to analyze the accuracy of methods on base classes and novel classes [23, 24].

Definition

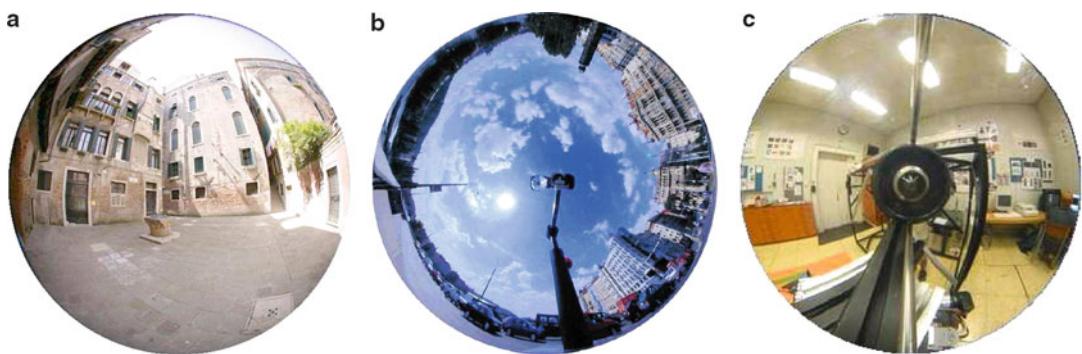

Field of view refers to the angular volume of 3D space sampled by the light rays of a camera.

Background

The pinhole camera is one of the most successful mathematical models in the field of computer vision, image processing, and graphics. People naturally accepted this imaging model because of its extreme simplicity and its closeness to an image perceived by the human visual system. In a pinhole camera, the projection rays from scene points (light rays) intersect at a single point (optical center). Typically, these conventional cameras have a very small field of view, around 50°. Omnidirectional cameras have a larger field of view and have been extremely useful in several applications like videoconferencing, augmented reality, surveillance, and large-scale 3D reconstruction. These cameras can be constructed in a simple manner, for they can be made from conventional cameras by using additional lenses or

mirrors. For example, Fig. 1a shows an E8 Nikon Coolpix camera appended with a fish-eye lens having a field of view of $183^\circ \times 360^\circ$. Another possibility is to use mirrors in addition to lenses to increase the field of view. These configurations are referred to as *catadioptric*, where “*cata*” comes from mirrors (reflective) and “*dioptic*” comes from lenses (refractive). Figure 1b, c show two catadioptric configurations with hyperbolic and parabolic mirrors, respectively.

the concept of focal length is not defined. For example, the focal length is not defined for the E8 fish-eye lens of Nikon which has a field of view of $183^\circ \times 360^\circ$. Several works have used fish-eye lenses for creating omnidirectional images [1–3]. Geometrically, omnidirectional cameras can be either single viewpoint or noncentral. Single viewpoint configurations are preferred to noncentral systems because they permit the generation of geometrically correct perspective images from the image(s) captured by the camera. In addition, most theories and algorithms developed for conventional cameras hold good for single-center omnidirectional cameras. In theory, fish-eye lenses do not provide a single viewpoint imaging system [4]. The projection rays pass through a small disk in space rather than a single point. Nevertheless, in practice, it is usually a

Theory and Camera Models

Fish-Eye Camera Model

Fish-eye lenses have a short focal length and a very large field of view (cf. Fig. 2a). However, when the field of view is greater than 180° ,

good assumption to consider these cameras as single viewpoint cameras [5]. Perspective images synthesized from fish-eye images are visibly very accurate without any distortions. Several distortion functions can be used to model fish-eye and central catadioptric images [6, 7]. Some of them are mentioned below.

- *Stereographic projection:* Several radially symmetric models [8] were used for fish-eye images. One of them is the stereographic projection. This model gives a relation between θ , the angle made by a scene point, the optical center and the optical axis, and the distance r between the associated image point and the distortion center

$$r = k \tan \frac{\theta}{2}$$

where k is the only parameter to be estimated.

- *Equidistant projection:*

$$r = k\theta$$

- *Equisolid angle projection:*

$$r = k \sin \frac{\theta}{2}$$

- *Sine law projection:*

$$r = k \sin \theta$$

On fitting the Nikon FC-E8 fish-eye lens with the four radially symmetric models (stereographic, equidistant, equisolid angle, and sine law), it was found that the stereographic projection gave the lowest error [9]. The error is the Euclidean distance between the original image pixels and the projected image pixels using the models.

- *Combined stereographic and equisolid angle model:* In [9], Bakstein and Pajdla followed a model-fitting approach to identify the right projection model for fish-eye cameras. Their

model is a combination of stereographic and equisolid angle models. The following relation was obtained with four parameters:

$$r = a \tan \frac{\theta}{b} + c \sin \frac{\theta}{d}$$

On the whole, they used 13 camera parameters: six external motion parameters (R, t), one aspect ratio (β), two parameters for the principal point (u_0, v_0) , and the four parameters of the above projection model (a, b, c, d) .

- *Polynomial lens distortion model:* Most distortion corrections assume the knowledge of the distortion center. Let r_d refer to the distance of an image point from the distortion center. The distance of the same image point in the undistorted image is given by

$$r_u = r_d \left(1 + k_1 r_d^2 + k_2 r_d^4 + \dots \right)$$

where k_1 and k_2 are distortion coefficients [10].

- *Field of view (FOV):* The distortion function is given by

$$r_u = \frac{\tan(r_d w)}{2 \tan \frac{w}{2}}$$

The above distortion correction function is based on a single parameter w . It is a good idea to correct the distortion using the polynomial model followed by the field of view model [6].

- *Division model (DM):* The distortion correction function is given by

$$r_u = \frac{r_d}{(1 + k_1 r_d^2 + k_2 r_d^4 + \dots)}$$

where the k_i are the distortion coefficients.

Catadioptric Camera Model

Vision researchers have been interested in catadioptric cameras [4, 11–17] because they allow numerous possibilities in constructing omnidirectional cameras. The possibilities arise from the differences in size, shape, orientation, and positioning of the mirrors with respect to the

camera. Please refer to the encyclopedia entry on ▶ “[Catadioptric Camera](#)” for more details.

Application

- *Larger field of view:* Fig. 2 shows images captured by three different omnidirectional cameras. The first image is captured by a fish-eye camera, the second is captured by a catadioptric system constructed using a hyperbolic mirror and a perspective camera, and finally, the third is captured by another catadioptric camera constructed using a parabolic mirror and an orthographic camera. One can make the following observation from the omnidirectional images. A very large scene, which usually requires several pinhole images, can be captured in a single omnidirectional image although of course at a lower resolution.
- *Stable motion estimation:* Motion estimation is a challenging problem for pinhole images, especially when a larger number of images are involved. On the other hand, omnidirectional cameras stabilize the motion estimation and improves its accuracy [18–20]. In the case of small rigid motions, two different motions can yield nearly identical motion fields for classical perspective cameras. However, this is impossible in the case of omnidirectional cameras. By improving the stability of motion estimation, omnidirectional cameras also contribute to a stable 3D reconstruction.

A detailed survey of various camera models, calibration, and 3D reconstruction algorithms is given in [21, 22].

[Rao metric](#)

Related Concepts

- ▶ [Fisher-Rao Metric](#)
- ▶ [Maximum Likelihood Estimation](#)
- ▶ [Riemannian Manifold](#)

Definition

The Fisher-Rao metric is a particular Riemannian metric defined on a parameterized family of conditional probability density functions (pdfs). If two conditional pdfs are near to each other under the Fisher-Rao metric, then the square of the distance between them is approximately equal to twice the average value of the log likelihood ratio of the conditional pdfs. If the log likelihood ratio of the two pdfs is near to zero, then it is difficult to distinguish between them using only sampled values.

Background

Suppose that a parameterized family of conditional pdfs is given and it is required to find the parameter value corresponding to the conditional pdf that best fits a given set of data. It is useful to

have a distance function defined on pairs of conditional pdfs, such that if a given conditional pdf is a close fit to the data, then all the conditional pdfs near to it are also close fits to the data. It is always possible to change the parameterization of the family of pdfs or to change the parameterization of the data without losing information and without gaining any new information. It follows that any meaningful distance function should be independent of the choice of parameterizations. The Fisher-Rao metric is the only known Riemannian metric that yields a distance function with both the required independence properties [1, 2].

Theory

Let X be an open subset of a Euclidean space \mathbb{R}^n , and let T be an open subset of a Euclidean space \mathbb{R}^d . Let x, θ be vectors in X and T , respectively, and let $p(x|\theta)$ be a probability density function defined for x in X and conditional on θ in T . The set T is a parameter space for the family of conditional pdfs $\theta \mapsto p(x|\theta)$. Let θ_i for $1 \leq i \leq d$ be the components of θ . With these choices of parameterization for X and T , the Fisher-Rao metric on T is defined by the following family of $d \times d$ matrices:

$$J_{ij}(\theta) = - \int_X \left(\frac{\partial^2}{\partial \theta_i \partial \theta_j} \ln p(x|\theta) \right) p(x|\theta) dx, \quad 1 \leq i, j \leq d, \theta \in T. \quad (1)$$

The same matrix $J(\theta)$ is also defined by the formulae

$$J_{ij}(\theta) = \int_X \left(\frac{\partial}{\partial \theta_i} \ln p(x|\theta) \right) \left(\frac{\partial}{\partial \theta_j} \ln p(x|\theta) \right) p(x|\theta) dx, \quad 1 \leq i, j \leq d, \theta \in T. \quad (2)$$

Rao notes in [3] that $J(\theta)$ defines a Riemannian metric on T . For information about (1) and (2), see [1], Section 2.3.

Let $\theta + \Delta\theta$ be a point in T near to θ , and let $\text{dist}(\theta, \theta + \Delta\theta)$ be the length of the shortest path in T from θ to $\theta + \Delta\theta$, as measured using the Fisher-Rao metric. This shortest path is called the geodesic between θ and $\theta + \Delta\theta$. The matrix $J(\theta)$ provides an approximation to the geodesic distance, in that

$$\Delta\theta^\top J(\theta)\Delta\theta = \text{dist}(\theta, \theta + \Delta\theta)^2 + O(\|\Delta\theta\|^3). \quad (3)$$

The Fisher-Rao metric is also defined for probability distributions on finite sets. Let X be a finite set with n elements and let θ_i be the probability of the i th element of X . The θ_i for $1 \leq i \leq n$ sum to 1. Let θ be the vector formed from the probabilities θ_i for $1 \leq i \leq n - 1$. The parameter space T is the open subset of \mathbb{R}^{n-1} consisting of vectors θ with components θ_i such that

$$0 < \theta_i < 1, \quad 1 \leq i \leq n - 1,$$

$$0 < \sum_{i=1}^{n-1} \theta_i < 1.$$

The Fisher-Rao metric is defined on T by the following $(n - 1) \times (n - 1)$ matrix:

$$J_{ij}(\theta) = \theta_n^{-1}, \quad 1 \leq i, j \leq n - 1, i \neq j,$$

$$J_{ii}(\theta) = \theta_n^{-1} + \theta_i^{-1}, \quad 1 \leq i \leq n - 1.$$

Let θ and $\theta + \Delta\theta$ be nearby points in T . Then the approximation (3) to the square of the distance between the pdfs $p(x|\theta)$ and $p(x|\theta + \Delta\theta)$ is

$$\sum_{i=1}^n \theta_i^{-1} (\Delta\theta_i)^2.$$

Let $D(\theta(1)\|\theta(2))$ be the Kullback-Leibler divergence between the conditional pdfs $p(x|\theta(1))$ and $p(x|\theta(2))$ [1]. In the continuous case, in which X is an open subset of \mathbb{R}^n , the Kullback-Leibler divergence is given by

$$D(\theta(1)\|\theta(2)) = \int_X \ln \left(\frac{p(x|\theta(1))}{p(x|\theta(2))} \right) p(x|\theta(1)) dx. \quad (4)$$

On setting $\theta = \theta(1)$, $\theta + \Delta\theta = \theta(2)$, it follows from (4) that

$$\frac{1}{2} \Delta\theta^\top J(\theta)\Delta\theta = D(\theta\|\theta + \Delta\theta) + O(\|\Delta\theta\|^3). \quad (5)$$

An equation similar to (5) holds when X is a finite set.

The matrix $J(\theta)$ used to define the Fisher-Rao metric appears in the theory of maximum likelihood estimation [4]. Suppose that N points $x(i)$ for $1 \leq i \leq N$ are sampled independently from X using the conditional pdf $p(x|\theta)$. Let $\hat{\theta}$ be the maximum likelihood estimate of θ :

$$\hat{\theta} = \underset{\phi}{\operatorname{argmax}} \phi \mapsto \prod_{i=1}^N p(x(i)|\phi).$$

If N is large, then the distribution of $\theta - \hat{\theta}$ is closely approximated by a Gaussian distribution with expected value 0 and covariance:

$$N^{-1} J(\theta)^{-1}.$$

Let N be any fixed positive integer, let $\phi \equiv \phi(x(1), \dots, x(N))$ be any unbiased estimator of θ , and let C be the covariance of ϕ . Then the matrix

$$C - N^{-1} J(\theta)^{-1}$$

is positive semi-definite. The matrix $N^{-1} J(\theta)^{-1}$ is known as the Cramér-Rao lower bound for C [1].

In the continuous case, in which X is an open subset of \mathbb{R}^n , it is rare to find a closed-form expression for the Fisher-Rao metric. However, an example of a closed-form expression is provided by the family of Gaussian densities for which $X = \mathbb{R}$. Let $\theta = (\mu, t)$, such that μ, t are points in \mathbb{R} with $t > 0$. The parameter space T is the upper half plane in \mathbb{R}^2 . Let $p(x|\theta)$ be the Gaussian pdf for x in \mathbb{R} with expected value μ and standard deviation $t/\sqrt{2}$. In this case, the scaled Fisher-Rao metric, $(1/2)J(\theta)$, coincides with the Poincaré metric on T ,

$$\frac{1}{2} J(\theta) = \frac{1}{t^2} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \theta \in T.$$

It is shown in [5] that under certain conditions the Fisher-Rao metric can be closely approximated by a simpler metric.

Applications

The Fisher-Rao metric provides a theoretical basis for the Hough transform which is used to detect geometrical structures such as lines and circles. The size and shape of the Hough transform accumulators and the number of accumulators can be calculated using the Fisher-Rao metric [5]. Peter and Rangarajan [6] describe planar shapes using weighted sums of Gaussian pdfs. The associated Fisher-Rao metric is used to define geodesics in the parameter manifold for the shape pdfs. Each segment of a geodesic specifies a continuous family of shapes which interpolate between the two shapes represented by the end points of the segment. An algorithm to find geodesics is described in [7]. Ceolin and Hancock [8] use the Fisher-Rao metric to compute geodesics in a shape space of faces.

- [Omnidirectional Vision](#)

Definition

A fisheye lens is a lens giving a field of view of about 180° or larger.

Background

The terms fisheye camera and fisheye view seem to have been introduced by Wood in 1906 [1]. Wood was interested in the way a fish perceives objects outside the water. Besides studying the problem theoretically, he also built a camera that mimics the fisheye view. To do so, he immersed a pinhole camera in a casing filled with water and that had a glass plate as one of its faces, through which the camera could acquire images of the outside world. One basic observation Wood made is that since the camera looks from a denser medium (water) into a lighter one (air), its effective field of view is larger than its native one, due to the refraction happening at the interface between the media. This effect is related to the so-called Snell's window. In particular, when looking from water into air and supposing that the water surface is still, the entire hemisphere above the water can be seen within a circular cone-shaped field of view with an opening angle of about 96°.

Fisheye Lens, Fig. 1 Two images of a fisheye conversion lens and an image taken with a fisheye lens. The image is necessarily heavily distorted since it “contains” an entire hemispheric field of view

In the 1920s, Bond and Hill independently invented purely glass-based fisheye lenses that, like Wood’s water-based camera, gave hemispherical fields of view [2, 3]. Many improvements were made subsequently, for instance, on chromatic aberrations; see, for example, [4–6]. Fisheye lenses can achieve larger than hemispheric fields of view, for example, Martin reports a design with a 310° field of view [6]. An example of a fisheye lens and an image acquired using one is given in Fig. 1.

Theory

Since fisheye cameras capture an entire hemisphere or more in a single image, the image is bound to show strong distortions. These cameras can thus not be modeled using a pinhole model and even classical polynomial distortion models are insufficient. Better suited models have been proposed [4, 7, 8], as follows. Let ϕ be the angle between the optical axis and an incoming light ray and θ the angle between the optical axis and the ray leaving the lens towards the image plane. Then, we can make the following definitions:

$$\text{Perspective projection : } \theta = \phi$$

$$\text{Stereographic projection : } \tan \theta = k \tan \frac{\phi}{2}$$

$$\text{Equidistant projection : } \tan \theta = k \phi$$

$$\text{Equi-solid angle projection : } \tan \theta = k \sin \frac{\phi}{2}$$

$$\text{Sine-law projection : } \tan \theta = k \sin \phi,$$

where k is a free parameter.

It is sometimes useful to express these projection models with respect to the distance r of an image point from the principal point:

$$\text{Perspective projection : } r = m \tan \phi$$

$$\text{Stereographic projection : } r = m \tan \frac{\phi}{2}$$

$$\text{Equidistant projection : } r = m \phi$$

$$\text{Equi-solid angle projection : } r = m \sin \frac{\phi}{2}$$

$$\text{Sine-law projection : } r = m \sin \phi,$$

where m is a free parameter, proportional to the camera’s focal length.

Various other models for fisheye lenses and other omnidirectional cameras have been proposed in the literature, for instance [5, 9–12]. These and other models are described in [13], which also provides references to calibration methods. It seems that most fisheye lenses are designed to approach the equidistant model. In practice, an accurate calibration of a fisheye camera may require to add a classical polynomial distortion model “on top” of a specific fisheye projection model.

Application

Among the first applications of fisheye lenses were meteorology, via the study of cloud formations, and forest management, via the assessment of leaf coverage via fisheye images of forest canopies. Other applications are the same as those of other omni-directional cameras, where a wide field of view is beneficial, for instance in mobile robotics or video surveillance.

Fluorescent Lighting

Stephen Lin
Microsoft Research Asia, Beijing Sigma Center,
Beijing, China

Definition

Fluorescent lighting is the illumination of a scene by the fluorescence of phosphor in a gas-discharge lamp.

Background

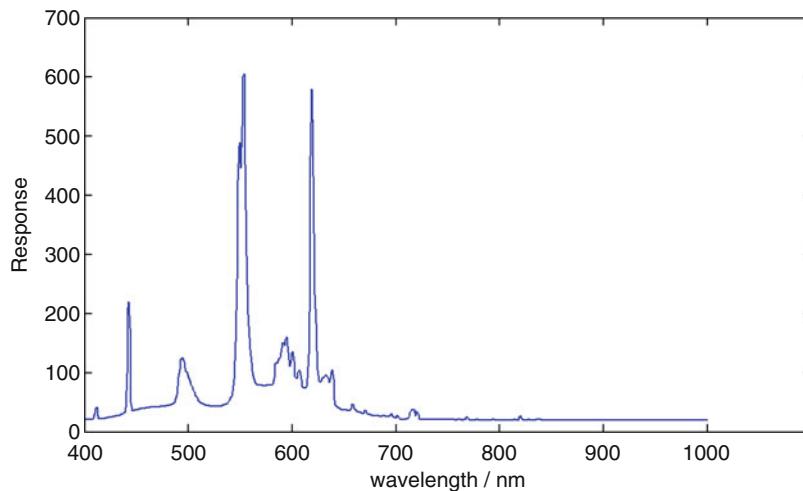

In fluorescent lighting, electrical energy is converted into radiant energy by a physical process in the fluorescent lamp. The lamp consists of a sealed glass tube containing mercury vapor, an inert gas (such as argon) at low pressure, and a phosphor coating on the inside surface. After ionizing the gas, electrical current flows through the gas between electrodes at the ends of the tube. The current excites the mercury atoms, which then emit ultraviolet light. Ultraviolet (UV) light is not visible to the human eye, but is used to cause fluorescence of the phosphor, which absorbs the UV radiation and produces light in the visible range of the color spectrum. Additional details on fluorescent lamp operation can be found in [1].

Fluorescent light has certain properties that distinguish it from other forms of illumination. These include a color spectrum with sharp peaks that correspond to the chemical composition of the phosphor and flicker at twice the frequency of the alternating current. Some computer vision algorithms are designed to take advantage of these properties for particular purposes.

Application

The color spectrum of fluorescent light contains peaks as exemplified in Fig. 1. These peaks originate from energy emission of the phosphor and lie at specific wavelengths according to the phosphor composition. The correspondence of spectrum peaks to particular wavelengths has been utilized in computer vision for calibration of multispectral sensing devices based on dispersive optics [2]. In [2], the spectrum peaks are also used to identify the presence of fluorescent lighting in a scene, as the characteristic peaks are detectable even in light reflected from object surfaces.

Fluorescent lighting also exhibits a regular, high-frequency flicker due to the cycles of electrical current flow in fluorescent lamps. This stro-

Fluorescent Lighting, Fig. 1 A typical color spectrum of fluorescent light

boscopic effect is used in the Mova ContourTM system for markerless motion tracking of human faces [3, 4]. The face is covered with a phosphorescent makeup and then illuminated by the flicker of a blacklight fluorescent lamp, which uses a phosphor that converts the shortwave UV radiation of the mercury vapor to a long-wave UV light that stimulates the makeup. At intervals of the flicker when the fluorescent lighting is off, emission from the phosphorescent makeup is recorded by multiple cameras. The random patterns of makeup formed by a rough applicator sponge are tracked and also triangulated to form 3D models.

Definition

The focal length has different, related, meanings. In optics, the focal length of a lens or optical system is the distance from the center to the point on the optical axis where a bundle of incoming

rays parallel to the optical axis get focused to. In geometric image formation models such as the pinhole model, the focal length usually represents the distance between the center of projection and the image plane.

Background

The concept of focal length stems from the area of optics. The focal length of a lens is generally defined as the distance from the center of the lens to the point where a set of incoming parallel light rays that are parallel to the optical axis get focused. It is thus related to the magnification operated by an optical system.

In computer vision, the image formation process carried out by the optics and electronics of a camera is usually modeled by simple geometric models.

In the following, the thin lens model and the pinhole model are discussed. More general background is given, for example, in [1–3].

Theory

Thin lens model. Consider first a simple “physical” model for a lens, the thin lens model, for the case of a lens whose two outer surfaces are convex and spherical. For simplicity, we assume here that the two spheres have the same radius R . Let n be the index of refraction of the lens material and n_0 that of the surrounding medium (for a vacuum $n_0 = 1$, for air $n_0 \approx 1.0008$).

Incoming rays get bent by the lens, due to the successive refractions in the two surfaces of the lens. For lenses with spherical surfaces, even incoming rays that are parallel to the optical axis do not converge to the same point on the optical axis after these refractions. Rather, they hit the optical axis in a segment; this is known as spherical aberration; see Fig. 1.

Let us now make two common approximations. First, under the thin lens approximation, one assumes that both refractions happen at the same point, on the lens’ plane instead of on

the two spherical surfaces. Second, we make the so-called paraxial approximation by assuming that along the path of the refracted light ray, all angles it forms with the optical axis and the normals of the spherical surfaces are small (leading, e.g., to the approximation $\sin\alpha \approx \alpha$ for such angles). Under these two simplifying assumptions, all incoming rays that are parallel to the optical axis are focused by the lens to a point on the optical axis that is at the following distance from the lens center:

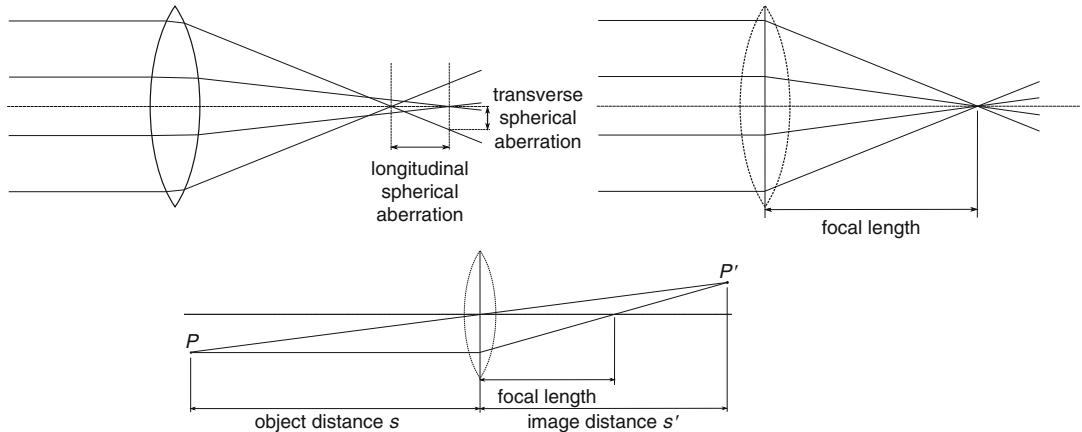

$$f = \frac{R n_0}{2(n - n_0)}.$$

This distance is the focal length of the lens, under the paraxial thin lens approximation. This formula can be generalized to lenses with two spherical surfaces of different radii, in the form of the so-called lensmaker’s equation [4, 5]. Lenses with other bounding shapes than spherical ones exist of course and can be studied similarly [2].

Under the above assumptions, if one wishes to take a sharp picture of a distant object, one would put the image plane at a distance of f from the lens. However, if the object is at a close distance s from the lens, then the light rays emerging from it converge at a distance s' from the lens that is different from f and that is given by [2, 6]:

$$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f}.$$

This classical relationship can be easily derived by considering similar triangles and the following two light rays emitted from a point P at a distance s from the lens; cf. the lower part of Fig. 1. The ray parallel to the optical axis (supposing here it enters the aperture) intersects the optical axis at a distance f from the lens, after being bent by it, as explained above. The ray going through the lens center does not get bent under the thin lens assumption. The two rays thus converge in a point P' at a distance of s' from the lens plane. To get a sharp picture, one would thus put the image plane at distance s' .

F

Focal Length, Fig. 1 *Upper left:* spherical aberration of a lens with two spherical surfaces. *Upper right:* focal length in the paraxial thin lens approximation. *Bottom:* image of

Pinhole model. In the pinhole model and other camera models, the focal length is defined differently than in optics, as the distance between the center of projection and the image plane. As seen above, this is in general different from the focal length of optical systems, even in the very simple case of the paraxial thin lens model thereof. The two definitions coincide however if a camera is focused to infinity and if the center of the thin lens model is considered as center of projection in the pinhole model.

The focal length of the pinhole model is often expressed in the nonmetric unit “number of pixels” (true focal length divided by the density of pixels). For real cameras, the focal length is usually given in millimeters. An often used convention is to characterize a camera by the focal length that an equivalent 35-mm-format camera would have: the focal length of a lens that, if used with a 35-mm-format image area, would have the same field of view as the camera under consideration.

Application

The focal length of the pinhole or other camera models typically used in computer vision is part of the camera’s intrinsic parameters, which can be computed by camera calibration. Camera

an object point P at finite distance from the lens, under the paraxial thin lens model

calibration is an important requirement in most applications where geometric information about the scene or the camera movement is to be determined from images.

The difference between the meaning of the pinhole model’s focal length and that of a true optical system made of lenses (the pinhole model is lens-less) is stressed again here. A consequence of what is explained above is that when calibrating a camera using the pinhole model, that model’s focal length is affected by both a change in focus and zoom of the actual camera [7].

Definition

The four Fresnel equations express the reflection and transmission coefficients of light components whose electric-field vector is either parallel or perpendicular to the plane of incidence.

Background

Based on the theory of electromagnetism, the Fresnel equations express the reflection and transmission coefficients of light that hits an interface between two media. This entry introduces amplitude reflectivity, amplitude transmissivity, intensity reflectivity, and intensity transmissivity.

Theory

Figure 1 illustrates a light ray that hits the interface between two materials, the refractive indices of which are denoted by n_1 and n_2 , respectively. Part of the light is reflected from the interface, while another part penetrates the surface and refracts as it enters the second material. The plane including the surface normal and the incident light ray is called the plane of incidence (POI). The incident light, the reflected light, and the transmitted light are denoted as the subscripts i , r , and t , respectively.

Being an electromagnetic wave, light carries an oscillating electric field. The oscillating field (called E-vector) has amplitude components that are parallel or perpendicular to the POI. These components are denoted by p and s , respectively. Here, p is associated with the term “parallel,” while s is associated with the word “senkrecht,” which means “perpendicular” in German. The incidence, reflection, and transmission angles are defined as θ_1 , θ_1' , and θ_2 , respectively, as illustrated in Fig. 1.

For optically smooth objects, the incidence and reflection angles are equal, $\theta_1 = \theta_1'$, while θ_1 and θ_2 are related by Snell’s law (cf. Sect. 1.5.1 in the 5th edition of Born and Wolf [1], Sect. 4.4.1 in the 4th edition of Hecht [2]):

$$n_1 \sin \theta_1 = n_2 \sin \theta_2. \quad (1)$$

The ratio of the amplitude of the reflected light to that of the incident light is called reflection coefficient (or, amplitude reflectivity), r . The ratio of the amplitude of the transmitted light to that of the incident light is called transmission coefficient (or, amplitude transmissivity), t . These coefficients are generally different for the two E-vector components. The coefficients for the p -component and s -component are derived from the theory of optics as (cf. Sect. 1.5.2 in the 5th edition of Born and Wolf [1], Sect. 4.6.2 in the 4th edition of Hecht [2]):

$$r_p = \frac{\tan(\theta_1 - \theta_2)}{\tan(\theta_1 + \theta_2)} \quad (2)$$

$$r_s = -\frac{\sin(\theta_1 - \theta_2)}{\sin(\theta_1 + \theta_2)} \quad (3)$$

$$t_p = \frac{2 \sin \theta_2 \cos \theta_1}{\sin(\theta_1 + \theta_2) \cos(\theta_1 - \theta_2)} \quad (4)$$

$$t_s = \frac{2 \sin \theta_2 \cos \theta_1}{\sin(\theta_1 + \theta_2)}. \quad (5)$$

These coefficients are plotted in Fig. 2. These equations are called Fresnel equations.

The intensity reflectivity of the p -component R_p and that of the s -component R_s , and the inten-

sity transmissivity of the p -component T_p and that of the s -component T_s are (cf. Sect. 1.5.3 in the 5th edition of Born and Wolf [1]):

$$R_p = \frac{\tan^2(\theta_1 - \theta_2)}{\tan^2(\theta_1 + \theta_2)} \quad (6)$$

$$R_s = -\frac{\sin^2(\theta_1 - \theta_2)}{\sin^2(\theta_1 + \theta_2)} \quad (7)$$

$$T_p = \frac{\sin 2\theta_1 \sin 2\theta_2}{\sin^2(\theta_1 + \theta_2) \cos^2(\theta_1 - \theta_2)} \quad (8)$$

$$T_s = \frac{\sin 2\theta_1 \sin 2\theta_2}{\sin^2(\theta_1 + \theta_2)}. \quad (9)$$

They are plotted in Fig. 3.

From the above equations, $R_p = 0$ can be obtained at a special incidence angle. This angle is referred to as the Brewster angle, θ_B . The Brewster angle is obtained by substituting $\theta_1 + \theta_2 = \pi/2$ (namely, $R_p = 0$) into (Eq. 1), yielding (cf. Sect. 1.5.3 in the 5th edition of Born and Wolf [1]):

$$\tan \theta_B = \frac{n_2}{n_1}. \quad (10)$$

From (Eq. 1) to (Eq. 6)–(Eq. 9), and defining $\theta = \theta_1$, $n = n_2/n_1$, the following can be derived (cf. Appendix A.6 in Miyazaki [3]):

$$R_p = \frac{1 + n^2 - (n^2 + 1/n^2) \sin^2 \theta - 2 \cos \theta \sqrt{n^2 - \sin^2 \theta}}{1 + n^2 - (n^2 + 1/n^2) \sin^2 \theta + 2 \cos \theta \sqrt{n^2 - \sin^2 \theta}} \quad (11)$$

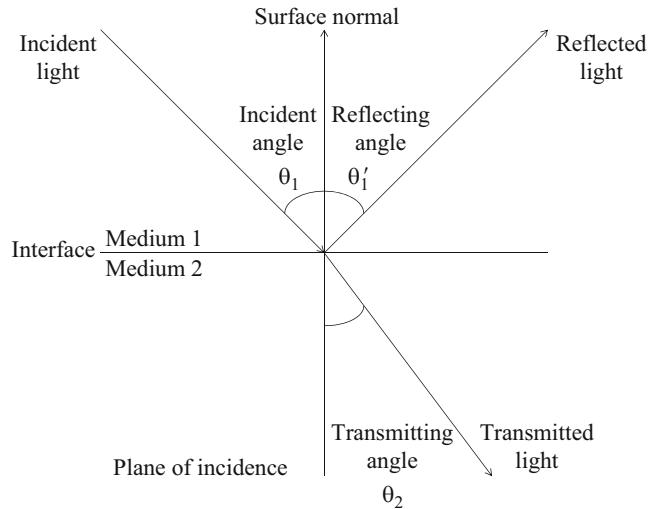

$$R_s = \frac{1 + n^2 - 2 \sin^2 \theta - 2 \cos \theta \sqrt{n^2 - \sin^2 \theta}}{1 + n^2 - 2 \sin^2 \theta + 2 \cos \theta \sqrt{n^2 - \sin^2 \theta}} \quad (12)$$

$$T_p = \frac{4 \cos \theta \sqrt{n^2 - \sin^2 \theta}}{1 + n^2 - (n^2 + 1/n^2) \sin^2 \theta + 2 \cos \theta \sqrt{n^2 - \sin^2 \theta}} \quad (13)$$

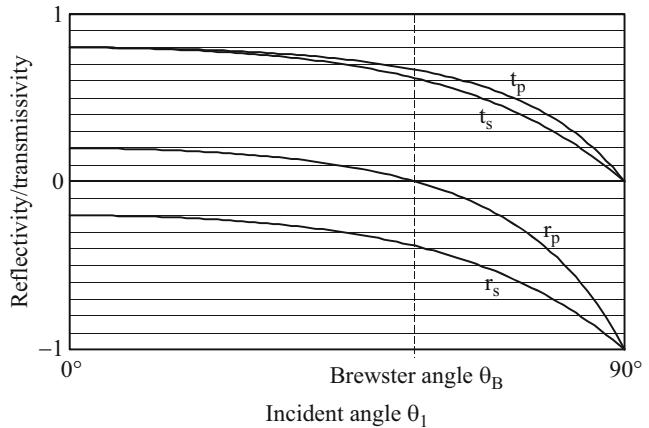

$$T_s = \frac{4 \cos \theta \sqrt{n^2 - \sin^2 \theta}}{1 + n^2 - 2 \sin^2 \theta + 2 \cos \theta \sqrt{n^2 - \sin^2 \theta}}. \quad (14)$$

**Fresnel Equations, Fig. 2**

Amplitude reflectivity of the *p*-component r_p and *s*-component r_s . Amplitude transmissivity of the *p*-component t_p and *s*-component t_s . The plots correspond to the case where $n_2/n_1 = 1.5$

**Fresnel Equations, Fig. 3**

Intensity reflectivity of the *p*-component R_p and *s*-component R_s . Intensity transmissivity of the *p*-component T_p and *s*-component T_s . The plots correspond to the case where $n_2/n_1 = 1.5$

Application

Fresnel equations are mainly used to model and analyze light transmission and specular reflection. Intensity transmissivity ((Eq. 8) and (Eq. 9)) is also used for analyzing diffuse reflection and thermal radiation, since they are caused by radiation from beneath the object surface.

Related Concepts

► [Epipolar Geometry](#)
► [Essential Matrix](#)

Definition

Fundamental matrix is a special 3×3 matrix which captures the geometric relationship between two cameras or between two locations of a single moving camera.

Background

See entry ► “[Epipolar Geometry](#)” for details.

F

Theory

If two points \mathbf{m} and \mathbf{m}' , expressed in pixel image coordinates in the first and second camera, are in correspondence, they must satisfy the following equation

$$\tilde{\mathbf{m}}^T \mathbf{F} \tilde{\mathbf{m}}' = 0, \quad (1)$$

where

$$\mathbf{F} = \mathbf{A}^{-T} \mathbf{E} \mathbf{A}'^{-1}, \quad (2)$$

$$\mathbf{E} = [\mathbf{t}]_{\times} \mathbf{R}, \quad (3)$$

\mathbf{A} and \mathbf{A}' are respectively the intrinsic matrix of the first and second camera, and (\mathbf{R}, \mathbf{t}) is the rigid transformation between the first and second camera. This is a fundamental constraint for two pixels to be in correspondence between two images. The 3×3 matrix \mathbf{F} is called the *fundamental matrix*, and the 3×3 matrix \mathbf{E} is known as the *essential matrix* (see entry ► “[Essential Matrix](#)”).

As can be seen in Eq. (2), the fundamental matrix and the essential matrix are related. If the cameras are calibrated, i.e., if \mathbf{A} and \mathbf{A}' are known, we can use the normalized image coordinates, and the fundamental matrix becomes the essential matrix.

Because $\det \mathbf{E} = 0$, we have $\det \mathbf{F} = 0$. Thus, the fundamental matrix is singular (rank 2). From

Eq. (1), it is also clear that \mathbf{F} is defined up to a scale factor, which depends on the translation magnitude that cannot be determined from image alone. Therefore, a fundamental matrix only has 7 degrees of freedom. Given one pair of corresponding image points, we have one constraint on \mathbf{F} as expressed by Eq. (1). We thus need at least seven or more point correspondences in order to determine the fundamental matrix between two

images. The reader is referred to [1] for various algorithms of determining the fundamental matrix from point correspondences.

Definition

The way a person walks (or runs) combined with their posture is known as gait. Recognizing individuals by their particular gait using automated vision-based algorithms is known as gait recognition.

Gait Recognition: Databases, Representations, and Applications

Yasushi Makihara¹, Mark S. Nixon², and Yasushi Yagi¹

²Department of Electronics and Computer Science, University of Southampton, Southampton, UK

Background

Gait is increasingly used when a person cannot be identified by more conventional means: in the recent high-profile Hatton Gardens robbery in the UK, “Basil” covered his face and other identifying marks, Fig. 1, only to be convicted in part by identification by his gait. Gait has some important advantages over other biometrics. Gait can be observed at a distance when other biometrics are obscured or the resolution is insufficient. It does not require subject cooperation and can be acquired in a noninvasive manner. It is easy to observe and hard to disguise as walking is necessary for human mobility. Gait can be acquired from a temporal sequence of images (e.g., a video) and may be partly acquired even

from a single still image (e.g., a single still image at the double support phase may contain a stride as one of gait information).

Shakespeare made several references to the individuality of gait, e.g., in *The Tempest* [Act 4 Scene 1], Cares observes “*High’st Queen of state, Great Juno comes; I know her by her gait,*” and in Henry IV Part II [Act 2, Scene 3] “*To seem like him: so that, in speech, in gait, in diet, in affections of delight, in military rules, humours of blood, he was the mark and glass, copy and book.*”

The aim of medical research has been to classify the components of gait for the treatment of pathologically abnormal patients (e.g., Parkinson’s disease, degenerative hip disease, and idiopathic normal pressure hydrocephalus). Pathologically normal people usually have standard movement patterns. Those patterns were then used to identify pathologically abnormal patients [11].

The biomechanics literature makes observations concerning identity: “A given person will perform his or her walking pattern in a fairly repeatable and characteristic way, sufficiently unique that it is possible to recognize a person at a distance by their gait” [17].

Psychophysiological studies have shown [4] that humans can recognize friends and the sex of a person solely by their gait with 70–80% accuracy. Moreover, a biological motion study

has shown that several factors such as the sex, the body weight, feeling (e.g., nervous or relaxed), and emotion (e.g., happy or sad) clearly appear in their gaits even if the gaits are displayed as a simple biological motion (i.e., point-light sources attached to the human joints). One early work highlighted the human ability to recognize people by gait, where subject tried identifying six individuals on the basis of their gait under conditions of simulated daylight and simulated dusk and via point-light displays [15]. These and similar studies via human perceptions have inspired the use of gait as a biometric trait via machine perception.

Recently, there has been a rapid growth in the number of surveillance systems, aimed to improve safety and security. These systems are yet to include recognition capabilities, and automatic gait recognition through machine perception (e.g., pattern recognition from CCVT footage) could be a most suitable choice. The primary aim of surveillance videos is to monitor people. However, the video data can be of a low quality (poor resolution, time lapse, etc.), and the subject can conceal the more conventional biometrics. Nevertheless, such video can provide sufficient data for gait recognition technology, and there is already research in using gait biometrics for forensics. Gait recognition could be employed at border crossings or high-throughput environments. Gait contains very

rich information and is considered to be unique. Studies have shown that gait can also be used to reveal a person's identity, gender, age, and emotional state.

Recognition by gait is one of the newest biometrics, since its development only started when computer memory and processing speed became sufficient to process sequences of image data with reasonable performance. The potential for gait recognition is great, and hence there is a vast interest in computer vision and pattern recognition research in extracting and matching gait features [2].

Theory

Overview

A gait biometrics system is based on computer vision. A gait signature is created by extracting images of a walking subject which is then compared to the signatures of known subjects. Figure 2 shows an example of some of the basic stages of a gait recognition system.

Step 1: Data can be acquired using a single or multiple cameras. If data is acquired using a single color/monochrome camera, recognition can be performed using a 2D gait signature shown in stage 4. However, if a range finder (depth camera) or multiple but synchronized cameras are used, we have an option for 3D gait signatures with view invariance.

Step 2: An example of pre-processing stage is foreground/background segmentation using one of a plethora of computer vision techniques from background subtraction to recent deep learning-based semantic segmentation.

Step 3: As human gait is periodic, a gait sequence (sample) can consist of multiple gait cycles. Identifying the most suitable cycle can lead to better recognition rates. Signal processing techniques (e.g., peak detection or maximizing autocorrelation) can be applied to the foreground signal.

Step 4: There are number of approaches to produce a gait signature, some of which are described later. A baseline gait signature was

proposed in [12]. An example of a signature is shown in stage 4.

Step 5: A gait signature can be used directly within a classifier with a selection of classification techniques: k -nearest neighbor, a combination of principal component analysis (PCA) and the subsequent linear discriminant analysis (LDA), primal rank support vector machine (primal RankSVM), and recent deep learning-based classifiers.

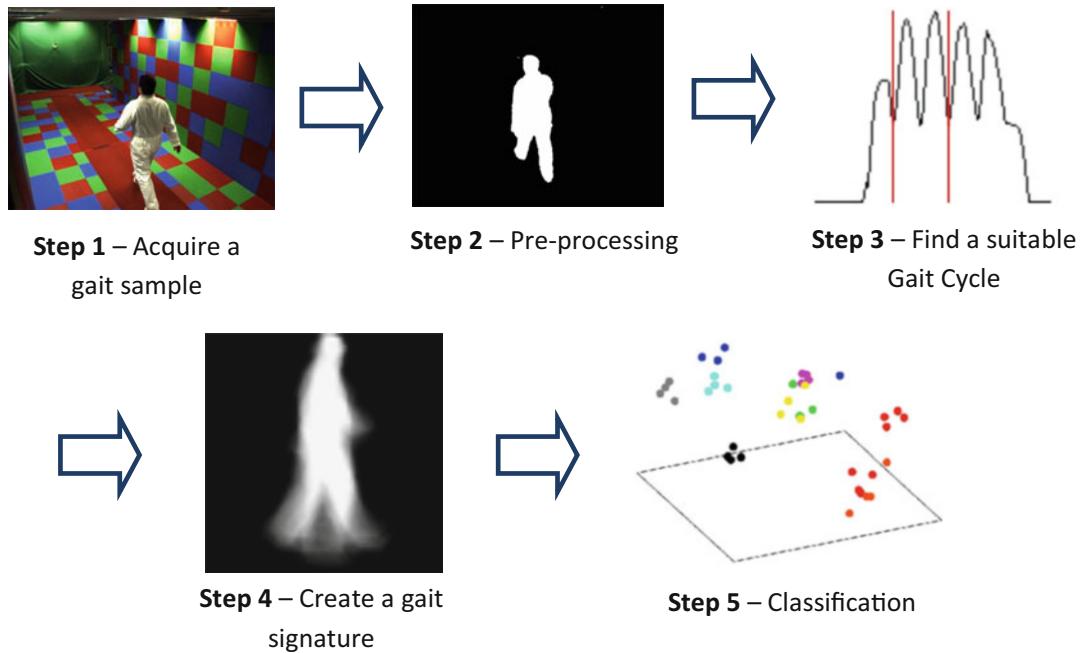

Gait Representation

Gait representations can be divided in two main groups: *model-based* and *model-free (appearance-based)*. Model-based approaches use the human body structure, and model-free methods use the whole motion pattern of the human body. Which approach is adopted depends on the acquisition conditions. Model-free approaches use the input images directly to produce a gait signature without fitting a model. These approaches can perform recognition at lower resolutions which makes them suitable for outdoor applications where a subject can be far from the camera. Model-based approaches require higher resolution images of a subject to be able to fit the model accurately though with relatively high computational cost.

We describe briefly each gait representation below, and more detailed surveys of model-based and model-free approaches are available [2, 9].

Model-Free Approaches

Model-free approaches derive the human silhouette by separating the moving object from the background. The subject can then be recognized by measurements that reflect the shape and/or movement. The simplest approach is to directly compute the dissimilarity (e.g., Euclidean, cosine, or Tanimoto distance) between two silhouette sequences (i.e., a probe and a gallery) in conjunction with phase synchronization by frame shift, which is called a baseline algorithm [12] in the gait recognition community. Another simple approach is a silhouette averaged over a complete gait cycle which is also known as gait energy image (GEI) [6] (see Fig. 3). Motion silhouette image (MSI) is a similar representation

Gait Recognition: Databases, Representations, and Applications, Fig. 2 General steps of a gait recognition system

to the GEI. The value of each pixel is computed as a function of motion in the temporal dimension over all silhouettes that are part of a single gait cycle (see Fig. 3). Both the GEI and MSI are easy to compute but are vulnerable to appearance changes of the human silhouette. A frieze pattern represents the information contained in a gait sequence by horizontal and vertical projections of the silhouettes. As its extension shape variation-based (SVB) frieze patterns use key frame subtraction in order to mitigate the effects of appearance changes on the silhouette (see Fig. 3). The gait entropy image (GEI) is another example of a compact gait representation (signature). GEI is computed by calculating the Shannon entropy for each pixel in a silhouette image sequence. The gait signatures for the approaches shown in Fig. 3 are usually used directly for classification. There are additional ways of extracting gait signatures without using a model.

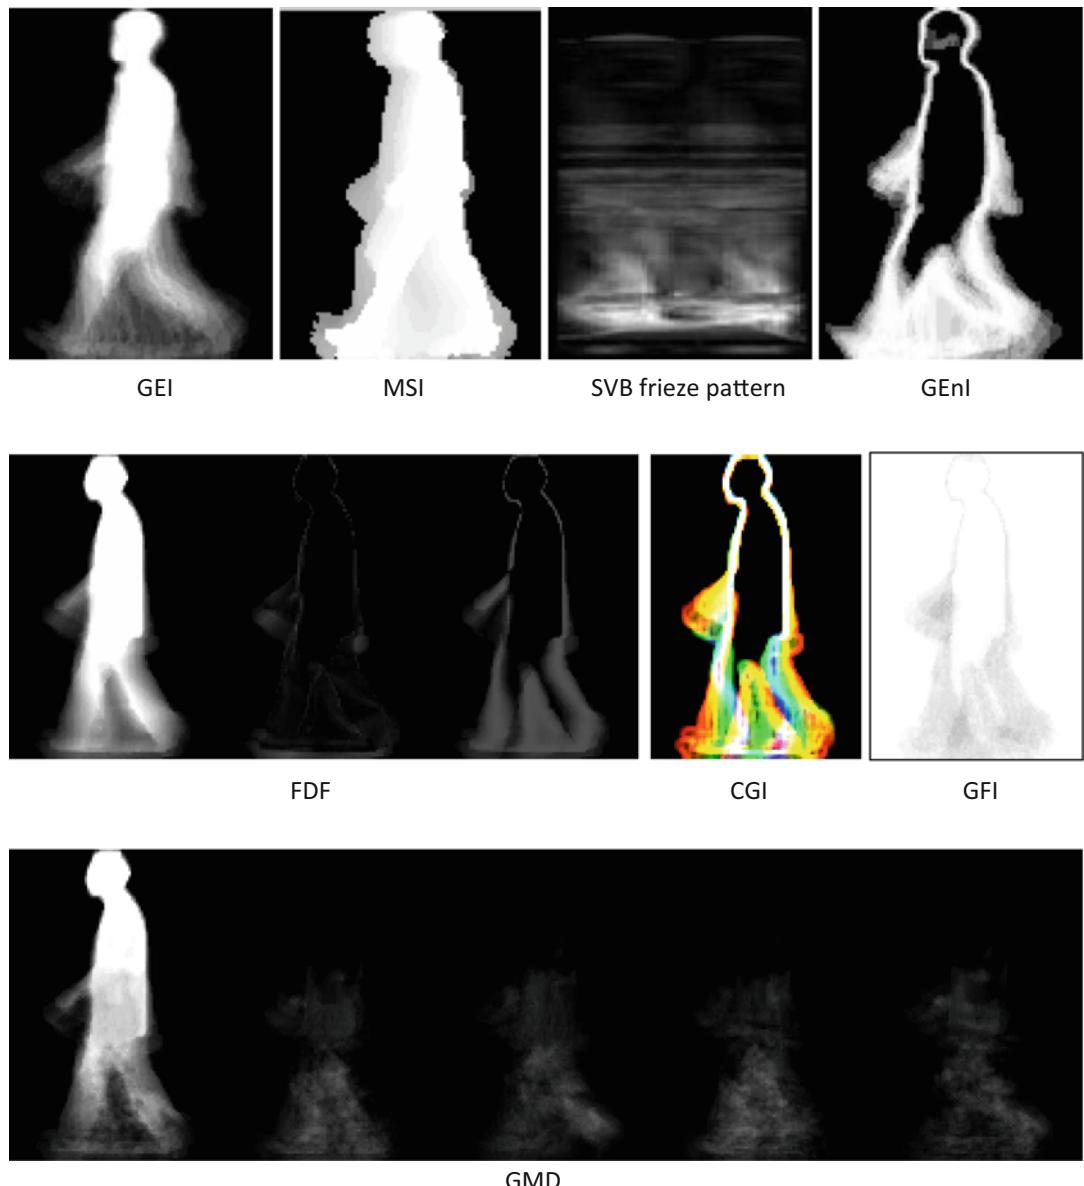

While many approaches use conventional RGB or grayscale images, we can also employ a depth image captured by a commercial and

inexpensive sensor (e.g., Microsoft Kinect™) which increases information and eases foreground segmentation. Some depth-based or three-dimensional volumetric representation-based approaches to the model-free analysis are introduced.

Model-Based Approaches

The advantages of the previous silhouette approaches are computational efficiency and simplicity. In contrast, model-based approaches have greater invariant properties and can handle better occlusion, noise, scale, and rotation [3].

Model-based approaches incorporate knowledge of the shape and dynamics of the human body into the extraction process. These approaches extract features that fit a physical model of the human body. A gait model consists of shapes of various body parts and how those shapes move relative to each other (motion model). The shape model for a human subject uses ellipses to describe the head and the torso, quadrilaterals to describe the limbs, and rectangles to describe the feet. Alternatively

Gait Recognition: Databases, Representations, and Applications, Fig. 3 Examples of model-free gait signatures.
(Reprinted with permission from [9] copyright 2015, Wiley)

arbitrary shapes could be used to describe the edges of the body parts. The motion model describes the dynamics of the motion of the different body parts. Using a model ensures that only image data corresponding to allowable human shape and motion is extracted, reducing the effect of noise. The models can be two or three dimensional. Most of the current models

are two dimensional but deliver good results on databases of more than 100 subjects.

There have been moves toward developing 3D gait models. Guoying et al. [5] use video sequences from multiple cameras to construct 3D human models. The motion is tracked by applying a local optimization algorithm. The length of key segments is extracted as static parameters,

and the motion trajectories of lower limbs are used as dynamic features. Linear time normalization is used for matching and recognition. 3D approaches are robust to changes in viewpoint and have much potential. However current experiments are limited to small databases by high computational requirements.

Gait depends on many parameters (joint angles and body segment size) which leads to complex models with many free parameters. Finding the best fit model leads to searching a high-dimensional parameter space. Therefore, there is a trade-off between the accuracy of the model (complexity) and computational cost. Models are often simplified based on assumptions, e.g., a constant walking speed. However, as computing power increases the problems, arising of high complexity can be mitigated. Also, recent deep learning-based pose estimators such as OpenPose significantly reduce computation time and have started to be used in model-based gait analysis.

Scenario-Dependent Choice of Gait Representation

We finally discuss the suitability of the approaches described above in the context of the two application scenarios: access control and surveillance. In the access control scenario, since we can design the environment as we have already discussed in the section of databases, it is possible to capture a subject with relatively high image resolution (i.e., capturing at a close distance). Consequently, not only model-free approaches but also model-based approaches are suitable. Moreover, it is allowed to use a depth camera in this scenario; recent depth-based gait features are promising since they have possibilities for higher accuracy due to richer information than two-dimensional silhouette-based approaches such as GEI.

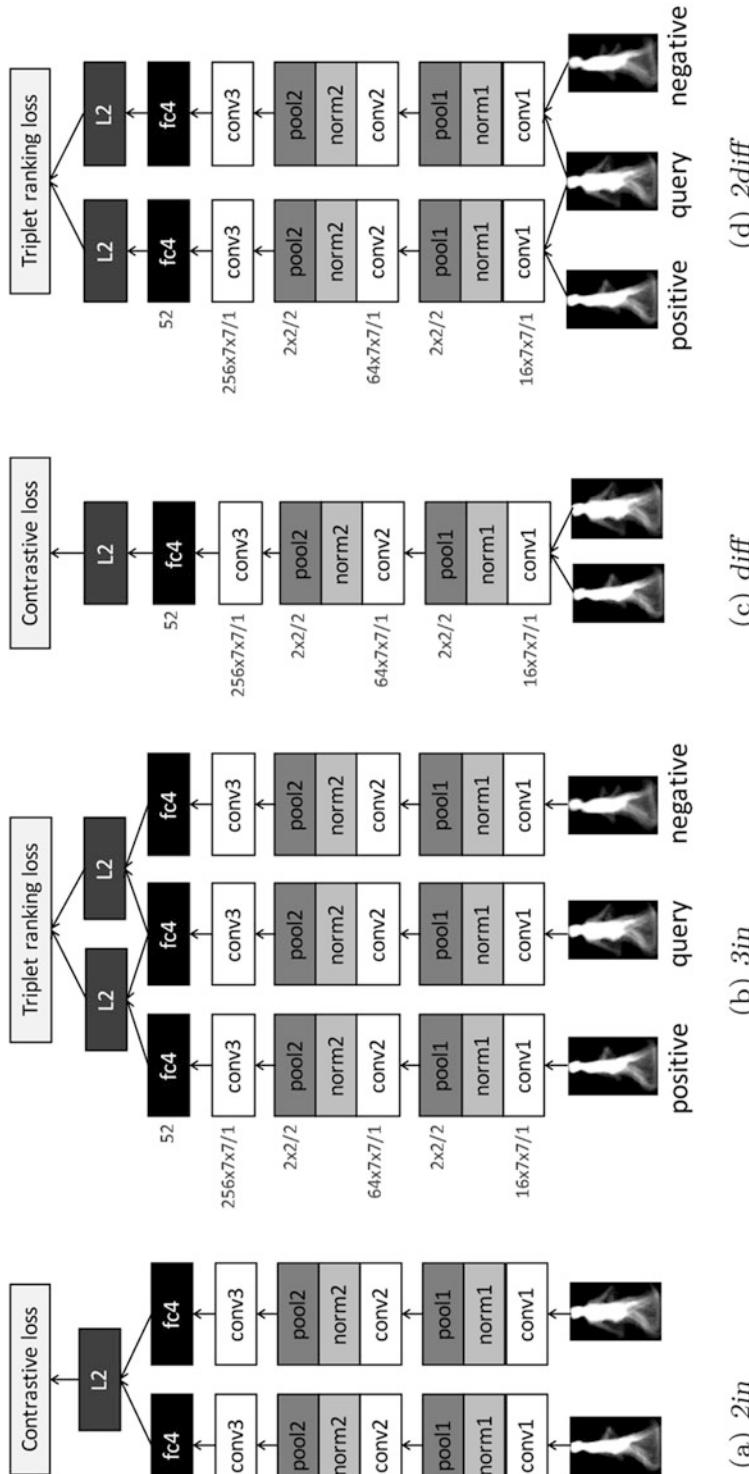

On the other hand, in surveillance or criminal investigation scenarios, the suitability of approaches is heavily dependent on the captured images. For example, when the spatial resolution of captured subjects is relatively high and where clothing conditions are different between a matching pair, the model-based approaches are

suitable due to invariance to clothing. In addition, when observation views are different, the 3D model-based approaches are useful. In contrast, when the spatial resolution is low, model-free approaches can be more suitable than model-based approaches. Although the model-free approaches are much affected by the individual factors such as view and clothing, SBV frieze pattern can mitigate the effect of the clothing variation to some extent.

Classification

At the early stage of gait recognition research, gait silhouette sequences or pose sequences were directly used for matching, and hence matching algorithms for time series were employed, for example, dynamic time warping, hidden Markov model, and parametric eigenspace method. Thereafter, gait representations which aggregate temporal information such as averaged silhouette or GEI got more popular, and then more standard image-based classification algorithms were introduced. One of the most popular ways is to apply PCA to reduce dimensions and then apply LDA to increase discrimination capability. Moreover, a plethora of machine learning techniques were employed, for example, subspace method, discriminant analysis with tensor representation, random subspace method, joint subspace analysis, SVM, multi-layer perceptron, etc.

Recently, similar to the other computer vision fields, gait recognition researchers started to employ deep learning-based approaches, more specifically convolutional neural networks (CNNs). The simplest one is GEINet [14] which outputs probabilities of individual training subjects given GEI as an input. Wu et al. [18] exploit a pair of input images and cast a gait recognition problem as a two-class classification problem into the same or different subject pairs, which is also beneficial in terms of increasing the number of training sample. Takemura et al. [16] designed input/output architectures (e.g., a triplet of input images and a triplet loss function), which are, respectively, suitable for verification/identification scenarios under small/large view variations (see Fig. 4). Yu et al.

Gait Recognition: Databases, Representations, and Applications, Fig. 4 Network architectures of CNN-based cross-view gait recognition, where conv, norm, pool, fc, and L2 denote convolution layer, normalization layer, pooling layer, fully connected layer, and L2 norm/distance of one/two outputs from the previous layer, respectively. Numbers written on the left-hand side of the conv, pool, and fc boxes indicate $(\#kernel) \times (\text{kernel size: width} \times \text{height}) / (\text{stride})$, $(\#outputnode)$, and $(\#outputnode)$, respectively. Copyright 2017 IEEE. (Reprinted, with permission from [16])

[20] introduced generative adversarial network (GAN) to generate a canonical view gait feature from another view gait feature. Most of the CNN-based approaches to gait recognition aim at increasing robustness against view variation, and they achieved significantly higher accuracy than conventional machine learning-based approaches such as a view transformation model and a support vector regression.

Databases

A database can be collected for various purposes. Primary concerns include uniqueness and practicality. A database should contain enough subjects/samples to allow for an estimate of inter- and intra-subject variation for statistically reliable performance evaluation and for effective training of classifiers. The current databases contain smaller number of subjects compared to databases used to evaluate performance of other biometrics (e.g., face, fingerprint). However, there are databases that include covariate factors and application potential. Some of the best-known databases and their characteristics are shown in Table 1.

While gait databases at the early stage of gait recognition research in the 1990s contained less than 100 subjects, those in the middle of the 2000s contained more than 100 subjects. For example, SOTON Large Database was the first gait database to contain over 100 subjects. USF HumanID is one of the most frequently used gait databases since it contains over 100 subjects as well as a variety of covariates: view, surface, shoes, bag, and time elapse, although each covariate has at most two variations (e.g., concrete and grass for surface covariate, with and without bag for bag covariate). CASIA B is a frequently used gait database since it contains large view variations from front view (0 deg) to rear view (180 deg) with 18-degree interval.

Some of gait databases in 2010s contain over thousand subjects, and the most recent databases contain over ten thousand subjects. OU-ISIR LP-Age contains the largest number of subjects, 63,846, in the world, as well as age and gender

labels, and it is useful for studying gait-based age and gender estimation. OU-ISIR LP-Bag also contains over 60,000 subjects with carrying status variation in the wild, where each subject has their own carried objects and can be used to study gait recognition variation with carried loads. OU-ISIR MVLP contains over 10,000 subjects captured from 14 views, that is, 7 views from frontal view to side view at 15-deg interval and the other 7 views from back view to side view at 15-deg interval. It is naturally useful for studying view-invariant gait recognition.

In summary, challenging aspects of individual gait databases roughly fall into three: subject diversity, individual factors (e.g., clothing, speed, carrying status), and environmental or scene factors (e.g., view directions and illumination changes in outdoor). Moreover, the importance of these challenging aspects is highly dependent on application scenarios. For example, in an access control scenario, the environment is usually fixed and even appropriately designed for better authentication (e.g., indoor environment such as a corridor in front of door, relatively close observation distance, multimodal information source such as an RGB camera and a depth camera, multimodal biometric cues such as face, ear, the height, as well as gait are acceptable). Moreover, the individual factors are controlled to some extent since a user (client) wants to be successfully authenticated (i.e., cooperative). Consequently, the subject diversity is the most important aspect in the access control scenario, and hence SOTON Multimodal, OU-ISIR LP, and TUM-GAID are suitable for evaluating the access control scenario.

On the other hand, in a surveillance or criminal investigation scenario, the environment is usually unfixed, and a subject such as a perpetrator or a suspect is uncooperative. Both the individual and environmental factors are therefore important as well as the subject diversity. SOTON Large Database and USF HumanID provide a variety of such individual and environmental factors, and hence they are suitable exploratory factor analysis in the surveillance and criminal investigation scenario. However, the variation of each factor is limited in SOTON Large Database and

Gait Recognition: Databases, Representations, and Applications. Table 1 Details of some of the well-known gait databases

| Name | Subjects | Sequences | Covariates | Viewpoints | Indoor(I)/Outdoor(O) |
|----------------------|----------|-----------|------------|------------|----------------------|

USF HumanID; other databases are still useful when focusing on each factor (e.g., CASIA B and OU-ISIR MVLP for view variations, OU-ISIR Treadmill A for speed variations, OU-ISIR Treadmill B for clothing variation, OU-ISIR LP-Bag for carrying status variation, SOTON Temporal for time-lapse variations, and WOSG for environmental variations).

Experimental Results

We introduce experimental results of cross-view gait recognition on OU-MVLP reported in [16] since cross-view gait recognition is one of the most challenging topics which many gait recognition researchers have paid efforts for a long time. In addition, OU-MVLP is one of the most

challenging gait databases for cross-view gait recognition, which contains over 10,000 subjects from 14 views. In fact, recent deep learning-based approaches to gait recognition require more and more training data in order to perform well; large-scale training data in OU-MVLP is beneficial to make the most of the algorithm's performance. In addition to the training aspect, the large-scale test samples enable statistically reliable performance evaluation of gait recognition. The data set was divided into two disjoint sets: training and test sets which contain approx. 5,000 subjects, respectively. In the experiments, the most popular gait representation, GEI, was used as an input. We show the results for eight benchmarks: direct matching (DM) as a baseline; LDA; view transformation model (VTM) [10]; GEINet [14]; low-level feature at bottom layer (LB) and

middle-level feature at top layer (MT) [18]; four network architectures 2in, 3in, diff, and 2diff; and its two combinations: 2in + diff and 2in + 2diff [16].

Table 2 shows gait recognition accuracies in verification scenario and identification scenarios. In the verification scenario (one-to-one matching), given a pair of gait samples, the system tries to judge whether they originate from the same subject pair or different subject pair. The typical performance criteria are equal error rate (EER) of false acceptance rate (FAR) of different subject pairs and false rejection rate (FRR) of the same subject pairs. On the other hand, in the identification scenario aka one-to-many matching, given a gait sample, the system tries to find the same subject from a gallery set. The typical performance criterion is rank-n identification rate, that is, a ratio that the same subject is included in the top-n gallery list. It turns out that state-of-the-art gait recognition achieves almost 90% rank-1 identification rate for the gallery size of approx. 5,000 and less than 1% EER for the same-view case (i.e., angular difference is zero). On the other hand, gait recognition accuracies decrease as the angular difference gets large, e.g., 55.0%, 33.0%, and 17.3% rank-1 identification rates for 30-deg,

60-deg, and 90-deg angular differences for 2in+2diff.

Applications

Gait recognition research is currently under transition from an evaluation stage to an application stage. The potential for gait recognition is great, since the complete unobtrusiveness without any subject cooperation or contact for data acquisition makes gait particularly attractive for identification purposes. It could be used in applications including forensics, security, immigration, and surveillance.

Many surveillance systems capture only a low resolution video at varying lighting conditions, and gait recognition might be the only plausible choice for automatic recognition. A bank robber may wear a mask so you cannot see his face, wear gloves so you cannot get fingerprints, and wear a hat so you cannot get DNA evidence – but they have to walk or run into the bank, and they could be identified from their gait.

Gait recognition has been used as evidence for conviction in some criminal cases. One forensic study has already used gait biometrics to provide evidence for identification [1]. In 2004, a

perpetrator robbed a bank in Denmark. The Institute of Forensic Medicine in Copenhagen was contacted by the police to perform gait analysis, as they thought the perpetrator had a unique gait. The institute instructed the police to establish a covert recording of the suspect from the same angles as the surveillance recordings for comparison. The gait analysis revealed several characteristic matches between the perpetrator and the suspect. For example, both the perpetrator (to the left) and the suspect showed inverted left ankle (white arrow) during left leg's stance phase and markedly outward rotated feet (see Fig. 5). The suspect was convicted of robbery, and the court found that gait analysis is a very valuable tool [8]. Criminal investigations might need the analysis of running, and that link has been investigated [19].

Moreover, a gait verification system for this criminal investigation has been developed in [7]. The system is equipped with a graphical user interface (Fig. 6) so as that a criminal investigator, who may not be a researcher on gait recognition, can obtain gait-based person verification results through appropriate manual interventions: target specification, interactive silhouette extraction,

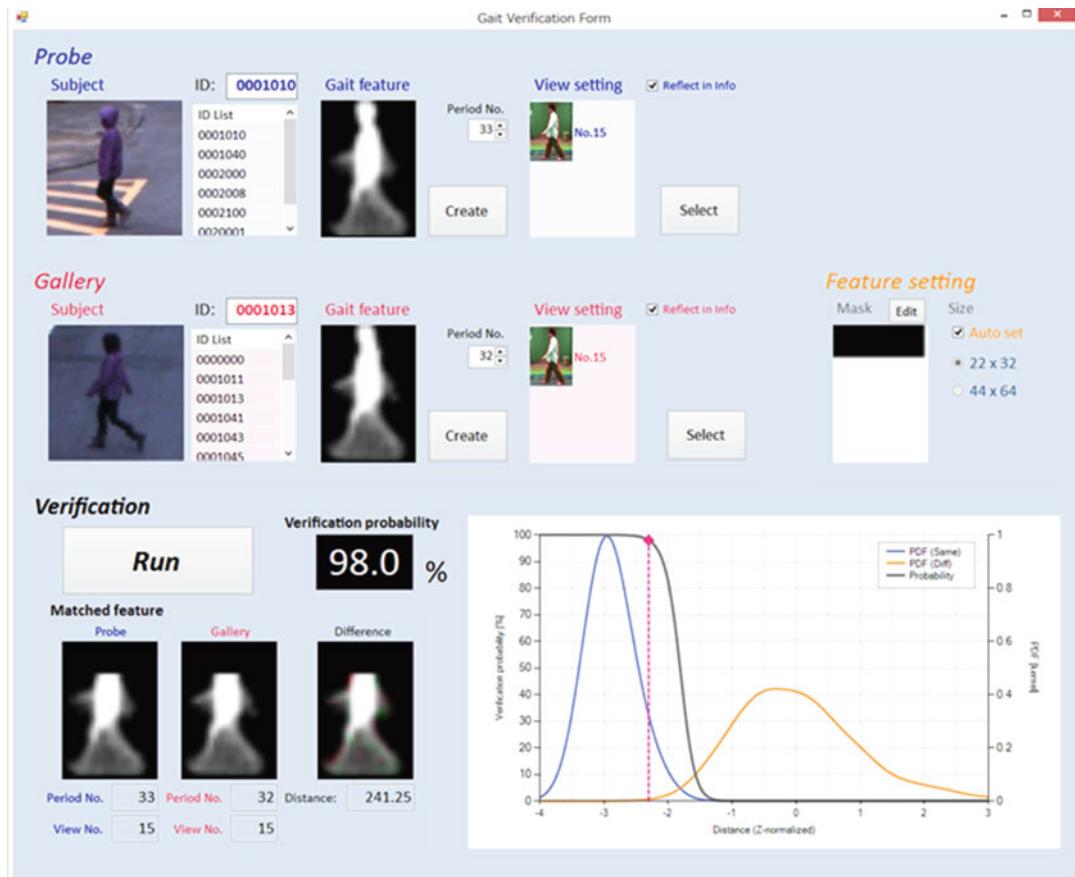

and undesired region masking (e.g., helmet) if necessary. The system outputs a posterior distribution that a pair of walking image sequences are generated from the same person based on circumstance-dependent probability distribution functions of dissimilarity scores from the same person's pairs and different persons' pairs. The system is now under a trial use phase by the National Research Institute of Police Science in Japan.

One system called the biometric tunnel [13] led to the first live demonstration of gait as a biometric and could suggest a possible route for future deployment of the technology. The left side of Fig. 7 depicts the system. It consists of a simple corridor with 12 synchronized and fixed cameras. The subjects are asked to walk through the middle, and the lighting and background are controlled to facilitate analysis. The right side of Fig. 7 shows the details of the arrangement. The system is designed with high throughput in mind.

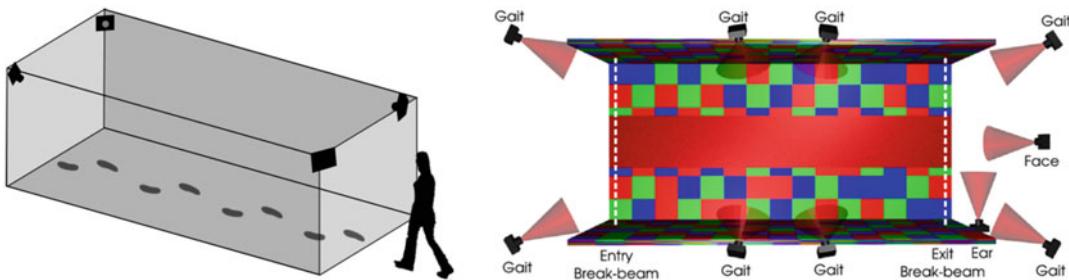

Recently, the first commercial software of gait recognition has been released by Watrix in Oct. 2018, which was incubated by the Institute of Automation, Chinese Academy of Sciences (CASIA). According to their website, once a user

Gait Recognition: Databases, Representations, and Applications, Fig. 5
Bank robbery

Gait Recognition: Databases, Representations, and Applications, Fig. 6 Gait verification system

Gait Recognition: Databases, Representations, and Applications, Fig. 7 The biometric tunnel

offers the software videos to be inspected and an example video of a target, then the software can complete a search through 1 hour of video in 10 min with 94% accuracy. The software has been piloted in the public security system for more than 1,000 h, being used for detection in more than 20 cases so far.

Open Problems

Robustness of gait recognition against each covariate such as view, walking speed, clothes, carrying status, etc. has increased thanks to a series of gait recognition studies. One of the open problems is robustness against multiple

covariates at the same time, e.g., matching of gaits with different walking speeds as well as from different viewing angles. In addition, since most of the current gait databases are collected under relatively controlled environments (e.g., a single walking person without occlusions under a simple background), it is also necessary to investigate gait recognition in more realistic situations (e.g., cluttered backgrounds, occlusions by other people). Moreover, because recent deep learning-based approaches require more and more training data to achieve high accuracies, it is also an important issue how to construct such large-scale gait databases, which preferably include multiple covariates conditions as well as are collected in realistic situations.

Definition

Gamut Mapping refers to the process of translating colors in one device's color space to that of another. This process is performed on colors in images and video so as to create a rendition of a source image (typically in a capture device's color space) in an output device's color space while meeting several rendering intents: absolute and relative colorimetric fidelity, perceptual accuracy, and the problem of saturation – each of which trades off one color property at the expense of another.

Background

Different media – cameras, printers, displays – have different achievable gamuts, depending on the manner in which color is either captured or reproduced. This typically means that one medium can have colors that may not be reproducible on another. The color gamut of a device may be displayed as a volume of achievable colors, and typically this is shown in a CIELAB or CIELUV (see Fig. 1), or as a projection on the CIE xy or u“v” chromaticity diagram (see Fig. 2). The three-dimensional representation is far more informative than the two-dimensional projection as it captures the nuances of the color space, specifically around the luminance of the primaries and the associated black and white levels of the medium. The two-dimensional projection requires multiple luminance slices to be plotted for it to be comparably informative.

Theory

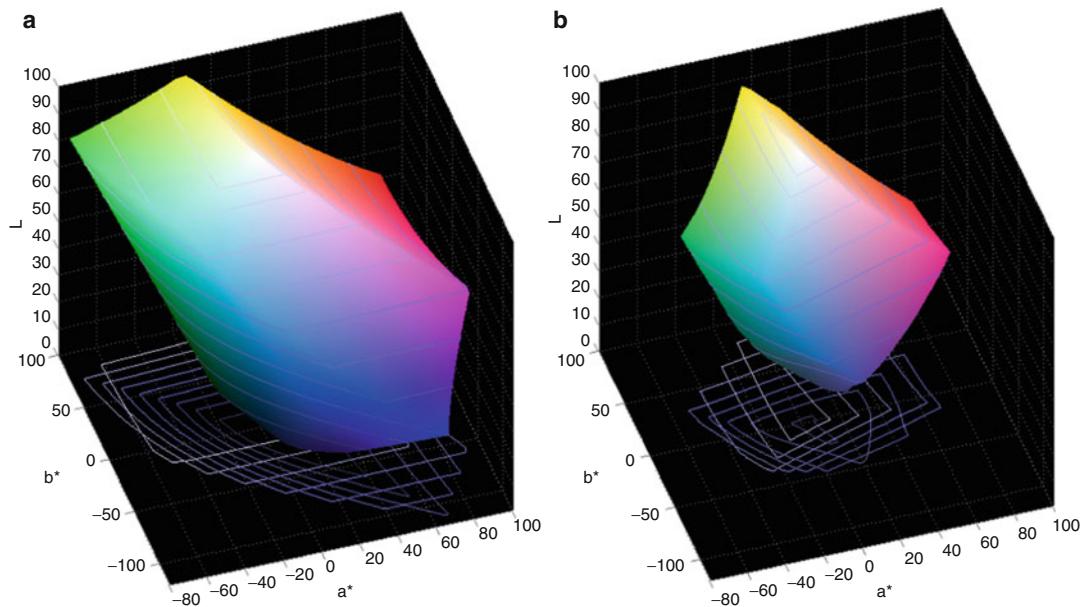

The challenge of gamut mapping may be described by means of an example of a case where an image stored within an sRGB color space needs to be reproduced in a print medium with SWOP colors: Fig. 3 shows two color gamuts – the sRGB color gamut (wireframe) almost enclosing a SWOP color space (solid). It is interesting to note that there are regions of the color space that are represented by the sRGB

color space but are not represented by the SWOP color space and vice versa. In performing such a mapping, the following challenges arise:

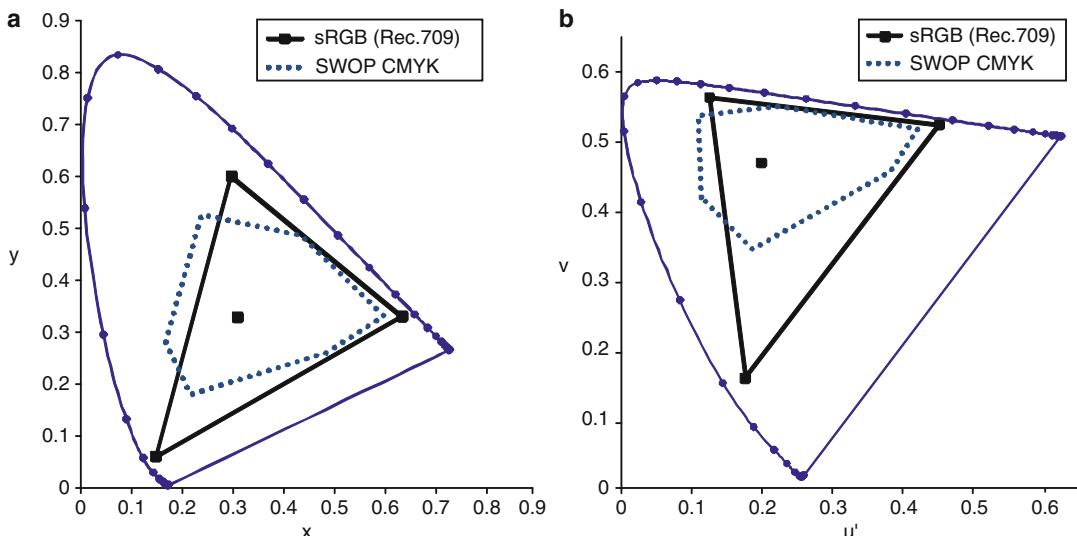

- How should black and white be mapped?
- Should colors in the intersection of the two gamut volumes be reproduced as such, or should they be compressed?
- How should input colors that are outside the output color space be reproduced?
- What must be done with colors that can be created with the output color space but cannot be represented in the input color space?

The objective of gamut mapping algorithms is to translate colors in the input color space to achievable colors in the output color space so as to meet certain key criteria that are referred to as rendering intents (per ICC guidelines [3]):

- *ICC-absolute colorimetric intent*: “Chromatically adapted tristimulus values of in-gamut colors are unchanged.” This intent preserves the relationship among in-gamut colors at the expense of out-of-gamut colors while maintaining accuracy. Again, nothing is specifically stated about the mapping of out-of-gamut colors.
- *Media-relative colorimetric intent*: “The use of media-relative colorimetry enables colour reproductions to be defined which maintain highlight detail, while keeping the medium white, even when the original and reproduction media differ in colour.” This intent also preserves the relationship between in-gamut colors at the expense of out-of-gamut colors while maintaining accuracy. Nothing is specifically stated about the mapping of out-of-gamut colors.
- *Perceptual intent*: “The exact gamut mapping of the perceptual intent is vendor specific and is useful for general reproduction of pictorial images, typically includes tone scale adjustments to map the dynamic range of one medium to that of another, and gamut warping to deal with gamut mismatches.” This objective of this intent is clear from the definition, and typically involves proprietary algorithms

Gamut Mapping, Fig. 2 Two-dimensional renderings of color gamuts of a device with sRGB color space and one with SWOP color space in (a) CIE xy chromaticity diagram, (b) CIE $u''v''$ chromaticity diagram

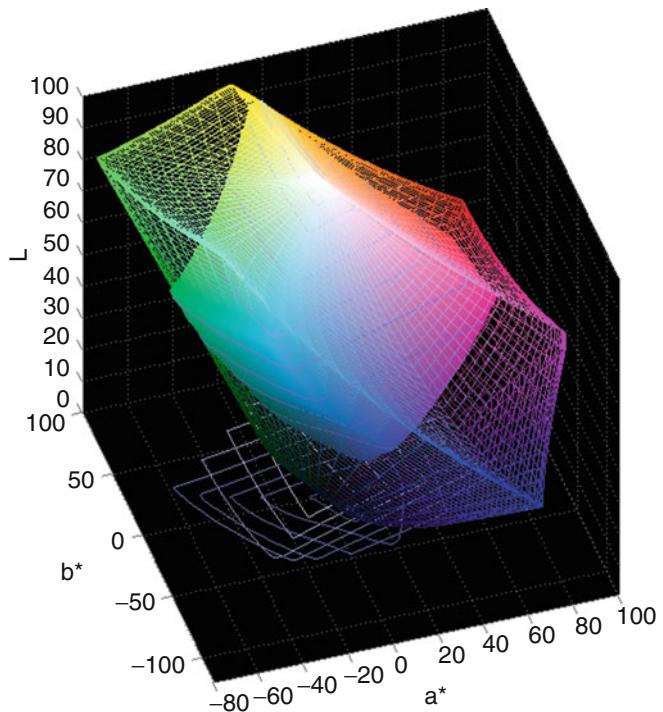

to perform the gamut mapping for general reproduction of images, particularly pictorial or photographic-type images.

- *Saturation intent:* “The exact gamut mapping of the saturation intent is vendor specific and involves compromises such as trading off

preservation of hue in order to preserve the vividness of pure colours.” This objective of this intent is also clear from the definition, and also typically involves proprietary algorithms to perform the gamut mapping for images and video that contains charts and diagrams.

Gamut Mapping, Fig. 3

Three-dimensional renderings of color gamuts of an sRGB color space (wireframe) and a SWOP color space (solid)

Most gamut mapping algorithms are performed in either the device space or in a perceptual space: the choice of which space to use is highly application and preference dependent. For the sake of simplicity, in this article, we will restrict ourselves to a CIELAB space along with its perceptual correlates: CIELAB Lightness, Chroma, and Hue. However it should be noted that gamut mapping algorithms could be defined in a variety of spaces, making use of each space's general perceptual correlates of hue, chroma/colorfulness, and lightness/brightness.

Typical color gamuts are shown in Fig. 3 and particular Hue slices for red-green, and yellow-blue are shown in Fig. 4. That is, these slices each show a vertical slice through a color solid, each at a particular position around the surrounding circle we consider to be Hue – i.e., is a color red, is it green, etc. The Chroma increases from zero in the center of the solid to a maximum value on the outside of the solid, and Lightness (the correlate of brightness) goes from minimum (black) at the bottom to maximum (white) at the top. To ease illustration, Hue slices will be abstracted using

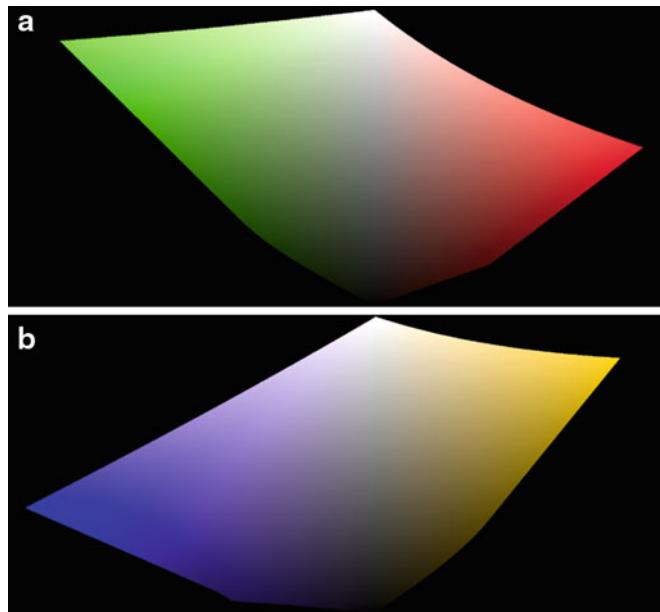

figures like those in Fig. 5 composed of highly simplified shapes (triangles in this case) – real-world color gamuts can be far more complicated and not included in these illustrations. It is to be noted that the point $L_{M\text{-out}}$ is often referred to as the *cusp* for that Hue slice.

Multiple variations of different scenarios of Hue slices are shown in Fig. 6 to illustrate the variety of problems one might encounter with gamut mapping even when the shape of the gamut is simplified using triangles. These four cases show the input gamut to be larger (in the Lightness scale) than the output gamut, but it is straightforward to envision the opposite set of cases (swapping input and output color spaces) to be possible as well for different gamut pairs. It is also straightforward to envision gamut pairs for which the Lightness scales match. Clearly, even for one gamut pair, one chosen approach for “mapping” the gamuts may work for most Hue slices, but might fail for a different Hue slice.

In general, gamut mapping algorithms may be classified based on which of four approaches is taken:

- Gamut Clipping Algorithms
- Gamut Compression/Expansion Algorithms
- Spatial Gamut Mapping Algorithms
- Memory-Color-Aware Gamut Mapping Algorithms

Gamut Clipping

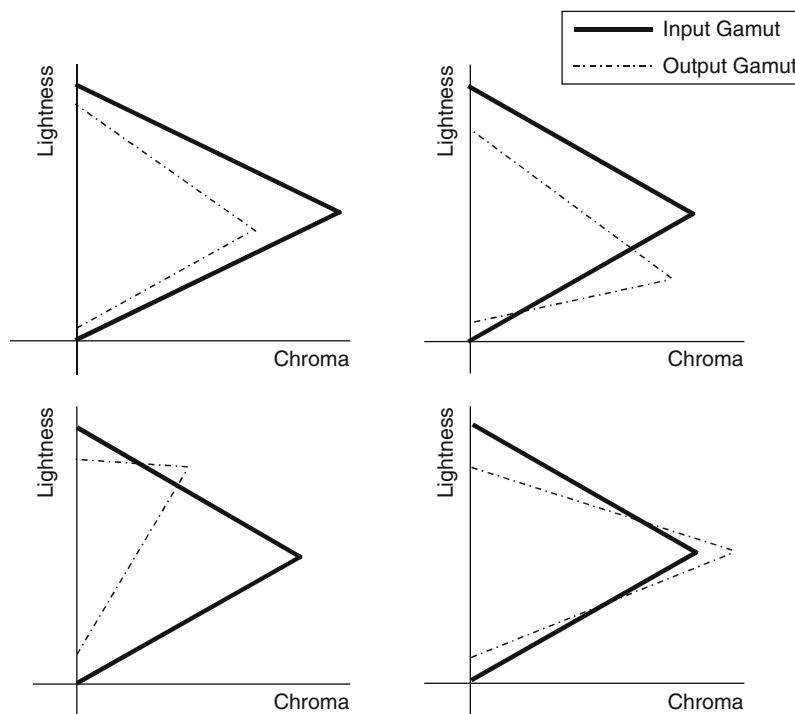

Gamut clipping approaches may be described as those that address those colors that are outside the gamut of the output color space. Some of the most

common approaches include those that are *nearest neighbor* and those that are *Hue-preserving*. Nearest-neighbor approaches map the color in the input gamut's color space to a color in the output gamut's color space that is nearest as defined by one of the following criteria:

- Nearest color in the output color space along a vector of constant Lightness: Mapping along the vector of constant Lightness tends to

Gamut Mapping, Fig. 6

Four variations of Hue slices showing challenges that gamut mapping algorithms have to address. The complement of these approaches also exist wherein the input and output gamuts are reversed in these pictures

address the mapping issue as a simple one-dimensional problem of changing only the Chroma of a color. This is shown as approach (a) in Fig. 7, with the mapping occurring along the dashed blue lines.

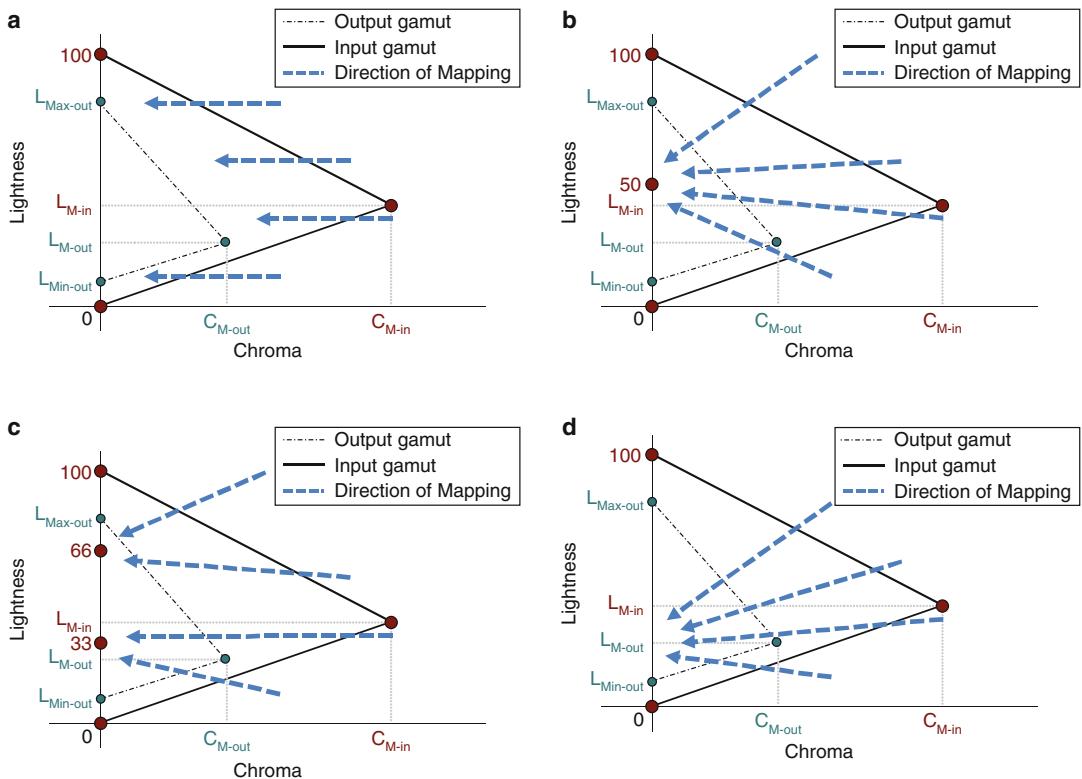

- Nearest color in the output color space along a vector to the point in the Hue slice with a Lightness of 50. Mapping along the vector pointing to a Lightness of 50 has the advantage that both Lightness and Chroma are adjusted, which helps maintain contrast between colors. This is shown as approach (b) in Fig. 7. This approach is sometimes further divided as a mapping to a different Lightness value for colors above and below the *cusp* of the input gamut, shown as approach (c) in Fig. 7.
- Nearest color in the output color space along a vector to the point in the Hue slice with a Lightness of the *cusp* ($L_{M\text{-out}}$ in Fig. 5): Mapping to the cusp has the advantage of maintaining the general trend of the Lightness in the input and output color spaces. This is shown as approach (d) in Fig. 7.
- Nearest color in the output color space based on a color difference measure: If one were to use the CIELAB difference measure ΔE_{ab}^* ,

which is approximately perceptually uniform, a color would be mapped to an output color that is perceptually closest to the input color as defined by the ΔE_{ab}^* measure. A slightly different variant of this approach would be to use a different color difference measure, such as ΔE_94 , or ΔE_{00}^* (CIEDE2000), or some other preferred color difference measure. *It is to be noted that this can result in shifts in the Hue descriptor for a color.*

Gamut Compression/Expansion

One of the challenges that arises with gamut clipping is that this invariably results in loss of detail in images when multiple input colors map to the same output color, especially when large differences in color gamuts are to be overcome. If this behavior is not desired, gamut compression (or alternatively expansion) is typically performed. The approaches for gamut compression/expansion may be classified as belonging to one of three classes:

- *Lightness compression/expansion* approaches operate only along the Lightness/luminance axis when the largest difference is along

Gamut Mapping, Fig. 7 Different directions for mapping colors showing the (a) mapping along lines of constant Lightness, (b) mapping along lines of fixed Light-

ness, (c) mapping along lines of varying Lightness with a simple example of two different Lightnesses, (d) mapping along the vectors to the output gamut's cusp

this axis of the color space. The resulting Chroma (after Lightness mapping) could either be clipped or get compressed/expanded appropriately.

- *Chroma compression/expansion* approaches operate only along the Chroma axis. The resulting Lightness (after Chroma mapping) could either be clipped or get compressed/expanded appropriately.
- *Lightness and chroma compression* approaches operate on both Lightness and Chroma at the same time by mapping colors along various directions, as for those shown in Fig. 7a–d.

In all these approaches, independent of which dimension of the color space is compressed/expanded, or which direction of compression/expansion is chosen, the choice of the input–output relationship impacts the outcome significantly. Figure 8 shows various input–output relationships for the two parameters –

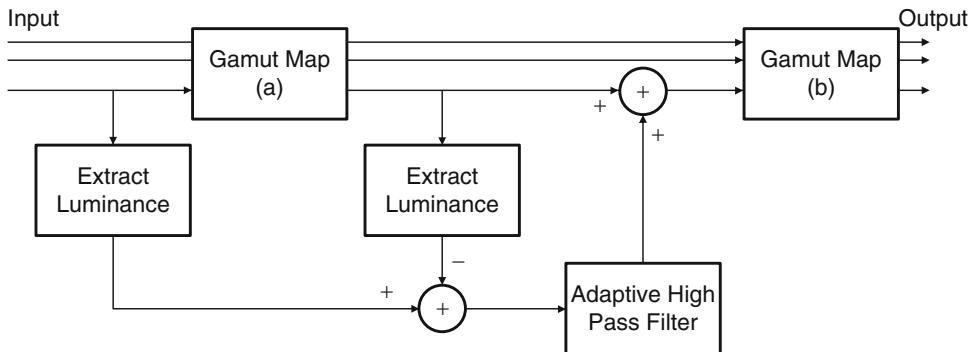

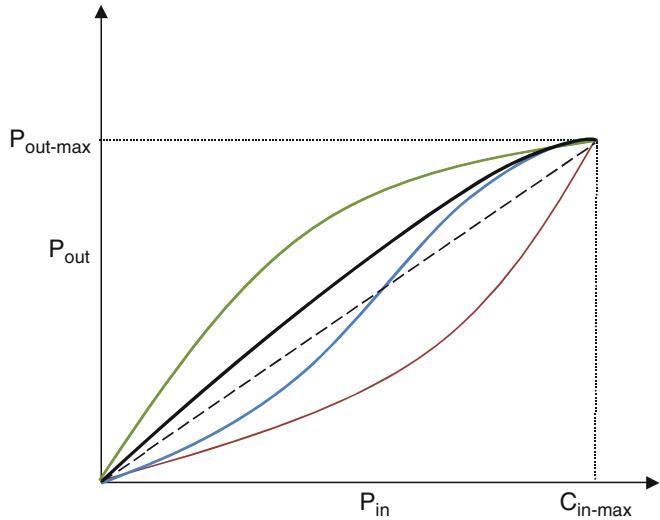

Lightness and Chroma – that may be used for the above approaches. All these approaches are typically performed on a hue-by-hue basis.

Spatial Gamut Mapping Algorithms

The gamut mapping approaches discussed thus far consider individual colors in an image in isolation, aside from their relationship in the color space. This disregards key factors that are known to impact the appearance of colors to human observers, such as spatial frequency of the image/color, surround colors, and other color appearance phenomena that can greatly change the perception of a color. Discounting these factors typically results in loss of detail in images or a degradation in the perception of the image – although specific colors may have been “accurately” mapped. A generic class of approaches called spatial gamut mapping algorithms take the spatial relationships of colors into account when mapping colors. A simple, yet robust, framework

Gamut Mapping, Fig. 8

Different input–output relationships for gamut compression/expansion, represented for parameter P which denotes Lightness and/or Chroma

**Gamut Mapping, Fig. 9** A generic framework for spatial gamut mappers

proposed by Balasubramanian et al. [1] is shown in Fig. 9 where the two gamut mappers (a) and (b) are tuned for the specific application. The objective of the spatial high-pass filter is to allow for Lightness variations in the signal when high-frequency content in the image is encountered. This is based on the observation that humans possess the most visual acuity in the brightness dimension of color, and so high spatial frequency content is more perceived along the Lightness axis.

Memory-Color-Aware Gamut Mapping Algorithms

Although this class of algorithms may be combined with the three other classes of gamut mapping solutions, it is important to address this issue separately as this is at the core of high-

quality gamut mapping algorithms. One of the most challenging tasks of a gamut mapping algorithm arises from the fact that its performance is typically evaluated by a human observer. Human observers have visual systems that, apart from being highly complex in terms of the appearance phenomena that determine their behavior, have preferences: the sky has to be a certain shade of blue, human skin tone rendition has to be a “certain” desired color, the color of green grass has to be a very specific shade of green, etc. This requires gamut mapping algorithms to comprehend these colors, deemed *memory colors*: colors that the human observer “knows” to be a certain shade, especially in the context in which they are presented. Approaches that attempt to maintain the rendition of memory colors tend to be proprietary to the vendors. These approaches

tend to be mostly probabilistic in nature, taking into account a very large database of memory colors as rendered in the output media and deemed suitable by the solution providers.

Open Problems

The rendering intents as specified by the ICC say little about how the mapping needs to be performed [5]. Open questions like the following still remain unanswered:

- *What must be done when there is a combination of the rendering intents?* This is a relatively common problem when a pictorial image containing the logo of a corporation needs to be gamut mapped – the logo needs to be accurate while the image may need to be perceptually mapped.
- *What attributes of the appearance of colors must be used?* Colors may be defined by their Lightness, Chroma, and Hue; or by their brightness, colorfulness, and Hue. The choice of which triplet needs to be used will help determine the color space that is to be chosen for gamut mapping.
- *What color space is best suited to perform gamut mapping?* In the case of colorimetric intents, it is relatively clear that the tristimulus values need to be maintained/adapted, and the chromatic-adaptation transform is specified to be the linear Bradford model. Even if one were to know clearly which appearance attributes to use, for each set of appearance attributes, and application, different color spaces lend themselves differently. More importantly, different color spaces provide different “predictors” for these appearance attributes and the gamut mapping algorithm needs to rely on the accuracy of these predictors.

Interested readers are referred to works by various authors in the general field of color imaging and reproduction that address not just the immediate needs of gamut mapping algorithms but the more important aspect of their interaction

with the larger image and color processing chain in typical capture, display, and print systems [2, 4, 6].

Definition

Generative adversarial network (GAN) is a framework that was invented for the purpose of creating an artificial distribution that mimics a given target distribution, and it consists of a generator function that produces the imitator distribution from a seed prior and a discriminator function that distinguishes the artificial distribution from the target.

Background

The task of approximating the probability density from empirically collected dataset (i.e., the training dataset)—or, in short, the task of learning a generative model—is a central problem of machine learning. The most straightforward way

of carrying out this task is the method of maximum likelihood estimation (MLE). However, a naive application of MLE with arbitrary choice of models won't suffice. For the learning of a complex probability distribution like the underlying distribution of image datasets, one needs a family of models that are complex enough to mimic the original; one popular choice is the family of neural networks. A problem that arises in applying the method of MLE to a complex model is the difficulty of evaluating the normalizing constant, which is also known in physics literature by the name of *partition function*. With appropriate design of models, however, we may compute the probability density $p(\mathbf{x})$ with relative ease. This is the central philosophy of auto-regressive model [14] and normalizing flow [24]; these models can all be trained by directly maximizing the likelihood function. There is also a family of methods that gives up on the direct optimization of the likelihood and instead settles with the maximization of a *lower bound*. Evidence lower bound (ELBO) is a particularly popular lower bound of the log-likelihood that is used by the celebrated variational autoencoder (VAE) [13]. Still another family of methods goes even so far to avoid the direct confrontation with the likelihood estimation and uses a different energy that behaves like the likelihood. Score matching [11] and noise-contrastive estimation [9] fall into this category.

Generative adversarial network (GAN) [8] is a method of generative modeling that is particularly popular for the task of image generation, and it falls into still another category called *implicit* model [21]. GAN are *implicit* model in that it allows the probability density to remain *implicitly* defined as a part of the generator model. But of course, this advantage comes at the cost of difficulty in estimating the log-likelihood of the data. As subjective as it may sound, GAN is more popular than VAE, auto-regressive model, and normalizing flow simply for its outstanding ability to generate *photorealistic* images. From a more practical view point, GAN is useful because it can be built from a wide variety of generator models. We just want the model of GAN to

allow us to (1) sample from the artificial distribution and (2) take derivative with respect to the parameters. The training of GAN does not require much more than some blunt knowledge of how the target distribution is generated; GAN is thus especially handy when there is a physical simulator of the environment.

In what follows, we will go over the basic theory of GAN and introduce some notable applications of GAN including video generations and inverse-reinforcement learning. We will then close this entry with several important open problems of GAN.

Theory

Let us denote the training dataset by $\mathcal{D} = \{\mathbf{x}^{(n)}\}_{n=1}^N$, $\mathbf{x} \in \mathbb{R}^{d_x}$. If the dataset consists of a set of grayscale images, for example, each coordinate of \mathbf{x} may represent a pixel intensity at the corresponding pixel. We also need a placeholder for the true distribution from which the dataset \mathcal{D} is collected. Let $q(\mathbf{x})$ be the density of the true distribution at \mathbf{x} . Typically, the generator distribution in GAN is constructed by applying a parametric function $G_\theta : \mathbb{R}^{d_z} \rightarrow \mathbb{R}^{d_x}$ to a latent variable $\mathbf{z} \in \mathbb{R}^{d_z}$ sampled from some prior distribution $p(\mathbf{z})$. In application, G_θ is oftentimes a neural network, and the parameter θ is the vector of the parameters of the network. Gaussian and uniform distributions are popular choices of the prior distribution. We often refer to the deterministic function G_θ as the *generator* in the context of GAN.

In the training algorithm of GAN, the generator function is trained together with the *discriminator*, which is in charge of evaluating “how close” the generator distribution is to the true distribution. Ever since the first invention of GAN by [8], numerous measures of the “closeness” have been developed together with different types of discriminators. The original formulation introduced in [8] is a good place to start. In the original formulation, the discriminator function is a parametric function $D_\phi : \mathbb{R}^{d_x} \rightarrow [0, 1]$ that takes a sample \mathbf{x} in \mathbb{R}^{d_x} and outputs the

probability that \mathbf{x} could have been sampled from q . For the training of the parameter ϕ , [8] used the objective function of the form below:

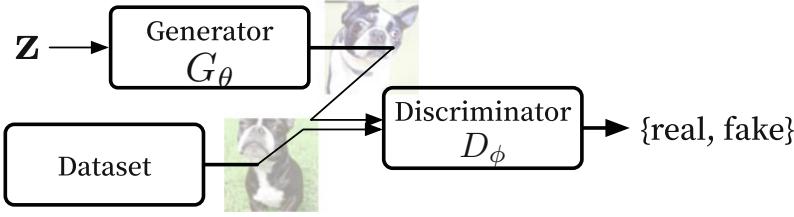

$$\min_{\theta} \max_{\phi} V(\theta, \phi)$$

$$\text{where } V(\theta, \phi) \equiv \mathbb{E}_{\mathbf{x} \sim q} [\log(D_\phi(\mathbf{x}))] + \mathbb{E}_{\mathbf{z} \sim p} [\log(1 - D_\phi(G_\theta(\mathbf{z})))]. \quad (1)$$

G

Of course, in actual implementation, the expectation in the expression above is both computed empirically by using the samples from the dataset \mathcal{D} and the samples from the prior distribution $p(\mathbf{z})$. Let us dissect this equation and elaborate the meaning of each piece. The \max_{ϕ} part of this equation is the classic likelihood-based objective function for binary classification; this part is in charge of training the discriminator to more accurately discriminate the *sample from the generator* from the *sample from the true distribution*. The \min_{θ} part, on the other hand, is responsible for training the generator to better deceive the discriminator—that is, to generate a sample that cannot be distinguished from the samples from true distribution. Figure 1 is the schematic of the GAN model. The training process proceeds by recursively updating the discriminator and the generator in turn. It is often customary to apply several steps of stochastic gradient descent (SGD) to the discriminator for each update of the generator. The name “generative adversarial network” comes from this training process, in which the generator and the discriminator act as a pair of adversaries that attempt to deceive one another.

Not so surprisingly, the optimal value of the objective function $\max_{\phi} V(\theta, \phi)$ of the discriminator at any stage of the training is the Jensen-Shannon divergence (JSD) between the true distribution $q(\mathbf{x})$ and the current generator distribution $p_\theta(\mathbf{x})$. Thus, we can interpret the training process of the discriminator as the estimation of the JSD. As it turns out, we can modify the objective function so that the training

Generative Adversarial Network (GAN), Fig. 1 The schematic of the GAN

Algorithm 1 Generative adversarial network with gradient descent

- Given dataset $\mathcal{D} = \{\mathbf{x}^{(n)}\}_{n=1}^N$, initial generator and discriminator parameters θ, ϕ .
- For t in $\{1, \dots, T\}$

1. For k in $\{1, \dots, K\}$

Update discriminator D_ϕ for fixed $G_{\hat{\theta}}$ with learning rate $\alpha > 0$:

$$\phi \leftarrow \phi + \alpha \nabla_\phi V(\hat{\theta}, \phi). \quad (2)$$

2. Update generator G_θ for fixed $D_{\hat{\phi}}$ with learning rate $\beta > 0$:

$$\theta \leftarrow \theta - \beta \nabla_\theta V(\theta, \hat{\phi}). \quad (3)$$

of the discriminator will amount to the estimation of f-divergence. See [22] for a concise list of common f-divergence and the corresponding objective function (Lucic et al. [17] also presents results that suggest that the quality of images produced by GAN is not much affected by the choice of the divergences.).

The Algorithm 1 is the pseudo-code of the training process of GAN. Some words of caution are in order for the implementation of this training process. In general, a naive update of the generator based on the Algorithm 1 tends not to work well in practice. As magical as it may sound,

$$\nabla_\theta \left(- \mathbb{E}_{\mathbf{z} \sim p} [\log(D_{\hat{\phi}}(G_\theta(\mathbf{z})))] \right) \quad (4)$$

is usually used in place of $\nabla_\theta V(\theta, \hat{\phi})$. This is in fact what is done in the original article of [8] as well. The work of [1] attributes the failure of

the original vanilla formulation to the phenomena of vanishing gradient that takes place when the support of the generator distribution and the true distribution is disjoint. We also shall note that, in practice, the discriminator is never updated until the objective function reaches the JS divergence; instead, it is updated only a few numbers of times (~ 5) for each update of the generator. As suggested by [5], the study of GAN's training process from the perspective of divergence minimization is thus a Pandora's box; much ambiguities still remain unresolved.

As GAN became more widely applied, a more major problem came to light; the training of GAN tends to be very unstable, and numerous studies tackled this problem from different perspectives (e.g., [1, 18]). As of 2019, the unspoken consensus is that one can alleviate the problem by imposing appropriate regularity condition onto the choice of the discriminator. Arjovsky and Bottou [1] required the discriminator to be 1-Lipschitz function with \mathbb{R} range and showed that the training based on their objective function amounts to solving the dual problem of minimizing the 1-Wasserstein distance between the generator distribution and the true distribution (WGAN). In their original article, Arjovsky and Bottou realized this regularization by using the method of weight clipping. Miyato et al. [20] pointed out that weight clipping is in fact requiring more than just the Lipschitz condition and improved their approach by controlling the spectral norm of each layer in the discriminator function. Many methods of GAN today regularize the Lipschitz constant of the map in some way or another. Mescheder et al. [18] takes the approach of penalizing the gradient of the discriminator with respect to the input.

Numerous variants of GAN have been proposed to date. MMDGAN [15] is an extension of moment matching networks [16], and it formulates the problem as an optimization problem in RKHS. Together with WGAN, MMDGAN is oftentimes referred to as the GAN of integrated probability metric type (IPM, [27]). All variants of GAN, however, stick to the common strategy of training the discriminator and the generator in turn, and one may regard this strategy as *the sole defining ingredient of GAN*. Likewise in the discussion of f-divergence, some studies report that the performance of GAN does not change much with the choice of the objective function [17]. At the same time, there is some room for discussion for the choice of the evaluation metric used in their work, and one cannot say for sure that the choice of the objective function does not affect the behavior of GAN. We will further explore the choice of the evaluation metric in the open problem section.

Applications

Image and video generation The history of the theories of GAN is tightly bound to the history of GAN' applications. The first notable application of GAN to image generation was done by [23], and they used convolutional neural networks for both discriminator and generator. Karras et al. [12] has built on their work and succeeded in producing super photo-realistic images using their *progressive GAN*, which successively generate a high-resolution image from a low-resolution image by gradually augmenting both the generator and discriminator with additional sets of layers. Miyato et al. [20] used the aforementioned spectral normalization technique and succeeded in using a single pair of discriminator and generator to learn the distribution on ImageNet, a massive benchmark dataset that consists of images of 1000 categories. More recently, [4] discovered that one can significantly improve the image generation of GAN by training large networks with large batch size (~ 2048) (conventional size had been ~ 256). There are applications of GAN to the video generation as well [25].

The quality of these results, however, has not yet reached the levels of [12] and [4], and there is still a long way to go for application of GAN, the video generation tasks.

Unpaired Image Translation Unpaired image translation is a particularly interesting application of GAN. The translation of a dataset from one domain to another seems to require a set of paired images of the two domains as a training dataset. However, [30] succeeded in using the framework of GAN to change the domain of the images without the dataset of paired images. Zhu et al. [30] achieved this feat by augmenting the objective function of GAN with what is so-called *cycle consistency loss*, which requires that the original image can be retrieved from the translated image by the domain translation in other direction.

G

Adversarial Imitation Learning Also, the recent surge of interests in autonomous AI has given a birth to an interesting application of GAN to inverse reinforcement learning [6]. The goal of inverse reinforcement learning is to learn a good policy from the histories of actions taken by the *experts*. In more precise terms, the task of inverse reinforcement learning is to learn both the cost function $c(s, a)$ and the policy function $\pi(s, a)$ with respect to state-action pair (s, a) in such a way that (1) $c(s, a)$ is trained to be low on the trajectory of the expert while being high on the trajectory of the agent following the policy $\pi(s, a)$ and (2) $\pi(s, a)$ is trained to optimize $c(s, a)$. A keen reader might have noticed that this formulation is akin to the formulation of GAN, because c is acting as like a "discriminator" that discriminates the policy of the expert from the policy of the agent and π is acting like a generator that strives to mimic the expert. In fact, with the above correspondence, the objective function of the inverse reinforcement learning coincides with GAN's objective function augmented with a term that penalizes the entropy of π . Numerous variants of inverse-reinforcement learning based on this formulation have been developed to date. Recent variants include [2]'s model-based method in which one can back-propagate

the trajectories, and [7]’s method that promotes the robustness of the trained policy against the change in the dynamics of the environment. This is an active field of research for which there is still much room for improvement. For more extensive surveys, please consult [6].

Open Problems

Mode Collapse The users of GAN are often vexed by the issue of *mode collapse*, phenomena in which the generator produces a single output from multiple inputs. Salimans et al. [26] was the first one to investigate this problem in depth. In their original article, [26] attempted to alleviate this problem by introducing the idea of mini-batch discrimination to promote the diversity of the images within each mini-batch. Later, [19] proposed *unrolled optimization* that takes the discriminator’s update into account in the design of the generator’s update, and [29] proposed a method that encourages the entropy of the generator distribution using a functional-gradient-based interpretation of GAN’s update.

Evaluation Metrics The most essential problem in the research of GAN is the absence of a natural evaluation metric. Recall that, in application, the max part of the minimax objective function of GAN is almost never fully optimized during the training process. The learning curve of GAN therefore does not mean much; let alone JSD, it does not correspond to the upper bound of any divergence measure that measures how close the generator distribution is to the true distribution. Naturally, this becomes a serious problem in comparing one method of GAN to another—researchers will be left to just scream to each other that “my image is better than yours”! [26] endeavored to resolve this problem and proposed to use the inception model [28] as a judge. In their work, they showed that their evaluation metric based on the mutual information with the output of the inception model is closely correlated with the human evaluation. The inception score is given by

$$\exp \left(\frac{1}{M} \sum_{m=1}^N \text{KL}(p(Y|\mathbf{x}^{(m)}) || p(Y)) \right), \quad (5)$$

where $\mathbf{x}^{(m)}$ is the m -th sample from the trained generator that is subject to the evaluation, $p(Y|\mathbf{x})$ is the trained inception model, and $p(Y) := \frac{1}{N} \sum_{m=1}^N p(Y|\mathbf{x}^{(m)})$ is the aggregated posterior. Inception score is widely used as an evaluation metric of GAN. We shall not forget, however, that the human evaluation that is used to validate the use of the inception score is also subjective, and it does not take the diversity of images into account. The later proposed evaluation metrics including Frechet inception distance [10] and Kernel inception distance [3] partially addresses this issue by considering the high-order moment of the generator distributions. However, their methods too depend on the choice of the *judge model*. A practical and natural statistical evaluation metric is still yet to be discovered.

Definition

Geodesics are locally the shortest paths in some space. Equivalently, geodesics are curves for which small perturbation increases their length according to some measure. A minimal geodesic corresponds to the shortest geodesic connecting two points. In computer vision and pattern recognition, the way distance is measured and the resulting geodesics define the specific application, see [1] for a pedagogical introduction to the field of numerical geometry of images.

Background

Edge detectors can be defined from a variational perspective where an edge is a curve along which the image gradient aligns with the curve's normal [2–6]. These types of edges are geodesics in the sense of integrating the inner product between the curve's normal and the image gradient and by Green's Theorem can be shown to be the Marr-Hildreth edge detectors [7], also known as LZC or Laplacian zero crossings. In fact, the more sophisticated Canny-Haralick [8, 9] edge detector can be viewed in a similar geometric-variational manner [3].

The first to formulate computer vision problems from a variational axiomatic view point was probably Horn [10]. For example, shape from shading, the problem of shape reconstruction from an intensity image, can be casted into a minimal geodesic computation problem. In a similar fashion, the image domain can be separated into meaningful regions by treating the image either as a set of pixels, each tries to place itself in the right segment, or as contours that attempt to locate themselves along the boundaries between objects. These kinds of contours live somewhere between histogram segmentation and edge detection and could be referred to as *edge integrators*. The *geodesic active contour* (GAC) model was first presented in [11]; see also [12] for a link between vector quantization and the GAC model. It is a computational framework to find local geodesics in a domain weighted by some edge indicator function. Its first implementation was

via the Osher-Sethian level set framework [13]. Minimal geodesics in that metric were shown to be the solution of an eikonal equation [14] that could be efficiently solved by the *fast marching method* [15, 16]; see also its extension to surfaces [17].

Eikonal solvers compute distance maps in a specific metric. Shape morphology, which defines algebra of shapes via Minkowski operations on sets of points, can also be related to distance maps. For an intuitive explanation, one can think of adding two shapes as the process of adding two numbers A and B . The result can be thought of as adding n times the number $\frac{1}{n}B$ to A . As $n \rightarrow \infty$, addition can be considered as a differential process. In a similar manner, erosion and dilation operations in mathematical morphology of shapes have a differential interpretations. Its continuous formulation was put forward in a number of publications [18–20] relating to level sets and eikonal solvers.

The *geodesic active contour* model evolves a given contour into a local geodesic via a heat flow in the space of weighted contours. Other heat flows evolve the image level sets themselves towards geodesics in Euclidean, affine, or perspective geometries. For example, the curvature scale space [21, 22] and the affine scale space [23, 24] can simplify the image structure in a topology preserving manner, where topology refers to the connectivity of the image level sets.

Theory

Consider the *geodesic active contour* functional

$$E(C) = \int g(C(s)) ds, \quad (1)$$

where g is some edge indicator function, e.g., $g(x, y) = (|\nabla I| + \epsilon)^{-1}$, and $C(s) = \{x(s), y(s)\}$ is an arclength parametrized planar contour, for which the first variation is given by

$$\frac{\delta E}{\delta C} = - (kg - \langle \nabla g, \mathbf{n} \rangle) \mathbf{n}, \quad (2)$$

where \mathbf{n} is the curve's normal and κ its curvature. One could either find geodesics under that metric by a gradient descent process $C_t = -\frac{\delta E}{\delta C}$, that in a level set formulation reads

$$\phi_t = \operatorname{div} \left(g \frac{\nabla \phi}{|\nabla \phi|} \right) |\nabla \phi|.$$

Here, ϕ is an implicit representation of the curve C . The way to find minimal geodesics under the same metric would be by solving the eikonal equation $|\nabla u| = g$ with $u(p) = 0$ at some source point p in the image domain, and then extract the minimal geodesic by gradient descent flow $C_t = -\nabla u$ from some target point q to the source point p .

Interesting Measures

In the shape from shading problem, the surface $z(x, y)$ is reconstructed from the shading image $I(x, y) = \langle N, l \rangle$, where N is the surface normal and l is the light source direction. For $l = \hat{z}$, one needs to solve for z in the eikonal equation

$$|\nabla z| = \sqrt{\frac{1 - I^2}{I^2}}$$

The Marr-Hildreth edge detector is given by the extremal curves of

$$E(C) = \int \langle n, \nabla I \rangle ds,$$

for which the first variation vanishes for $\Delta I = 0$, while the Canny-Haralick edge detector integrates the extremal curves of

$$E(C) = \int \langle n, \nabla I \rangle ds - \iint_{\Omega_C} k(I) |\nabla I| dx dy.$$

In this case the first variation w.r.t. C (provided by Euler-Lagrange equation) vanishes for $I_{\xi\xi} = 0$. Equivalently, edges are found where the second derivative of the image along the image gradient direction $\xi = \frac{\nabla I}{|\nabla I|}$ is equal to zero.

Minimizing the Euclidean arclength $s = \int |C_p| dp$ leads to the curvature flow, $C_t = C_{ss}$ or equivalently $C_t = k \mathbf{n}$, that for an image simultaneous evolution of all its level sets reads

$$I_t = \operatorname{div} \left(\frac{\nabla I}{|\nabla I|} \right) |\nabla I|.$$

The Equi-Affine arclength $v = \int |\det(C_p, C_{pp})|^{1/3} dp$ leads to the affine heat flow $C_t = C_{vv}$, or equivalently $C_t = k^{1/3} \mathbf{n}$, that for all image level sets simultaneous evolution is given by

$$I_t = \left(\operatorname{div} \left(\frac{\nabla I}{|\nabla I|} \right) \right)^{1/3} |\nabla I|.$$

G

Application

Total variation [25] methods in image processing, edge detection and integration, segmentation, structure reconstruction SFS [26, 27], and shape morphology (algebra of shapes) are all applications of computing geodesics and geodesic distances. Each application has its own distance measure and computational preferred flavor.

Open Problems

The theoretical machinery and concepts that motivated the usage of differential geometry and geodesics were adopted to the field of shape matching, processing, and analysis. Further links to metric geometry in general and open problems in this field can be found in [28].

[Clifford algebra](#)

Definition

Geometric algebra is an algebra based on a geometric product of vectors in an inner product space (a.k.a. the Clifford product). It naturally extends common geometrical techniques from linear algebra, to process subspaces and operations between them in a direct, coordinate-free manner. It permits division by subspaces (notably vectors), which leads to much more compact expression of common operations and algorithms in linear algebra, and more direct solutions to equations. Geometric algebra includes quaternions, in a real construction as a ratio of vectors, and extends them to encode rigid body motions. Geometric algebra also extends vector calculus to permit direct differentiation with respect to geometrical quantities and operators, thus allowing classically scalar optimization techniques to be transferred directly to geometric settings.

Background

Geometric algebra (GA) (or Clifford algebra) and its predecessor Grassmann algebra date from the 1870s and 1840s and are therefore older than linear algebra (LA). They formed the first formalization of how to compute with linear subspaces. Simplification of the ideas by Gibbs and others with the intention to construct a compact algebraic system for 3D computations in engineering around 1900 then led to the neglect of these more general frameworks. Now that parts of their structure have effectively been patched onto LA in an *ad hoc* manner with ideas like homogeneous coordinates and quaternions, it may pay to reconsider the use of GA to unify geometric computations. Hestenes was the first to realize this in the 1980s [4], initially for physics. In the 1990s, his ideas percolated into robotics, computer vision, and computer graphics.

Theory

Geometric algebra assumes a vector space V^n with inner product, denoted “.” (aka dot product) between vectors. GA views this dot product as the symmetric part of an underlying *geometric product* denoted “ ” (a half space, or juxtaposition); the other, antisymmetric part being the outer product, denoted “ \wedge ”, signifying the *span* of vectors. The axioms of the geometric product are surprisingly few: it is bilinear, associative, distributive over vector addition, scalars commute, and the geometric product of a vector \mathbf{v} with itself is a scalar equal to $\mathbf{v} \cdot \mathbf{v}$.

From this, it follows that for a (non-null) vector \mathbf{v} , the geometric product is invertible with $\mathbf{v}^{-1} = \mathbf{v}/(\mathbf{v} \cdot \mathbf{v})$. This makes division by a vector a permissible operation. That in turn simplifies many geometric expressions. For instance, a reflection of a vector in a plane with normal \mathbf{n} at the origin can be rewritten in a much simpler form than the classical linear algebra expression:

$$\begin{aligned}\mathbf{x} &\mapsto \mathbf{x} - 2 \frac{\mathbf{x} \cdot \mathbf{n}}{\mathbf{n} \cdot \mathbf{n}} \mathbf{n} = \mathbf{x} - 2 \left(\frac{\mathbf{x} \mathbf{n} + \mathbf{n} \mathbf{x}}{2} \right) \mathbf{n}^{-1} \\ &= -\mathbf{n} \mathbf{x} \mathbf{n}^{-1}.\end{aligned}$$

Planar reflection is an orthogonal transformation, and concatenating such reflections leads to the general expression of an orthogonal transformation as being characterized as a product of invertible vectors – an algebraic and computationally practical consequence of the famous Cartan-Dieudonné theorem. In particular, a rotation in 3D may be represented as the product of two reflections, i.e., an element $\mathbf{m}\mathbf{n}$ applied in a “sandwiching” manner to a vector:

$$\mathbf{x} \mapsto (\mathbf{m}\mathbf{n}) \mathbf{x} (\mathbf{m}\mathbf{n})^{-1}.$$

G

Taking the normal vectors to be normalized to unity, this element $(\mathbf{m}\mathbf{n})$ has the same algebraic properties as a *unit quaternion*. Quaternions in GA are therefore simply products (or ratios) of real vectors denoting double planar reflections. Parametrizing this product of vectors by their angle $\mathbf{I} \phi/2$ (i.e., $\phi/2$ from \mathbf{n} to \mathbf{m} to produce a rotation over ϕ in that sense), we may write

$$\mathbf{m} \mathbf{n} = \mathbf{n} \cdot \mathbf{m} - \mathbf{n} \wedge \mathbf{m}$$

$$= \cos(\phi/2) - \mathbf{I} \sin(\phi/2) = e^{-\mathbf{I}\phi/2},$$

where \mathbf{I} is the unit “bivector” $\mathbf{n} \wedge \mathbf{m}$ of the plane span (\mathbf{n}, \mathbf{m}) , with an orientation determined by the order of the spanning vectors. One may verify (by the axioms of the geometric product) that $\mathbf{I}^2 = -1$, so that the “complex” nature of the quaternions is merely a consequence of the axioms of the geometric product of a real vector space. The final expression as an exponent then follows from the usual Taylor series definition of the exponential, extended to GA elements.

This parametrization of an orthogonal transformation as the exponent of a bivector uses the minimal $\frac{1}{2}n(n-1)$ parameters in an n -D vector space. In applications estimating an orthogonal transformation from data, this is more convenient than the usual overparametrization as an $n \times n$ matrix M , needing to impose orthogonality as the $\frac{1}{2}n(n+1)$ constraints $M^T M = I$.

An element that can be made as the product of unit vectors, or expressed as the exponent of a bivector, is called a *rotor* in GA. In multiplying operators, this rotor representation is more

efficient than matrices (a generalization of the well-known advantage of unit quaternions over rotation matrices). For applying the operator to vectors only, matrices are faster; but rotors can be applied, without modification, to *any* geometric element. The reason behind this is that an orthogonal transformation represented by a rotor V trivially preserves the geometric product in a covariant manner:

$$V(AB)V^{-1} = (VAV^{-1})(VBV^{-1}).$$

As long as we make any construction in GA from a linear combination of geometric products, and as long as we can represent the transforma-

tions of interest as rotors, we have a *structure-preserving* implementation of our geometry. As we will see below, this may require choosing a clever embedding relationship between the space in which our geometric elements reside, and the geometric algebra that represents them.

As one multiplies elements of geometric algebra, elements of various *grades* appear. These can be decomposed on a basis consisting of *blades*, which are elements factorizable by the outer product. Such elements represent subspaces of a dimension equal to their grade. For instance, starting from a basis $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ for the vector space \mathbb{R}^3 , one obtains eight basis blades:

$$\left\{ \underbrace{1}_{\text{scalar basis}}, \underbrace{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3}_{\text{vector basis}}, \underbrace{\mathbf{e}_2 \wedge \mathbf{e}_3, \mathbf{e}_3 \wedge \mathbf{e}_1, \mathbf{e}_1 \wedge \mathbf{e}_2}_{\text{2-blade basis}}, \underbrace{\mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3}_{\text{3-blade basis}} \right\}.$$

Geometrically, these can be interpreted as the point at the origin, three vector directions, three 2-directions of planar elements, and a volume element. A geometric algebra of an n -dimensional vector space has a basis of 2^n elements (like its Grassmann algebra). The high dimensionality of a geometric algebra is not an argument against its use, since the possibility to generate all structure-preserving interactions between such elements automatically at compile time offsets much run time complexity [3]; also, the geometrically meaningful elements tend to be obtained by multiplication of basis elements, and those are sparse on this basis. (Incidentally, such multiplicative generation of meaningful elements may be taken as a distinction between geometric algebra and Clifford algebra, since the latter permits arbitrary addition in its theoretical construction.) In fact, the “extra” elements are mostly geometric objects one would make anyway in classical LA, but now integrated in one consistent framework.

Scalar and vector *calculus* is naturally extended to GA elements. This makes it possible to optimize orientation estimations by differentiating a well-chosen cost criterion with respect to rotors, and demanding that the

result be zero. Such capabilities are beginning to provide powerful coordinate-free geometrical optimization methods (see, e.g., [10]), in which specific parametrizations can be chosen conveniently afterward.

The Conformal Model

In linear algebra, homogeneous coordinates are an embedding trick that permits us to use the linear transformations of an $(n+1)$ -dimensional space to represent *projective transformations* of an n -dimensional space computationally. In GA, there is an embedding which allows computing with *conformal transformations* in an n -dimensional space using the rotors (i.e., orthogonal transformations) from the algebra of an $(n+2)$ -dimensional space [1]. This space has an inner product with signature $(n+1, 1)$, i.e., one can provide it with an orthonormal basis of which $n+1$ vectors square to $+1$, and 1 vector squares to -1 . A more commonly used basis is a “null basis” involving the vector n_∞ representing the point at infinity, and n_o , an arbitrarily chosen finite point (which can serve as an origin, similarly to the extra dimensions in homogeneous

coordinates). The products of the two non-Euclidean dimensions obey $n_o^2 = n_\infty^2 = 0$, and $n_o \cdot n_\infty = -1$. This, combined with a well-chosen embedding of points, permits the space to be an isometric image of Euclidean space (which homogeneous coordinates are not). The resulting geometric algebra is often referred to as CGA (for conformal geometric algebra).

The embedding of Euclidean space into CGA is that a point P at Euclidean location \mathbf{p} relative to n_o is represented by a vector $p \in \mathbb{R}^{n+1,1}$ given by

$$p = \alpha \left(n_o + \mathbf{p} + \frac{1}{2} \mathbf{p}^2 n_\infty \right), \text{ with } \alpha \in \mathbb{R}$$

(which may be viewed as an extension of the homogeneous coordinate representation $\alpha(n_o + \mathbf{p})$). Note that p is a null vector: $p^2 = 0$. A simple computation now shows that the squared Euclidean distance between two normalized points is effectively the inner product between their representative vectors:

$$-\frac{1}{2} \|\mathbf{p} - \mathbf{q}\|^2 = \left(\frac{p}{-n_\infty \cdot p} \right) \cdot \left(\frac{q}{-n_\infty \cdot p} \right).$$

The factor $-n_\infty \cdot p$ is the homogeneous weight α of the point representation, so dividing by it provides a normalization. It follows that orthogonal transformations of $\mathbb{R}^{n+1,1}$ which preserve the point at infinity n_∞ preserve Euclidean distances, and hence represent rigid body motions of \mathbb{R}^n . Their rotors (sometimes called *motors*) form a more general form of unit quaternion which can represent rotations around a general axis, combined with a shift along that axis. When n_∞ is not preserved, a rotor of the algebra represents a general conformal transformation.

As to the blades in CGA, a general vector of the space $\mathbb{R}^{4,1}$ (to be specific) represents a Euclidean 3D sphere in a dual manner (with a hyperplane as a special case). A point is merely a dual sphere of zero radius. A 4-blade (i.e., the outer product of four points) represents the oriented sphere through those points, unless one of them is n_∞ , in which case it represents an oriented plane. Similarly, 3-blades are oriented

circles or lines, and 2-blades are oriented point pairs. Other useful geometric elements obtain an algebraic definition, such as tangent vectors, tangent planes, and purely directional elements. In CGA, therefore, classical primitives already used effectively in the specification of geometrical algorithms finally obtain an algebraic expression that permits automatic generation of their transformation properties under the rotors representing the operators of interest. The generating capabilities of CGA are quite powerful: e.g., $\mathbf{P} = (\mathbf{X} \cdot \mathbf{A})/\mathbf{A}$ represents the projection of a blade \mathbf{X} onto a blade \mathbf{A} ; if \mathbf{X} is a line and \mathbf{A} is a sphere, then \mathbf{P} is a great circle. Such geometrical nuggets may be found in tutorial texts like [3].

G

Application

While on paper GA may look more involved than LA, its structure-preserving properties make for cleaner software for geometrical applications; the algebra playing the role – at compiler time if required – of generating the transformation methods for the various geometric data objects automatically [3]. The formalism presumably allows for the expression of all desired geometry, and helpfully hampers the construction of elements without geometric meaning (if certain simple construction rules are followed).

The novel representation of rigid body motions and the associated geometric primitives has already permitted compact treatment of such geometrical computer vision tasks as camera calibration [6, 10], pose estimation [8], and pose interpolation [2]. Image transformations in space and value can be given their own geometric algebra [5] and signal processing [9]. Applications to color processing or quaternionic Fourier transforms are so far less compelling.

Open Problems

Currently, the GA equivalents of a suite of techniques from applied linear algebra are being uncovered and turned into practical tools. These include eigenproblems, singular value decomposition, spectral analysis, calculus

(Lagrange optimization) and statistics (geometric noise characterization [7]), and more. Since linear algebra and vector calculus are contained within geometric algebra, one can always defer to known techniques, but the employment of the full suite of GA techniques in sample problems is showing promise.

Moreover, other useful GA models are being identified: for 3D projective geometry, the geometric algebra of 3D lines involving the space $\mathbb{R}^{3,3}$ can represent projective transformations as orthogonal transformations, and hence perform them through structure-preserving rotor computations.

Definition

Geometric calibration is the process of determining the geometric property of a camera such as its intrinsic and extrinsic parameters. It is often referred to as simply *camera calibration* in computer vision. The reader is referred to entry ▶ “[Camera Calibration](#)” for a discussion on other camera calibration tasks.

Background

Much work has been done, starting in the photogrammetry community (see [1, 2] to cite a few) and more recently in computer vision ([3–10] to cite a few). According to the dimension of the calibration objects, we can classify those techniques roughly into four categories.

3D reference object-based calibration. Camera calibration is performed by observing a calibration object whose geometry in 3-D space is known with very good precision. Calibration can be done very efficiently [11]. The calibration object usually consists of two or three planes orthogonal to each other. Sometimes, a plane undergoing a precisely known translation is also used [5], which equivalently provides 3D reference points. This approach requires an expensive calibration apparatus and an elaborate setup.

2D plane-based calibration. Techniques in this category require to observe a planar pattern shown at a few different orientations [12, 13]. Different from Tsai's technique [5], the knowledge of the plane motion is not necessary. Because almost anyone can make such a calibration pattern by himself/herself, the setup is easier for camera calibration.

1D line-based calibration. Calibration objects used in this category are composed of a set of collinear points [14, 15]. As will be shown, a camera can be calibrated by observing a moving line around a fixed point, such as a string of balls hanging from the ceiling.

Self-calibration. Techniques in this category do not use any calibration object and can be considered as 0D approach because only image point correspondences are required. Just by moving a camera in a static scene, the rigidity of the scene provides in general two constraints [9, 16] on the cameras' internal parameters from one camera displacement by using image information alone. Therefore, if images are taken by the same camera with fixed internal parameters, correspondences between three images are sufficient to recover both the internal and external parameters which allow us to reconstruct 3-D structure up to a similarity [17, 18]. Although no calibration objects are necessary, a large number of parameters need to be estimated, resulting in a much harder mathematical problem.

Other techniques exist: vanishing points for orthogonal directions [19, 20] and calibration from pure rotation [21, 22].

Theory

What follows is an excerpt of the review on camera calibration [23]. The reader is referred to [23] for a complete review of various geometric calibration techniques.

Geometric calibration depends on which camera model is used. The reader is referred to entry ▶ “[Camera Model](#)” for a presentation of

various camera models. In the sequel, we use the perspective camera model.

Camera Calibration with 3D Objects

The traditional way to calibrate a camera is to use a 3D reference object such as those shown in Fig. 1. In Fig. 1a, the calibration apparatus used at INRIA [11] is shown, which consists of two orthogonal planes, on each a checker pattern is printed. A 3D coordinate system is attached to this apparatus, and the coordinates of the checker corners are known very accurately in this coordinate system. A similar calibration apparatus is a cube with checker patterns painted in each face, so in general three faces will be visible to the camera. Figure 1b illustrates the device used in Tsai's technique [5], which only uses one plane with checker pattern, but the plane needs to be displaced at least once with known motion. This is equivalent to knowing the 3D coordinates of the checker corners.

According to the perspective camera model, the relationship between the 3D point M and its image projection m is given by

$$s\tilde{m} = \underbrace{\mathbf{A}[\mathbf{R} \ t]\tilde{M}}_{\mathbf{P}} \equiv \mathbf{PM}, \quad (1)$$

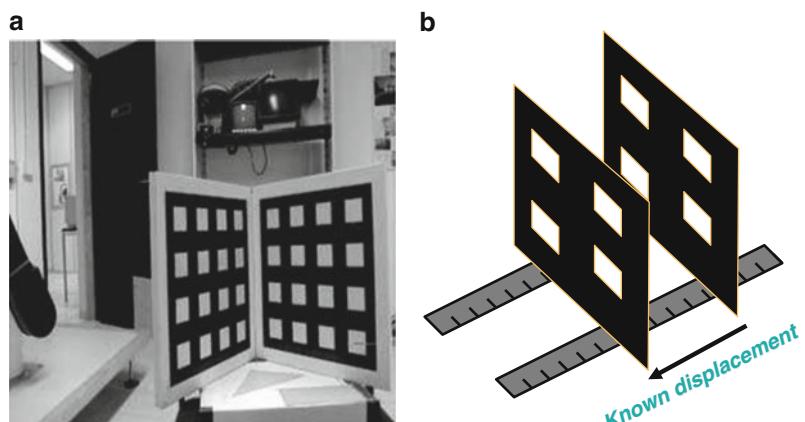

$$\text{with } \mathbf{A} = \begin{bmatrix} \alpha & \gamma & u_0 \\ 0 & \beta & v_0 \\ 0 & 0 & 1 \end{bmatrix} \quad (2)$$

$$\text{and } \mathbf{P} = \mathbf{A}[\mathbf{R} \ t] \quad (3)$$

where s is an arbitrary scale factor; (\mathbf{R}, \mathbf{t}) , called the extrinsic parameters, is the rotation and translation which relates the world coordinate system to the camera coordinate system; and \mathbf{A} is called the camera intrinsic matrix, with (u_0, v_0) the coordinates of the principal point, α and β the scale factors in image u and v axes, and γ the parameter describing the skew of the two image axes. The 3×4 matrix \mathbf{P} is called the camera projection matrix, which mixes both intrinsic and extrinsic parameters. Matrix \mathbf{P} is defined up to a scale factor, so it only has 11 free parameters.

Given one 2D-3D correspondence $(\mathbf{m}_i, \mathbf{M}_i)$, we can write down two equations based on Eq. (1). There are in total 11 unknowns (5

Geometric Calibration,
Fig. 1 3D apparatus for
calibrating cameras

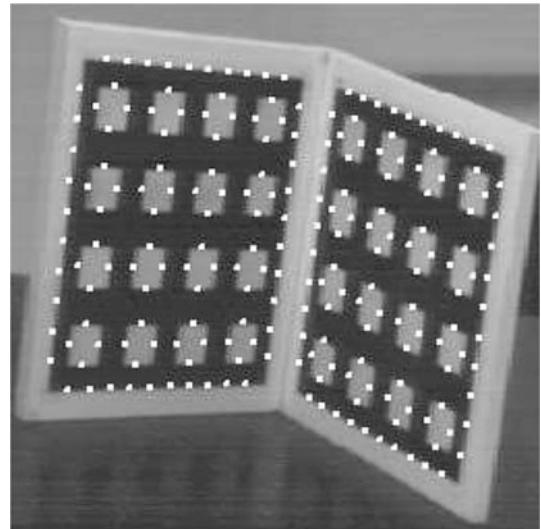

intrinsic parameters and 6 extrinsic parameters). If we have 6 or points that do not lie on a single plane, a unique solution is available.

A popular technique in this category consists of four steps [11]:

1. Detect the corners of the checker pattern in each image.
2. Estimate the camera projection matrix \mathbf{P} using linear least squares.
3. Recover intrinsic and extrinsic parameters \mathbf{A} , \mathbf{R} , and \mathbf{t} from \mathbf{P} .
4. Refine \mathbf{A} , \mathbf{R} , and \mathbf{t} through a nonlinear optimization.

Note that it is also possible to first refine \mathbf{P} through a nonlinear optimization and then determine \mathbf{A} , \mathbf{R} , and \mathbf{t} from the refined \mathbf{P} .

It is worth noting that using corners is not the only possibility. We can avoid corner detection by working directly in the image. In [24], calibration is realized by maximizing the gradients around a set of control points that define the calibration object. Figure 2 illustrates the control points used in that work.

Geometric Calibration, Fig. 2 Control points used in a gradient-based calibration technique

Given an image of the model plane, a homography between the known model plane and the image can be estimated. Let us denote it by $\mathbf{H} = [\mathbf{h}_1 \mathbf{h}_2 \mathbf{h}_3]$. Without loss of generality, we assume the model plane is on $Z = 0$ of the world coordinate system. This yields

$$[\mathbf{h}_1 \mathbf{h}_2 \mathbf{h}_3] = \lambda \mathbf{A} [\mathbf{r}_1 \mathbf{r}_2 \mathbf{t}],$$

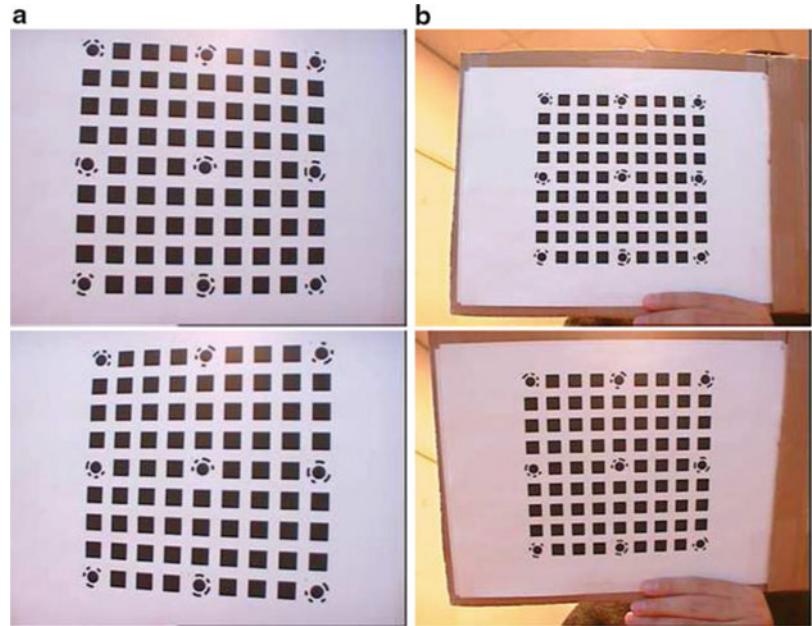

where λ is an arbitrary scalar. The reader is referred to [12, 25] for the derivation. Using the knowledge that \mathbf{r}_1 and \mathbf{r}_2 are orthonormal, we have

**Camera Calibration with 2D Objects:
Plane-Based Technique**

This technique only requires the camera to observe a planar pattern from a few different orientations [12, 13]. An example is shown in Fig. 3.

Geometric Calibration,

Fig. 3 Two sets of images taken at different distances to the calibration pattern. Each set contains five images. On the *left*, three images from the set taken at a close distance are shown. On the *right*, three images from the set taken at a larger distance are shown

G

$$\mathbf{h}_1^T \mathbf{A}^{-T} \mathbf{A}^{-1} \mathbf{h}_2 = 0 \quad (4)$$

$$\mathbf{h}_1^T \mathbf{A}^{-T} \mathbf{A}^{-1} \mathbf{h}_1 = \mathbf{h}_2^T \mathbf{A}^{-T} \mathbf{A}^{-1} \mathbf{h}_2. \quad (5)$$

These are the two basic constraints on the intrinsic parameters, given one homography. Because a homography has 8 degrees of freedom and there are 6 extrinsic parameters (3 for rotation and 3 for translation), we can only obtain 2 constraints on the intrinsic parameters.

If the camera is shown with the model plane at N general orientations, we have $3N$ constraints on five intrinsic parameters. With $N \geq 3$, a unique solution is available. There is a degenerate configuration in this technique when planes are parallel to each other. See [15] for a more detailed description.

A recommended calibration procedure is as follows:

1. Print a pattern and attach it to a planar surface.
2. Take a few images of the model plane under different orientations by moving either the plane or the camera.
3. Detect the feature points in the images.
4. Estimate the five intrinsic parameters and all the extrinsic parameters using the closed-form solution.

5. Estimate the coefficients of the radial distortion.
6. Refine all parameters, including lens distortion parameters, through maximum likelihood estimation.

Solving Camera Calibration with 1D Objects

A 1D object consisting of three or more points on a line. An example is shown in Fig. 4.

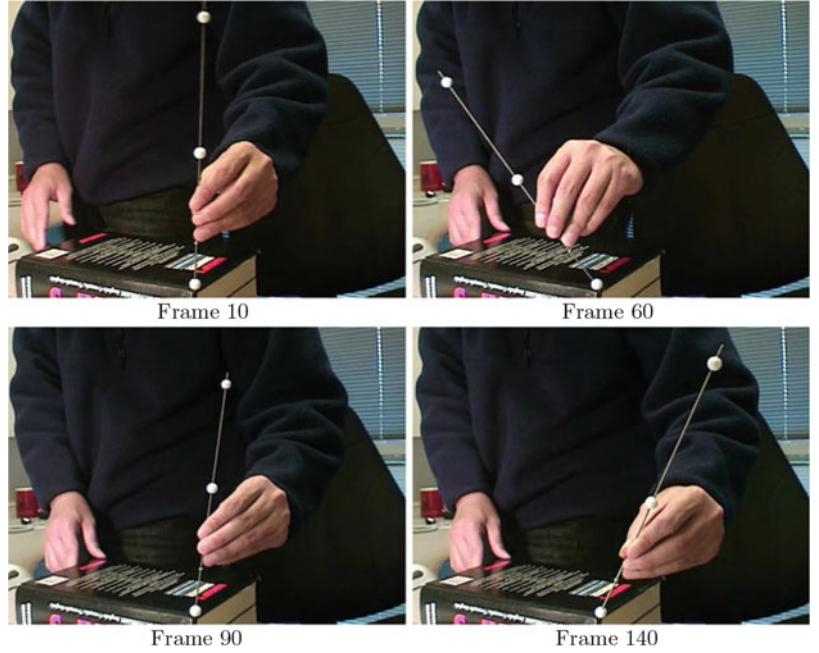

As discussed in [14, 26], calibration is impossible with a free moving 1D calibration object, no matter how many points on the object. It is, however, possible if the 1D object moves around a fixed point. In the sequel, let the fixed point be point \mathbf{A} , and \mathbf{a} is the corresponding image point. We need three parameters, which are unknown, to specify the coordinates of \mathbf{A} in the camera coordinate system, while image point \mathbf{a} provides two scalar equations according to (Eq. 1).

Two Points with Known Distance

They could be the endpoints of a stick, and we move the stick around the endpoint that is fixed. Let \mathbf{B} be the free endpoint and \mathbf{b} , its corresponding image point. For each observation, we need two parameters to define the orientation

Geometric Calibration,

Fig. 4 Sample images of a 1D object used for camera calibration

of the line \mathbf{AB} and therefore the position of \mathbf{B} because the distance between \mathbf{A} and \mathbf{B} is known. Given N observations of the stick, we have five intrinsic parameters, three parameters for \mathbf{A} and $2N$ parameters for the free endpoint positions to estimate, that is, the total number of unknowns is $8 + 2N$. However, each observation of \mathbf{b} provides two equations, so together with \mathbf{a} we only have in total $2 + 2N$ equations. Camera calibration is thus impossible.

Three Collinear Points with Known Distances

By adding an additional point, say \mathbf{C} , the number of unknowns for the point positions still remains the same, that is, $8 + 2N$. For each observation, \mathbf{b} provides two equations, but \mathbf{c} only provides one additional equation because of the collinearity of \mathbf{a} , \mathbf{b} , and \mathbf{c} . Thus, the total number of equations is $2 + 3N$ for N observations. By counting the numbers, we see that if we have six or more observations, we should be able to solve camera calibration, and this is the calibration technique as developed in [14, 26].

Four or More Collinear Points with Known Distances

Again, the number of unknowns and the number of independent equations remain the same

because of invariance of cross ratios. This said, the more collinear points we have, the more accurate camera calibration will be in practice because data redundancy can combat the noise in image data.

Self-calibration

Self-calibration is also called auto-calibration. Techniques in this category do not require any particular calibration object. They can be considered as 0D approach because only image point correspondences are required. Just by moving a camera in a static scene, the rigidity of the scene provides in general two constraints [9, 16, 17] on the cameras' internal parameters from one camera displacement by using image information alone. Absolute conic is an essential concept in understanding these constraints. Therefore, if images are taken by the same camera with fixed internal parameters, correspondences between three images are sufficient to recover both the internal and external parameters which allow us to reconstruct 3-D structure up to a similarity [17, 18]. Although no calibration objects are necessary, a large number of parameters need to be estimated, resulting in a much harder mathematical problem. The reader

is referred to two books [27, 28] which provide an excellent recount of those techniques.

Discussions

Although many calibration techniques exist, no single calibration technique is the best for all. It really depends on the situation a user needs to deal with. Following are my few recommendations:

- Calibration with apparatus vs. self-calibration. Whenever possible, if we can pre-calibrate a camera, we should do it with a calibration apparatus. Self-calibration cannot usually achieve an accuracy comparable with that of pre-calibration because self-calibration needs to estimate a large number of parameters, resulting in a much harder mathematical problem. When pre-calibration is impossible (e.g., scene reconstruction from an old movie), self-calibration is the only choice.
- Partial vs. full self-calibration. Partial self-calibration refers to the case where only a subset of camera intrinsic parameters are to be calibrated. Along the same line as the previous recommendation, whenever possible, partial self-calibration is preferred because the number of parameters to be estimated is smaller. Take an example of 3D reconstruction with a camera with variable focal length. It is preferable to pre-calibrate the pixel aspect ratio and the pixel skewness.
- Calibration with 3D vs. 2D apparatus. Highest accuracy can usually be obtained by using a 3D apparatus, so it should be used when accuracy is indispensable and when it is affordable to make and use a 3D apparatus. From the feedback I received from computer vision researchers and practitioners around the world in the last couple of years, calibration with a 2D apparatus seems to be the best choice in most situations because of its ease of use and good accuracy.
- Calibration with 1D apparatus. This technique is relatively new, and it is hard for the moment to predict how popular it will be. It, however, should be useful especially for calibration of

a camera network. To calibrate the relative geometry between multiple cameras as well as their intrinsic parameters, it is necessary for all involving cameras to simultaneously observe a number of points. It is hardly possible to achieve this with 3D or 2D calibration apparatus if one camera is mounted in the front of a room while another in the back. An exception is when those apparatus are made transparent; then the cost would be much higher. This is not a problem for 1D objects. We can, for example, use a string of balls hanging from the ceiling.

G

In this entry, we have only considered the linear projective projection. With real cameras, lens distortion sometimes has to be considered. The reader is referred to the entry ► “[Calibration of Projective Cameras](#)”.

Geons

Sven J. Dickinson¹ and Irving Biederman²

¹Department of Computer Science, University of Toronto, Toronto, ON, Canada

²Departments of Psychology, Computer Science, and the Neuroscience Program, University of Southern California, Los Angeles, CA, USA

Synonyms

Recognition-by-components (RBC) theory

Definition

Geons are a set of less than 50 qualitative 2-D or 3-D part classes derived from permuting a set of four dichotomous and trichotomous properties of a generalized cylinder (GC). The values of these properties are nonaccidental in that they can be resolved from a general viewpoint, e.g., whether the axis of a cylinder is straight or curved. Geons were originally introduced by Biederman [1, 2] as the foundation for his recognition-by-

components (RBC) theory for human shape perception, whereby object-centered models are represented as concatenations of geons, and object recognition from a 2-D image proceeds by matching recovered parts, typically segmented at regions of matched concavity, and their relations to object models.

Background

The concept of modeling an object as a composition of generalized cylinders dates back to Binford [3], who spawned a generation of object-recognition systems based on generalized cylinders, e.g., [4–8]. Generalized cylinders suffered from unbounded complexity, for arbitrarily complex functions could be used to define the axis, cross section, and sweep functions. As a result, it became popular to restrict the complexity of these functions, e.g., straight axis, constant or linear sweep, rotationally symmetric cross section, in order to facilitate their overconstrained recovery from sparse image data.

In the mid-1980s, two alternative restrictions on generalized cylinders emerged from the computer vision and human vision communities, respectively. Pentland [9] introduced the superquadric ellipsoid to the computer vision community – a 3-D, symmetry-based part representation that afforded a large degree of descriptive power with a small number of parameters. Around the same time, Biederman [1, 2] introduced geons to the human vision community as part of his recognition-by-components (RBC) theory. Like superquadric ellipsoids, geons exploited symmetry to reduce the complexity of a generalized cylinder. However, while the superquadric ellipsoid was a metric shape representation, the geon was a qualitative shape categorization. Thus, when a superquadric ellipsoid was recovered from an image, the recovered parameters defined a specific shape (a generative model), whereas when a geon was recovered from an image, it defined a symbolic part class (non-generative category) with only coarse (rather than exact) metric specification.

The appeal of the geon was twofold: (1) its properties were based on the sorts of judgments that humans are very good at, e.g., judging whether a line was straight or curved rather than estimating its exact curvature; and (2) each geon class afforded a high degree of within-class shape deformation, offering great potential for shape categorization and invariance over orientation in depth. Given extensive experiments with humans and primates that lent strong support of his RBC theory, the computer vision community quickly set out to develop computational models for geon recovery from 2-D images.

G

Theory

Geons define a partitioning of a subspace of the generalized cylinders. Like generalized cylinders, each geon is defined by its axis function, its cross-section function, and its sweep function. Biederman noted that humans are (1) much better at distinguishing between straight and curved lines than they are at estimating curvature; (2) much better at distinguishing parallelism from nonparallel symmetry than they are at estimating the angle between two causally related lines; and (3) good at distinguishing between various types of vertices produced by a cotermination of contours, such as a fork from an arrow from a L-junction. Drawing on these properties of the human visual system, Biederman mapped the spaces of the three generalized cylinder parameters to dichotomous and trichotomous values (Fig. 1):

- *Axis shape*: the axis takes on two possible values: straight or curved.
- *Cross-section shape*: the cross-section shape takes on two possible values: straight-edged or curved-edged.
- *Sweep function*: the cross-section sweep function takes on four possible values: constant, monotonically increasing (or decreasing), monotonically increasing and then decreasing, or monotonically decreasing and then increasing.

Geons, Fig. 1 The space of approximately 50 geons is defined by permuting the dichotomous and trichotomous properties of a restricted space of generalized cylinders

The set of geons is generated by variations in the production function for generalized cylinders that produce viewpoint-invariant (= nonaccidental) shape differences

1. Cross Section: Straight vs. Curved

2. Axis: Straight vs. Curved

3. Size of Cross Section:

Constant (parallel sides) vs. Expand vs. Expand & Contract vs Contract & Expand

4. Termination of Geon when Nonparallel: Truncated vs. Pointed vs. Rounded

© Irving Biederman

- *Termination*: given a nonconstant sweep function, the termination of a geon could be truncated, end in a point (projects into an L-vertex), or end as a curved surface.

Originally, Biederman [2] posited cross-section symmetry as another attribute (with three possible values: rotationally symmetric, possessing an axis of reflective symmetry, or asymmetry) but that attribute was dropped as experiments showed that people assume symmetrical cross-sections, even when the cross-section is asymmetrical (as with an airplane wing).

Permuting the possible values of these four functions defines a space of $2 \times 2 \times 4 \times 3 = 48$ 3-D geons, as illustrated in Fig. 1. Adding 2D geons, e.g., circle, quadrilateral, and triangle, and subtracting the eight instances of constant sweep (2 axis shape \times 2 cross-section shape \times 2 point and curved terminations) when the sweep function is constant brings the total to about 50.

viewpoint. In the computer vision community, Bergevin and Levine were the first to propose a computational model for geon recovery and geon-based recognition [12–16]. Dickinson et al. [17–19] introduced a hybrid object representation combining 3-D object-centered volumetric parts and 2-D viewer-centered aspects modeling the parts. While the framework was applicable to any vocabulary of volumetric parts, it was demonstrated on a qualitative shape vocabulary very similar to geons. Many geon-based frameworks followed, including probabilistic approaches [20], logic-based approaches [21], parametric geon recovery from range data [22–24], deformable contour-based approaches [25], deformable volume-based approaches [26], and active vision approaches [27, 28]. See [29] for a panel discussion on the strengths and weakness of geons and the challenges that lie ahead.

Open Problems

Related Work

Hummel et al. [10, 11] first proposed a connectionist model for recovering geons from line drawings that achieved invariance to

Geons have tremendous potential as a part representation in support of object categorization. They are qualitative and can support a high degree of within-class deformation, they (like generalized cylinders) map to the natural part

structure of objects (when such elongated part structure exists), they are viewpoint-invariant 3-D parts that support object-centered 3-D models (which, in turn, better support scaling to large databases), and there is psychophysical support for them (the human is still, by far, the best example of an object categorization system). Despite these advantages, geons declined as a subject of study in the computer vision community in the late 1990s, in part due to the advent of appearance-based recognition and a general movement away from shape features.

The main reason for their decline was not necessarily a shortcoming of the representation, i.e., geons, but rather the community's inability to extract qualitative shape from real images of real objects. Except for those approaches operating on range images, the work reviewed above operated on either line drawings or uncluttered scenes containing simple, textureless objects. The key assumption made by these systems was that a salient contour in the image maps one-to-one to a salient surface discontinuity (or occluding contour) on a geon. Unfortunately, in a real scene, objects contain texture, shadows, reflectance contours, and structural "noise" (surface discontinuities that are not salient with respect to the geon class), all of which introduce unwanted contours. Moreover, images of contours (both good and bad) may be broken or noisy, requiring complex perceptual grouping and multiscale analysis to restore and capture the salient shape of the contours. Yet despite these conditions, humans and primates have absolutely no trouble distinguishing (or abstracting) those contours that mark orientation and depth discontinuities – the critical contours for geon extraction – from contours reflecting variations in surface texture, color, lighting, shadows, etc.

As discussed in Dickinson [30], the recognition community's gradual movement from shape toward appearance, coupled with the community's interest in engineering practical systems, drew attention away from basic research on shape modeling in support of object categorization. However, the community is once again realizing that over the set of exemplars belonging to an object category, shape is far more

invariant than appearance. As a result, shape-based object categorization systems (mainly using contours) are beginning to reemerge, e.g., [31]. But a return to local contour-based features is not sufficient, as local shape features are still too exemplar-specific. Rather, such features must be perceptually grouped and abstracted to form more generic shape structures that offer the within-class deformation invariance required for effective categorization. Geons offer a powerful shape abstraction with great categorization potential, but only when more progress has been made on the mid-level challenges of perceptual grouping and intermediate-level shape abstraction. Some early work along these lines has started to appear [32].

G

Experimental Results: Computer Vision

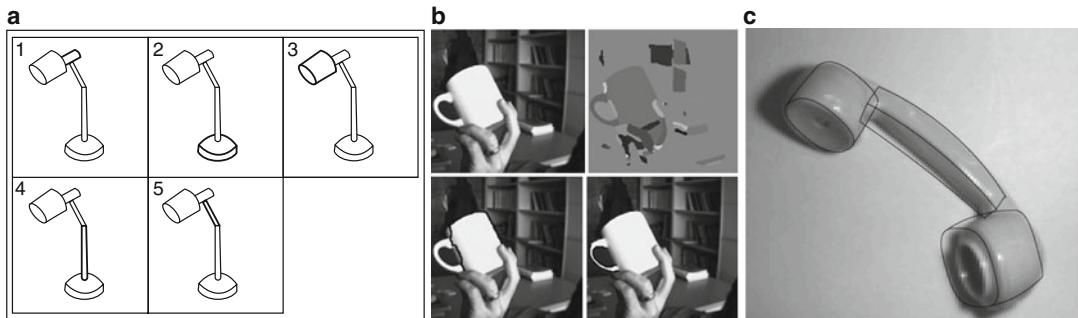

Figure 2 illustrates three examples of geon recovery systems in the computer vision community. In Fig. 2a, the system of Bergevin and Levine [15] recovers geons from line drawings. In Fig. 2b, the system of Dickinson et al. [27] recovers geon-like volumetric parts from real images of simple objects, as does the system of Pilu and Fisher [25], as shown in Fig. 2c.

Experimental Results: Human Vision

There is now substantial neural and behavioral evidence for the representation of objects as an arrangement of geons, as specified by the recognition-by-components theory. This evidence can be summarized in terms of six independent assumptions. Any one (or several) of these assumptions can be made independent of RBC but, to date, RBC is the only theory from which all six derive.

The representation of an object is largely edge-based – specifically, those edges specifying orientation and depth discontinuities – rather than surface-based (i.e., color, texture).

Reaction times (RTs) and error rates for naming briefly presented images of objects are as

Geons, Fig. 2 Three examples of geon recovery in the computer vision community: (a) decomposing a line drawing of a lamp into its constituent geon parts, with bold contours indicating parts: 1 – rear shade, 2 – base, 3 – front shade, 4 – lower neck, and 5 – upper neck (Bergevin and Levine [15]); (b) from a region segmentation (*upper*

right) of the image of an occluded cup (*upper left*), the two recovered constituent qualitative volumetric parts (with matched contours highlighted in black) are shown in *lower left* (body cylinder) and *lower right* (handle bent cylinder) (Dickinson et al. [27]); and (c) decomposing a phone into its constituent geons parts (Pilu and Fisher [25])

fast for line drawings as they are for full, color photography [33]. This is also true of verification in which the observer verifies whether a name (“chair”), provided prior to an image of an object, matches the object. The equivalence in performance for identifying line drawings and photography is evident even when the objects have a diagnostic color/texture, such as a fish, fork, or banana, as opposed to objects with nondiagnostic surface properties, e.g., a chair or a lamp, which can be any color or texture.

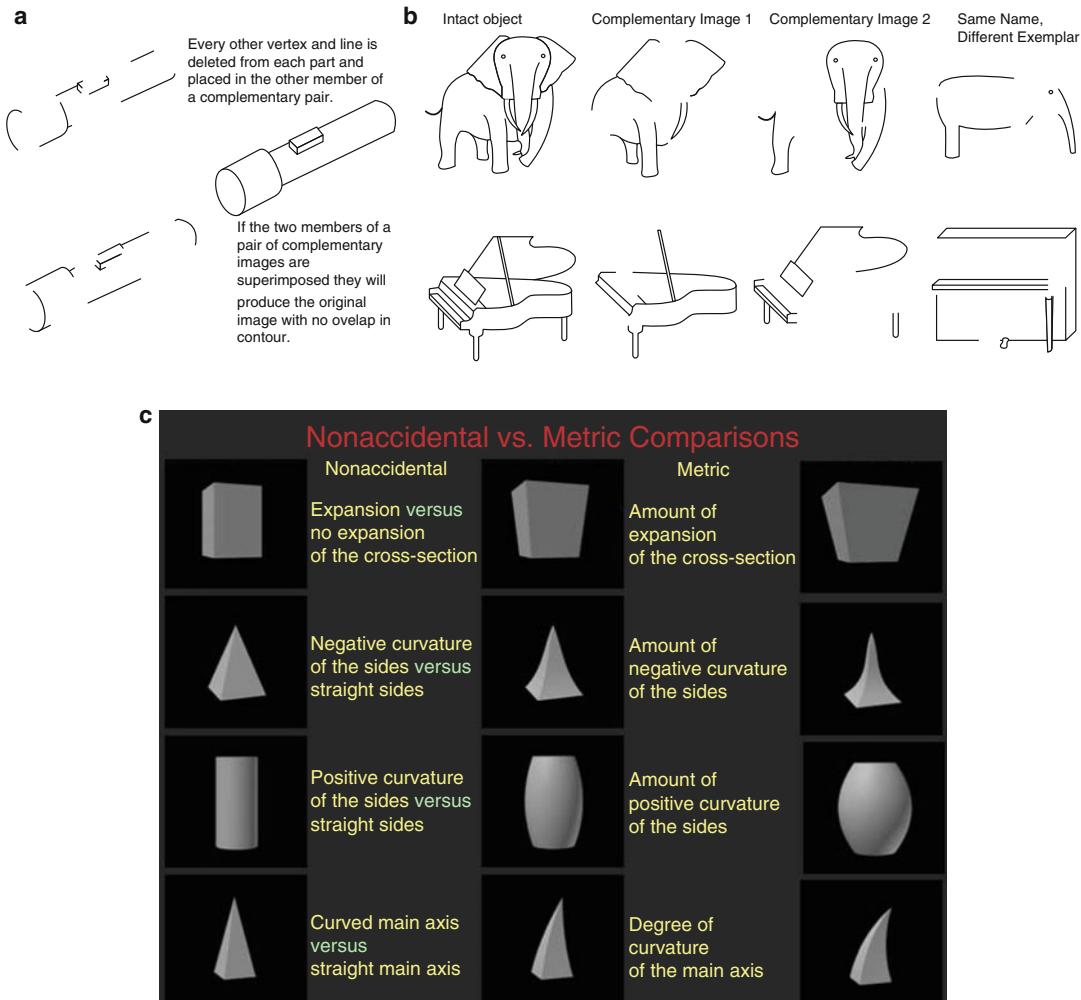

The equivalence of photography and line drawings is also witnessed in fMRI activity where the adaptation (i.e., the reduction) of the BOLD signal that is evident with a repetition of a stimulus, fMRI-a, is the same when the images have the same format, i.e., identical photographs or line drawings, as when they have different formats, one a photograph and the other a line drawing [34]. This invariance to surface properties is also seen in the response of many single neurons in object-sensitive areas in the macaque [35]. In fMRI, the processing of surface properties, color and texture, activates different cortical areas than those activated when processing shape [36].

There are few transformations to appearance as dramatic as rendering a line drawing from a photograph yet the readily achieved invariance to this transformation poses a major challenge to appearance-based theories of object recognition.

Objects are represented by parts rather than local features, templates, or concepts.

Object priming is the facilitation that ensues as a consequence of a prior perception of an object. It can be readily evidenced by a reduction in RTs and error rates in the naming of brief, masked presentations of objects and has been documented over a 14-month period from the first to second presentation of the images. (The reduction in the magnitude of the BOLD response to a repeated stimulus, termed fMRI adaptation, is generally attributed to more efficient coding and is interpreted as a neural correlate of priming.) Almost all of this priming is visual (i.e., perceptual) rather than lexical (easier access to the name itself) in that an object with the same name but a substantially different shape, e.g., a grand piano followed by an upright piano, evidences almost no facilitation.

Studies with complementary, contour-deleted line drawings document that all the priming can be attributed to the repetition of the parts (in their appropriate relations) as opposed to local features, i.e., the specific lines and vertices in the image [37]. Thus, if every other vertex and line from each geon is deleted from one image of an object and the deleted contour composes the other member of a complementary pair, as in the two images of a flashlight on the left side of Fig. 3a (so if the two were superimposed they would comprise an intact image with

Geons, Fig. 3 Psychophysical evidence in support of Geons: (a) members of a local contour-deleted complementary pair, which have the same parts but different local features, prime each other as much as they do themselves; priming is not attributable to local contours; (b) there is no visual priming between members of a complementary pair when they have no parts in common, as between

the images of the second and third columns [37]; and (c) equal image differences between nonaccidental (between center and left columns) and metric properties (between center and right columns). Geons are distinguished by nonaccidental properties. Discrimination is much faster and more accurate for differences in nonaccidental than metric properties

no overlap of contour), the degree of priming between members of a complementary pair – which depict the same parts though with different local contours – is equal to the priming between identical images. This implies that none of the priming can be attributable to the local contours (i.e., the local lines and vertices). Presumably, the local contours are required to activate a representation of the part, but once that part (in its appropriate relations) is activated

there is no contribution of the initial local image features.

Instead of deletion of local features, if the deletion is of half the parts of a complex object, as shown in Fig. 3b, then there is no visual priming between members of a complementary pair. Thus the priming is completely dependent on the overlap in the parts in the two images. These effects on behavioral priming have their exact counterpart in fMRI-a. Here, local feature

complements show the same reduction in the BOLD response as when the identical images are repeated, suggesting equivalent representations, but repetition of part complements show a complete loss of adaptation thus indicating that there is no overlap in visual representations when the images are composed of different parts, even though they are of the same subordinate concept, e.g., both grand pianos [38].

Evidence against a template representation derives from studies of the priming of depth-rotated stimuli. As long as the same parts can be readily extracted in two different images of the same object, recognition or matching of a rotated object will be achieved with virtually no cost. However, if because of self-occlusion some parts disappear and other parts emerge, then priming is reduced or object matching is impaired [39].

Single cell recordings in the inferior temporal lobe (IT) of the macaque, the area generally accepted to mediate object recognition, generally fire as strongly to one or two of the parts of an object as they do to the complete object [40].

Parts are distinguished by nonaccidental properties (NAPs) and only coarsely by metric properties (MPs).

Values of various dimensions of geons can be regarded as singular or nonsingular. A singular value, such as 0 curvature (i.e., a straight contour), retains that value as the object is rotated in depth. A nonsingular value, such as a nonzero value of curvature (i.e., a curved contour), can vary with the orientation in depth of that contour. In addition to curvature, parallelism of two contours can have a singular value of zero convergence (or divergence) or a nonzero value. Two or three contours that coterminate can be regarded as a singular value of zero separation between their terminations, forming vertices, such as Ls, arrows, or forks. This framework can define NAP differences as the difference between singular and nonsingular values as, e.g., a difference between a curved and a straight contour produced by the parallel sides of the cylinder on the left in the third row of Fig. 3c and the middle barrel. Metric differences are differences in non-singular values, such as two

contours with unequal nonzero curvatures, as with the slightly curved and more curved barrels in the third row.

The aforementioned invariance to rotation in depth holds only if the objects that are to be discriminated differ in NAPs [39, 41]. Objects differing only in metric properties incur high costs when they are encountered at a different orientation in depth. At equal orientations, the discrimination of two shapes as being same or different is markedly easier if the shapes differ in NAPs than MPs [42]. Cells in the IT region of the macaque modulate (i.e., vary their firing rate) much more to a change in a NAP compared to an MP [35, 43]. Even pigeons show greater sensitivity to differences in NAPs than MPs [44]. In these comparisons of the sensitivity of NAPs and MPs, the physical differences are equated according to a model of V1 [45], the first stage of cortical shape coding.

Dimensions of generalized cylinders (GCs) are independently coded and have psychophysical and neural reality.

The set of geons is generated by combinations of the values of the independent dimensions shown in Fig. 1. (In addition, as noted previously, there can be coarse variation in the metric of these geons, such as their aspect ratio or degree of axis curvature.) Are simple object parts actually coded by independent combinations of these dimensions (vs. just being nondimensionalized variations in shape templates)? One measure of independent coding of perceptual dimensions is whether human observers can selectively attend to one dimension without any cost from variations in another, to-be-ignored, dimension. For example, the speed and accuracy of discriminating different shapes is unaffected by whether the colors of those shapes are held constant or varied. It might seem plausible that shape could be attended while ignoring a surface feature such as color. Would efficient selective attention be manifested when observers are attending to one shape dimension, say axis curvature, while ignoring variations in another shape dimension, say aspect ratio. The answer is clearly yes [46]. Moreover, a multidimensional analysis of the firing

of a population of IT cells to a set of stimuli similar to that depicted in Fig. 3c shows that 95% of the variance of the spike rates can be modeled in terms of independent coding of the GC dimensions [40].

Low sensitivity for discriminating complex, irregular shapes (= texture?) compared to simple shapes but high sensitivity for distinguishing regular from irregular.

Geons are simple and regular. What about complex, highly irregular objects, such as a bush or a crumpled sweater? It would be highly unlikely that people are employing geons for the precise representation of such objects. Interestingly, the evidence is that people do not represent such variation in any detail beyond the fact that the shapes are irregular and some simple nonaccidental characterizations, e.g., whether the surfaces are round or pointed. This is also true of IT cells [47]. Essentially, objects with irregular parts are treated as texture, rather than shape.

There is a more general point to be made here. GCs (and geons) were criticized for their unwieldiness for modeling objects such as bushes. But this is confusing a graphics system, in which the goal is to achieve an exact replica of the image, with a biological recognition system designed to do basic- and subordinate-level classification in which irrelevant variation is best ignored.

Objects are represented by a structural description that specifies simple parts and relations.

Geons are the representation of the parts of an object, but objects are typically composed of more than one part. In the same manner that people are sensitive to the order of phonemes, so “rough” and “fur” have the same phonemes but in different order, people are sensitive to the arrangement of parts of an object, so they can say, e.g., that a vertical cylinder is attached end-to-middle and perpendicular to the top of a larger horizontal brick. That geons and their relations may be coded independently is documented by a remarkable patient with a left inferior temporal lesion who had no problem distinguishing objects differing in their geons but could not distinguish objects that differed in the relations among the

same geons [48]. Recent neuroimaging studies show that such relations are specified explicitly at the same cortical locus, the lateral occipital complex, that object shape is specified [49].

Definition

Vision-based gesture recognition is the process of recognizing meaningful human movements from image sequences that contain information useful in human-human interaction or human-

computer interaction. This is distinguished from other forms of gesture recognition based on input from a computer mouse, pen, or stylus, sensor-based gloves, touch screens, etc.

Background

Automatic image-based gesture recognition is an area of computer vision motivated by a range of application areas, including the analysis of human-human communication, sign language interpretation, human-robot interaction, multimodal human-computer interaction, and gaming. Human gesture has a long history of interdisciplinary study by psychologists, linguists, anthropologists, and others in the context of human communication [1], exploring the role of gesture in face-to-face conversation, universal and cultural aspects of gesture, the influence of gesture in human evolution and in child development, and other topics, going back at least to the work of Charles Darwin with *The Expression of the Emotions in Man and Animals* (1872). Research in computer vision-based gesture recognition began primarily in the 1990s as computers began to be capable of supporting real-time (or interactive time, fast enough to support human interaction) processing and recognition of video streams.

Several gesture taxonomies or categorizations have been developed by different researchers that underscore the breadth of the problem in general. Cadoz [2] described three functional roles of human gesture: semiotic (gestures to communicate meaningful information), ergotic (gestures to manipulate the environment), and epistemic (gestures to discover the environment through tactile experience). Most work in automated gesture recognition is concerned with the first role (semiotic gestures), whereas the area of activity analysis tends to focus on the latter two. Kendon [3] described a gesture continuum, defining five types of gestures: gesticulation, language-like gestures, pantomimes, emblems, and sign languages. Each of these has a varying association with verbal speech, language properties, spontaneity, and social regulation

[4], indicating that human gesture is indeed a complex phenomenon. Gesticulation, defined as spontaneous, speech-associated gesture, makes up a large portion of human gesture and is further characterized by McNeill [5] into four types:

- Iconic – Representational gestures depicting some feature of the object, action, or event being described
- Metaphoric – Gestures that represent a common metaphor, rather than the object or event directly
- Beat – Small, formless gestures, often associated with word emphasis
- Deictic – Pointing gestures that refer to people, objects, or events in space or time

These gesture types modify the content of accompanying speech and often help to disambiguate speech, similar to the role of spoken intonation. Cassell et al. [6] described early research in conversational agents that models the relationship between speech and gesture and generates interactive dialogs between three-dimensional animated characters that gesture as they speak.

Gestures can be seen as a type of activity, along with other activity types such as actions and interactions. Gestures are typically considered as shorter-duration and more simple movements, whereas actions can be longer-term (like walking) and consist of a sequence of gestures [7], and interactions consist of gestures or actions involving more than one person.

Theory and Application

A gesture may be considered as a continuous set of movements or as a sequence of discrete poses or postures. Gestures are inherently dynamic and time-varying, while postures are specific – and static – configurations; recognizing specific configurations (such as making a “victory sign”) should properly be referred to as posture recognition. Aspects of a gesture that may be critical to its interpretation include spatial information (where the gesture occurs and/or refers to), pathic

information (the path a gesture takes), symbolic information (sign(s) made during a gesture), and affective information (the emotional quality of a gesture, which may be related to the speed and magnitude of a gestural act, as well as to facial expression).

Hand, Head, and Body Gestures

Gestures can be performed by different body parts and combinations thereof, such as hands, head, legs, full body, or upper body. Hand gestures have received particular attention in gesture recognition. Hands provide the opportunity for a wide range of meaningful gestures, as evidenced by the rich history of human sign languages such as American Sign Language (ASL) (e.g., [8]). Hands may also be convenient for quickly and naturally conveying information in vision-based interfaces (e.g., [9]).

At the same time, gestures not involving hands are also important in various applications. In sign languages, head movements can carry grammatical information. As an example, in ASL, head movements can determine if a sentence is an affirmative statement, a negation, or a question [10]. Head and eye gesture recognition is used to design human-computer interfaces, especially for people with disabilities who may have limited control of other parts of their body [11]. Camera-based video game interfaces can recognize body gestures such as jumping or leaning to the side, and a choreography application may aim to recognize different types of dance moves [12].

Isolated and Continuous Gestures

Many existing methods and datasets concentrate on recognizing isolated gestures, whose start and end frame are known. Such methods can be applicable in various settings. For example, gestures may be constrained to a particular point in time with a “push to gesture” functionality, where the user pushes a button to indicate the start and/or end of a gesture [13]. Another example is a system for recognizing an isolated sign from a sign language, in which case the user would need to specify the start frame and end frame of the sign or provide a video containing only that sign [14]. At the same time, many real-world

applications require recognizing gestures whose start and end frame are unknown.

Temporal segmentation/detection of gestures is a challenging problem, particularly in less constrained environments where several kinds of gestures are possible amidst other movement [15]. While temporal detection and segmentation of gestures may be attempted as a first step, other approaches combine spatial (or spatiotemporal) segmentation with recognition [16]. Gesture segmentation can involve isolated gestures that are performed with pauses between them (e.g., when a user issues gesture commands to a robot [15]) or cases where gestures are signed in a continuous manner with no breaks between them (e.g., in continuous sign language recognition [8]).

For recognition of unsegmented gestures, an important parameter is whether each gesture must be recognized as soon as possible upon completion. Recognizing upon completion is a common requirement in human-computer interfaces and other real-time applications, where it is desirable to minimize the system response time. On the other hand, greater accuracy can often be achieved if the system waits until a longer sequence of gestures is observed. For example, in continuous sign language recognition, methods such as bidirectional Long Short-Term Memory and Viterbi alignment can use features from subsequent signs to recognize signs occurring earlier [8].

Modalities

Traditionally, gesture recognition methods mainly used data from RGB video, and RGB data is still commonly used. Some methods have used data from a single camera, where recovery of 3D information can be difficult, limiting accuracy and constraining the viewpoints from which a gesture can be recognized (e.g., [14]). Other methods rely on multi-camera setups, which however can be more cumbersome and expensive to deploy in real-world scenarios (e.g., [17]).

In the last decade, there has been a significant amount of work in gesture recognition from depth imagery (e.g., [18]) or combinations of video (RGB) and depth data (e.g., [19]). This development was largely initiated by the introduction

of the Microsoft Kinect sensor (and SDK/toolkit) and the use of body modeling, tracking, and gesture recognition in consumer applications using the Kinect [9]. Several depth sensors and associated toolkits are now available for developing consumer and industrial applications. Such toolkits can compute and output in real time (but not with perfect accuracy) the position of skeletal joints based on the video data. In such cases, skeletal information is often treated by gesture recognition methods as a separate modality, used by itself or in combination with the video data.

G

Processing Pipelines

A typical approach to human gesture recognition involves detecting and tracking component body parts, such as hands, arms, head, torso, legs, and feet, based on an articulated body model and subsequently classifying the movement into one of a set of known gestures. The output of the tracking stage is a time-varying sequence of parameters describing (2D or 3D) positions, velocities, and angles of the relevant body parts and features, possibly including a representation of uncertainty that indicates limitations of the sensor and the algorithms (e.g., [20]). An alternative is to take an appearance-based approach, which computes parameters directly from image and video data, generally bypassing human body modeling (e.g., [19]).

The classification step is typically performed using a temporal classifier. Some popular approaches used in the past include Hidden Markov Models [21], Hidden Conditional Random Fields [22], and Dynamic Time Warping [23]. In the last decade, deep neural networks have become prevalent, and current popular approaches include recurrent neural networks (RNNs) with Long Short-Term Memory (LSTM) and 3D convolutional neural networks [19]. Gesture recognition methods now commonly utilize CNNs for other pipeline components as well, such as feature extraction [24] and detection/tracking of body parts [25].

Training models to recognize gestures can be treated as a standard supervised learning problem, where the training set consists of video segments and an associated gesture class label for

each segment. Creating large training sets of this nature can be cumbersome, as it typically requires human effort to mark the start and end frames of gestures in longer videos, in order to generate the segmented samples [14]. An alternative that requires substantially less human effort is weakly supervised learning, where each training video contains multiple gestures, and the learning algorithm is provided with the sequence of gesture labels, but not with the start and end frame of each gesture [8].

Measures of Accuracy

For recognizing isolated, presegmented gestures, accuracy is typically evaluated based on the percentage of correctly classified gestures. For recognizing unsegmented gestures appearing in a continuous stream, different measures can be employed. If the start and end frame of each gesture are known, then accuracy can be measured at the frame level, as the percentage of frames to which the system assigned the correct gesture label [26]. Alternatively, the intersection-over-union (IoU) measure can be computed to evaluate the temporal overlap between each actual gesture and each gesture identified by the system [16]. By applying some predefined threshold on IoU, we can determine true/false positives and true/false negatives and measure precision, recall, and the corresponding F1 score. By varying the IoU threshold, we can obtain a precision-vs.-recall curve and compute the mean average precision (mAP) score [26].

Providing the start and end frames of each gesture as ground truth can be cumbersome or even impractical for large datasets. Ground truth can also be provided at a coarser level, by only specifying the sequence of gestures that occur in each video. In that case, accuracy can be evaluated based on the edit distance (Levenshtein distance) between the correct sequence and the sequence produced by the model [27].

An important factor in measuring gesture recognition accuracy is user independence. User-independent accuracy is the accuracy obtained when the humans who perform gestures in the

test set are disjoint from the humans performing gestures in the training set. User-independent accuracy can be significantly lower than user-dependent accuracy, due to both the differences in body types between different humans and the differences in the style in which different humans perform the same gesture.

Open Problems

Gesture recognition is a broadly defined set of problems and challenges, for which there are some domain-specific solutions that are adequate for commercial use, but the general problems are largely unsolved. At the low level, there are limitations to any choice of sensor type, and work still needs to be done on integrating data from multiple sensors. There is no agreement on how to best represent the sensed spatial and temporal information and its relationship to human movement. Temporal segmentation of natural dynamic gestures is unlikely to be solved without a deep understanding of the gesture semantics, i.e., the high level context in which the gestures take place. Despite the recent impact of depth sensors on this area, the field is still wide open for solutions that can provide precise and robust gesture recognition in a wide range of environments.

RGB-based gesture recognition methods are often viewpoint-dependent, due to the challenge of recovering 3D data from a single RGB camera. Complex and moving backgrounds can also significantly hurt accuracy. Intra-class variations can be challenging to model: a single person may perform a gesture differently at different times, for example, by varying the speed or range of motion. Intra-class differences are typically even greater when gestures are performed by different people. User-independent recognition of a large vocabulary of gestures, such as the thousands of distinct signs in a sign language, is particularly challenging for existing state-of-the-art methods, as it is a recognition problem combining large intra-class variations, small inter-class variations (signs looking relatively similar to other signs),

and a relatively small number of training examples per class.

Research in vision-based gesture recognition can be stimulated by the creation and sharing of thorough, annotated datasets that capture a wide range of spontaneous gestures and imaging conditions and by apples-to-apples comparisons such as several ChaLearn Gesture Challenges in the past decade [27].

Definition

Gradient vector flow is the vector field that is produced by a process that smooths and diffuses an input vector field and is usually used to create a vector field that points to object edges from a distance.

Background

Finding objects or homogeneous regions in images is a process known as image segmentation. In many applications, the locations of object edges can be estimated using local operators that yield a new image called an edge map. The edge map can then be used to guide a deformable model, sometimes called an active contour or a snake, so that it passes through the edge map in a smooth way, therefore defining the object itself.

A common way to encourage a deformable model to move toward the edge map is to take the spatial gradient of the edge map, yielding a vector field. Since the edge map has its highest intensities directly on the edge and drops to zero away from the edge, these gradient vectors provide directions for the active contour to move.

When the gradient vectors are zero, the active contour will not move, and this is the correct behavior when the contour rests on the peak of the edge map itself. However, because the edge itself is defined by local operators, these gradient vectors will also be zero far away from the edge, and therefore the active contour will not move toward the edge when initialized far away from the edge.

Gradient vector flow (GVF) is the process that spatially extends the edge map gradient vectors, yielding a new vector field that contains information about the location of object edges throughout the entire image domain. GVF is defined as a diffusion process operating on the components of the input vector field. It is designed to balance the fidelity of the original vector field, so it is not changed too much, with a regularization that is intended to produce a smooth field on its output.

Although GVF was designed originally for the purpose of segmenting objects using active contours attracted to edges, it has been since adapted and used for many alternative purposes. Some newer purposes include defining a continuous medial axis representation [1], regularizing image anisotropic diffusion algorithms [2], finding the centers of ribbon-like objects [3], constructing graphs for optimal surface segmentations [4], creating a shape prior [5], and much more.

Theory

The theory of GVF was originally described in [6]. Let $f(x, y)$ be an edge map defined on the image domain. For uniformity of results, it is important to restrict the edge map intensities to lie between 0 and 1, and by convention $f(x, y)$ takes on larger values (close to 1) on the object edges. The gradient vector flow (GVF) field is given by the vector field $\mathbf{v}(x, y) = [u(x, y), v(x, y)]$ that minimizes the energy functional:

$$\begin{aligned} \mathcal{E} = & \iint_{\mathbb{R}^2} |\nabla f|^2 |\mathbf{v} - \nabla f|^2 \\ & + \mu (u_x^2 + u_y^2 + v_x^2 + v_y^2) dx dy. \end{aligned} \quad (1)$$

In this equation, subscripts denote partial derivatives, and the gradient of the edge map is given by the vector field $\nabla f = (f_x, f_y)$. Figure 1 shows an edge map, the gradient of the (slightly blurred) edge map, and the GVF field generated by minimizing \mathcal{E} .

Equation (1) is a variational formulation that has both a data term and a regularization term. The first term in the integrand is the data term. It encourages the solution \mathbf{v} to closely agree with the gradients of the edge map since that will make $\mathbf{v} - \nabla f$ small. However, this only needs to happen when the edge map gradients are large since $\mathbf{v} - \nabla f$ is multiplied by the square of the length of these gradients. The second term in the integrand is a regularization term. It encourages the spatial variations in the components of the solution to be small by penalizing the sum of all the partial derivatives of \mathbf{v} . As is customary in these types of variational formulations, there is a regularization parameter $\mu > 0$ that must be specified by the user in order to trade off the influence of each of the two terms. If μ is large, for example, then the resulting field will be very smooth and may not agree as well with the underlying edge gradients.

Theoretical Solution

Finding $\mathbf{v}(x, y)$ to minimize Equation (1) requires the use of calculus of variations since $\mathbf{v}(x, y)$ is a function, not a variable. Accordingly, the Euler equations, which provide the necessary conditions for \mathbf{v} to be a solution can be found by calculus of variations, yielding

$$\mu \nabla^2 u - (u - f_x) (f_x^2 + f_y^2) = 0, \quad (2a)$$

$$\mu \nabla^2 v - (v - f_y) (f_x^2 + f_y^2) = 0, \quad (2b)$$

where ∇^2 is the Laplacian operator. It is instructive to examine the form of the equations in (2). Each is a partial differential equation that the components u and v of \mathbf{v} must satisfy. If the magnitude of the edge gradient is small, then the solution of each equation is guided entirely by Laplace's equation, for example, $\nabla^2 u = 0$, which will produce a smooth scalar field entirely dependent on its boundary conditions. The boundary conditions are effectively provided by the loca-

tions in the image where the magnitude of the edge gradient is large, where the solution is driven to agree more with the edge gradients.

Computational Solutions

There are two fundamental ways to compute GVF. First, the energy function \mathcal{E} itself (1) can be directly discretized and minimized, for example, by gradient descent. Second, the partial differential equations in (2) can be discretized and solved iteratively. The original GVF paper used an iterative approach, while later papers introduced considerably faster implementations such as an octree-based method [7], a multi-grid method [8], and an augmented Lagrangian method [9]. In addition, very fast GPU implementations have been developed in [10, 11].

G

Extensions and Advances

GVF is easily extended to higher dimensions. The energy function is readily written in a vector form as

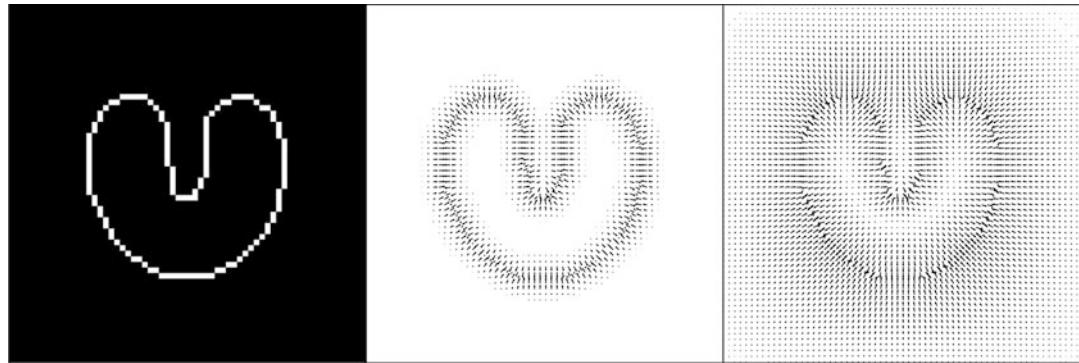

$$\mathcal{E} = \int_{\mathbb{R}^n} \mu |\nabla \mathbf{v}|^2 + |\nabla f|^2 |\mathbf{v} - \nabla f|^2 d\mathbf{x}, \quad (3)$$

which can be solved by gradient descent or by finding and solving its Euler equation. Figure 2 shows an illustration of a three-dimensional GVF field on the edge map of a simple object (see [12]).

The data and regularization terms in the integrand of the GVF functional can also be modified. A modification described in [13], called *generalized gradient vector flow* (GGVF), defines two scalar functions and reformulates the energy as

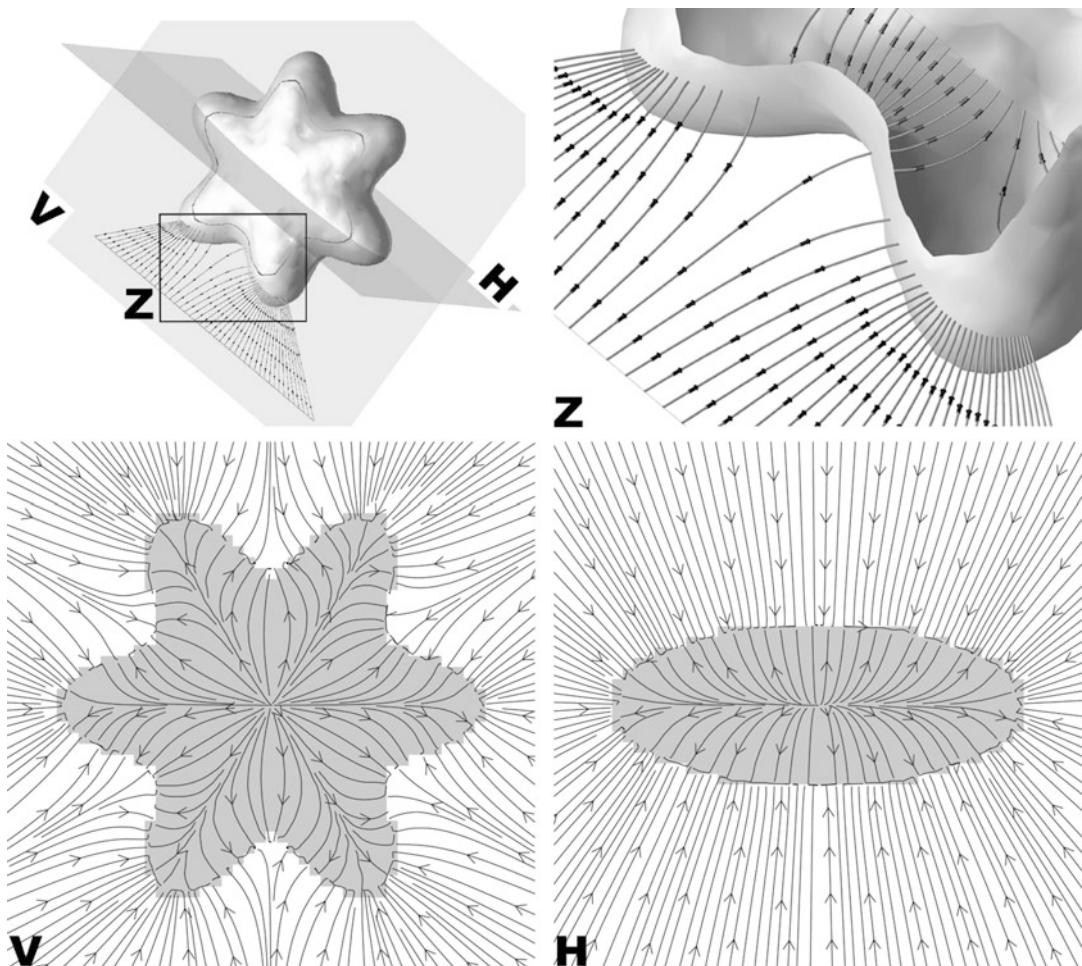

$$\mathcal{E} = \int_{\mathbb{R}^n} g(|\nabla f|) |\nabla \mathbf{v}|^2 + h(|\nabla f|) |\mathbf{v} - \nabla f|^2 d\mathbf{x}. \quad (4)$$

While the choices $g(\nabla f) = \mu$ and $h(\nabla f) = |\nabla f|^2$ reduce GGVF to GVF, the alternative choices $g(|\nabla f|) = \exp\{-|\nabla f|/K\}$ and $h(\nabla f) = 1 - g(|\nabla f|)$, for K a user-selected constant, can improve the trade-off between the data term and its regularization in some applications.

Gradient Vector Flow, Fig. 1 An edge map (left) describes the boundary of an object. The gradient of the (slightly blurred) edge map (center) points toward

the boundary but is very local. The gradient vector flow (GVF) field (right) also points toward the boundary but has a much larger capture range

Gradient Vector Flow, Fig. 2 The object shown in the top left is used as an edge map to generate a three-dimensional GVF field. Vectors and streamlines of the

GVF field are shown in the (Z) zoomed region, (V) vertical plane, and (H) horizontal plane

The GVF formulation has been further extended to vector-valued images in [14] where a weighted structure tensor of a vector-valued image is used. A learning-based probabilistic weighted GVF extension was proposed in [15] to further improve the segmentation for images with severely cluttered textures or high levels of noise.

The variational formulation of GVF has also been modified in *motion GVF* (MGVF) to incorporate object motion in an image sequence [16]. Whereas the diffusion of GVF vectors from a conventional edge map acts in an isotropic manner, the formulation of MGVF incorporates the expected object motion between image frames.

An alternative to GVF called vector field convolution (VFC) provides many of the advantages of GVF, has superior noise robustness, and can be computed very fast [17]. The VFC field \mathbf{v}_{VFC} is defined as the convolution of the edge map f with a vector field kernel \mathbf{k}

$$\mathbf{v}_{\text{VFC}}(x, y) = f(x, y) * \mathbf{k}(x, y), \quad (5)$$

where

$$\mathbf{k}(x, y) = \begin{cases} m(x, y) \left(\frac{-x}{\sqrt{x^2+y^2}}, \frac{-y}{\sqrt{x^2+y^2}} \right) & (x, y) \neq (0, 0) \\ (0, 0) & \text{otherwise} \end{cases} \quad (6)$$

The vector field kernel \mathbf{k} has vectors that always point toward the origin but their magnitudes, determined in detail by the function m , decrease to zero with increasing distance from the origin.

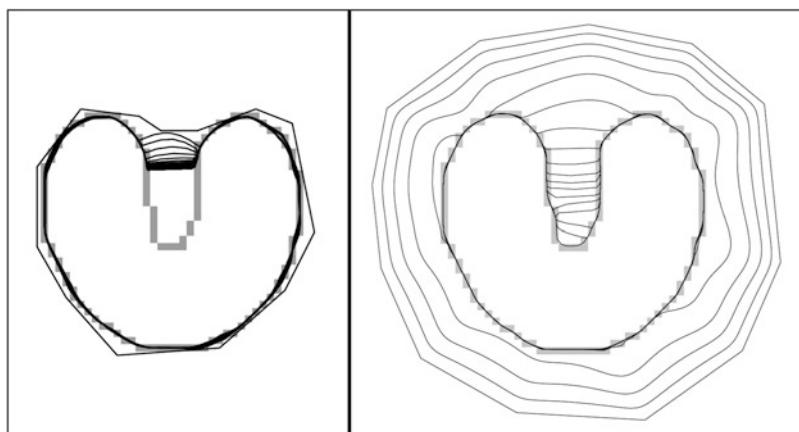

The beauty of VFC is that it can be computed very rapidly using a fast Fourier transform (FFT), a multiplication, and an inverse FFT. The capture range can be large and is explicitly given by the radius R of the vector field kernel. A possible drawback of VFC is that weak edges might be overwhelmed by strong edges, but that problem can be alleviated by the use of a hybrid method that switches to conventional forces when the snake gets close to the boundary.

G

Properties

GVF has characteristics that have made it useful in many diverse applications. It has already been noted that its primary original purpose was to extend a local edge field throughout the image domain, far away from the actual edge in many cases. This property has been described as an extension of the *capture range* of the external force of an active contour model. It is also capable of moving active contours into concave regions of an object's boundary. These two properties are illustrated in Fig. 3.

Previous forces that had been used as external forces (based on the edge map gradients and

Gradient Vector Flow, Fig. 3 An active contour with traditional external forces (left) must be initialized very close to the boundary, and it still will not converge to the true boundary in concave regions. An active contour using

GVF external forces (right) can be initialized farther away, and it will converge all the way to the true boundary, even in concave regions

simply related variants) required pressure forces in order to move boundaries from large distances and into concave regions. Pressure forces, also called balloon forces, provide a uniform force on the boundary in one direction (outward or inward) and tend to have the effect of pushing through weak boundaries. GVF can often replace pressure forces and yield better performance in such situations.

Because the diffusion process is inherent in the GVF solution, vectors that point in opposite directions tend to compete as they meet at a central location, thereby defining a type of geometric feature that is related to the boundary configuration, but not directly evident from the edge map. For example, *perceptual edges* are gaps in the edge map which tend to be connected visually by human perception [18]. GVF helps to connect them by diffusing opposing edge gradient vectors across the gap; and even though there is no actual edge map, active contour will converge to the perceptual edge because the GVF vectors drive them there (see [19]). This property carries over when there are so-called weak edges identified by regions of edge maps having lower values.

GVF vectors also meet in opposition at central locations of objects thereby defining a type of medialness. This property has been exploited as an alternative definition of the skeleton of objects [1] and also as a way to initialize deformable models within objects such that convergence to the boundary is more likely.

Applications

The most fundamental application of GVF is as an external force in a deformable model. A typical application considers an image $I(\mathbf{x})$ with an object delineated by intensity from its background. Thus, a suitable edge map $f(\mathbf{x})$ could be defined by

$$f(\mathbf{x}) = \frac{|\nabla(I(\mathbf{x}) * G_\sigma(\mathbf{x}))|}{\max_{\mathbf{x}} |\nabla(I(\mathbf{x}) * G_\sigma(\mathbf{x}))|}, \quad (7)$$

where G_σ is a Gaussian blurring kernel with standard deviation σ and $*$ is convolution. This

definition is applicable in any dimension and yields an edge map that falls in the range $[0, 1]$. Gaussian blurring is used primarily so that a meaningful gradient vector can always be computed, but σ is generally kept fairly small so that true edge positions are not overly distorted. Given this edge map, the GVF vector field $\mathbf{v}(\mathbf{x})$ can be computed by solving (2).

The deformable model itself can be implemented in a variety of ways including parametric models such as the original snake [18] or active surfaces and implicit models including geometric deformable models [20]. In the case of parametric deformable models, the GVF vector field \mathbf{v} can be used directly as the external forces in the model. If the deformable model is defined by the evolution of the (two-dimensional) active contour $\mathbf{X}(s, t)$, then a simple parametric active contour evolution equation can be written as

$$\gamma \dot{\mathbf{X}}_t = \alpha \mathbf{X}_{ss} - \mathbf{v}(\mathbf{X}). \quad (8)$$

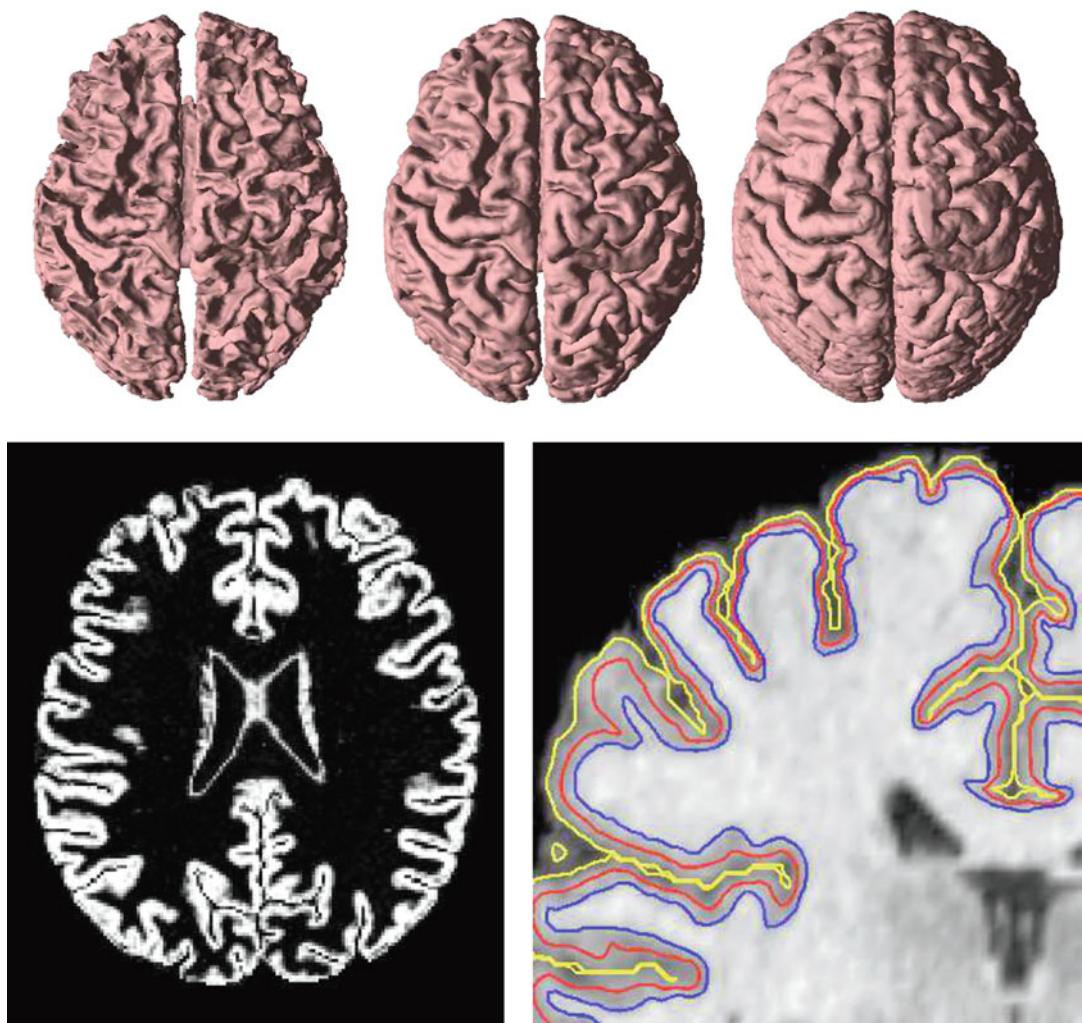

Here, the subscripts indicate partial derivatives and γ and α are user-selected constants.

In the case of geometric deformable models, then the GVF vector field \mathbf{v} is first projected against the normal direction of the implicit wave-front, which defines an additional speed function. Accordingly, then the evolution of the signed distance function $\phi_t(\mathbf{x})$ defining a simple geometric deformable contour can be written as

$$\gamma \dot{\phi}_t = \left[\alpha \kappa - \mathbf{v} \cdot \frac{\nabla \phi}{|\nabla \phi|} \right] |\nabla \phi|, \quad (9)$$

where κ is the curvature of the contour and α is a user-selected constant.

A more sophisticated deformable model formulation that combines the geodesic active contour flow with GVF forces was proposed in [21]. This paper also shows how to apply the Additive Operator Splitting Schema [22] for rapid computation of this segmentation method. The uniqueness and existence of this combined model were proven in [23]. A further modification of this model by using an external force term minimizing GVF divergence was proposed in [24] to

G

Gradient Vector Flow, Fig. 4 The inner, central, and outer surfaces of the human brain cortex (top) are found sequentially using GVF forces in three geometric deformable models. The central surface uses the gray matter membership function (bottom left) as an edge map

itself, which draws the central surface to the central layer of the cortical gray matter. The positions of the three surfaces are shown as nested surfaces in a coronal cutaway (bottom right)

achieve even better segmentation for images with complex geometric objects.

GVF has been used to find both inner, central, and outer cortical surfaces in the analysis of brain images [3], as shown in Fig. 4. The process first finds the inner surface using a three-dimensional geometric deformable model with conventional forces. Then the central surface is found by exploiting the central tendency property of GVF. In particular, the cortical membership

function of the human brain cortex, derived using a fuzzy classifier, is used to compute GVF as if itself were a thick edge map. The computed GVF vectors point toward the center of the cortex and can then be used as external forces to drive the inner surface to the central surface. Finally, another geometric deformable model with conventional forces is used to drive the central surface to a position on the outer surface of the cortex.

Several notable recent applications of GVF include constructing graphs for optimal surface segmentation in spectral-domain optical coherence tomography volumes [4], a learning-based probabilistic GVF active contour formulation to give more weights to objects of interest in ultrasound image segmentation [15], and an adaptive multi-feature GVF active contour for improved ultrasound image segmentation without hand tuned parameters [25].

Definition

Hand pose estimation is the process of estimating the 2D/3D positions of hand keypoints from a visual input, typically a single depth image or a single monocular RGB image.

Background

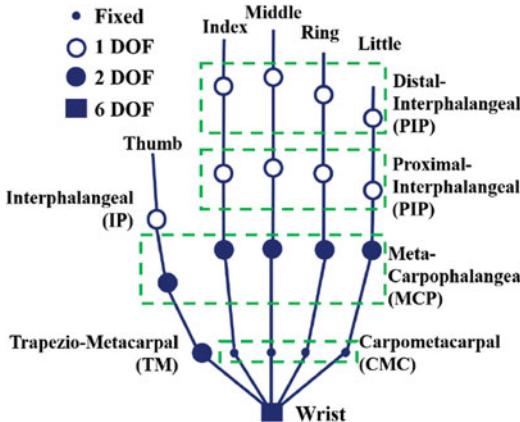

Vision-based hand pose estimation is a very important problem in computer vision and has

been studied for over 20 years since it is one of the core technologies for human computer interaction, especially in virtual reality and augmented reality applications [11, 16, 17]. For example, articulated 3D hand pose estimation provides a natural way for users to interact with virtual environments and virtual objects [3]. The estimated hand pose can also be used for hand gesture recognition.

Although hand pose estimation has aroused a lot of research attention in recent years, it is still challenging to achieve efficient and robust performance. First, estimating 3D hand pose from depth images is a high-dimensional and nonlinear regression problem. Due to the high-dimensional space of the hand pose parameters, it is difficult to find the optimal hand pose, and the mapping between the input image and the 3D hand pose is highly nonlinear. Second, hand pose in a single image often suffers from severe self-occlusion problem. Some parts of the hand may be occluded by other parts of the hand in a single image, which makes the estimation of 3D hand pose ambiguous. Third, articulated hand pose exhibits large variations due to the local and global hand motion.

Theory and Application

Hand pose estimation aims at estimating a set of 3D hand joint locations representing the 3D hand pose. The skeleton structure of the hand is shown in Fig. 1. As shown in this figure, the thumb finger

Hand Pose Estimation, Fig. 1 Hand skeleton structure defined in [2]. The thumb finger has 5 DOF; each of the other four fingers has 4 DOF; the wrist joint has 6 DOF

has 5 degrees of freedom (DOF), including 1 DOF for interphalangeal (IP) joint, 2 DOF for metacarpophalangeal (MCP) joint, and 2 DOF for trapeziometacarpal (TM) joint. Each of the other four fingers has 4 DOF, including 1 DOF for distal interphalangeal (DIP) joint, 1 DOF for proximal interphalangeal (PIP) joint, and 2 DOF for MCP joint, while the carpometacarpal (CMC) joints are fixed. The wrist joint has 6 DOF for global translation and rotation. Thus, the hand skeleton model has 27 DOF in total.

Methods for vision-based hand pose estimation can be categorized into generative approaches, discriminative approaches, and hybrid approaches.

Generative approaches fit an explicit deformable hand model to the input image by minimizing a hand-crafted cost function. The commonly used optimization methods are particle swarm optimization (PSO), iterative closest point (ICP), and their combination [10]. Many hand models have been proposed, as shown in Fig. 2. Oikonomidis et al. [9] propose a polygonal mesh hand model using geometric primitives. Qian et al. [10] approximate the 3D hand model using 48 spheres. Melax et al. [8] propose to use a rigid body representation of the hand model. Taylor et al. [13] create the hand model based on linear blend skinning and approximate loop subdivision. Tkach et al. [14]

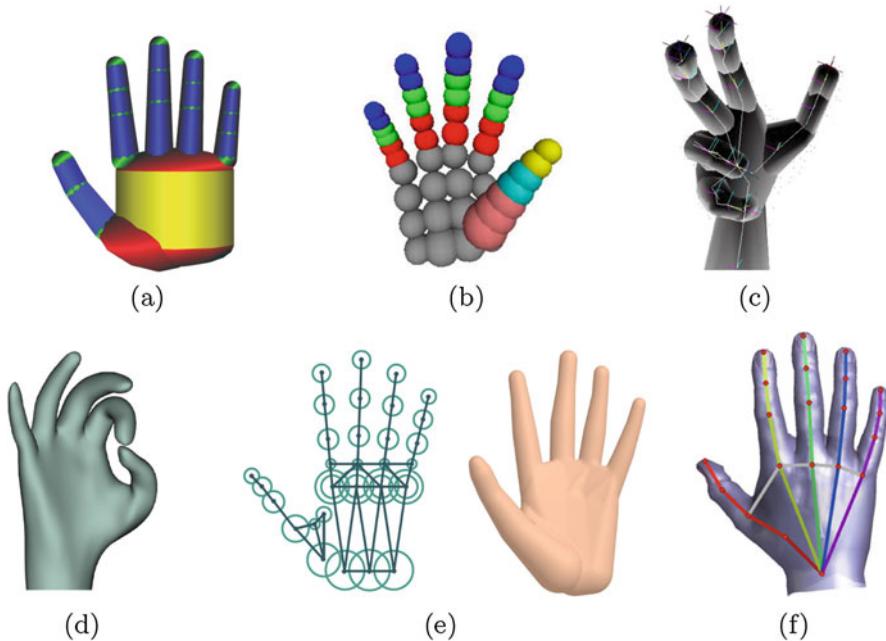

propose to use sphere meshes as the 3D hand model. Joo et al. [6] use a rigged hand mesh as the hand model for total capture of human.

Discriminative approaches learn a mapping from depth image to hand pose from training data. Some early works focus on example-based method that searches the most similar images in a dataset to the input hand image, but cannot work well in high-dimensional space. Some methods apply random forests and their variants as a discriminative model. Xu and Cheng [18] propose to use the random forest to directly regress the hand joint angles from depth images, in which a set of spatial-voting pixels cast their votes for hand pose independently and their votes are clustered into a set of candidates. The optimal one is determined by a verification stage with a hand model. Liang et al. [7] propose to apply Hough forest in hand pose estimation. The vote weights stored at the leaf nodes of a forest are learned to minimize average pose estimation error.

Some other approaches combine the model-based fitting and the data-driven methods in order to take advantages of both methods. Sharp et al. [12] infer hand pose using a multilayered discriminative model and optimize the hand pose by a model fitting stage based on the particle swarm optimization.

With the success of deep neural networks in various computer vision tasks and the emergence of large hand pose datasets [15, 19], many of the recent methods applied convolutional neural networks (CNNs) as the discriminative model for 3D hand pose estimation. Tompson et al. [15] first propose to apply CNNs to generate heat maps representing the 2D probability distributions of hand joints in the depth image and recover 3D hand pose from estimated heat maps and corresponding depth values using model-based inverse kinematics. Ge et al. [3] propose to encode the hand depth images as 3D volumes and apply 3D CNNs for inferring the 3D hand pose. A PointNet-based method [5] is proposed to estimate 3D hand pose directly from 3D point cloud.

Deep learning methods have also been recently adopted for 3D hand pose estimation from monocular RGB images [1, 4, 20]. Different from depth images that contain absolute depth

information, single-view RGB images exhibit inherent depth ambiguity, which makes 3D hand pose estimation from monocular RGB images a challenging problem. Most of recent methods estimate root-relative and scale-invariant 3D hand pose from monocular RGB images. Zimmermann et al. [20] proposed a deep network that learns an implicit 3D articulation prior of hand from single RGB images. Cai et al. [1] proposed a weakly supervised method, adapting from fully annotated synthetic dataset to weakly labeled real-world dataset with the aid of a depth regularizer.

Open Problems

Although much progress has been made in 3D hand pose estimation, there are still many research problems in this field that need to be resolved, e.g., hand pose estimation from hand-object or hand-hand interactions and hand pose tracking in videos.

► Camera Calibration

Definition

The hand-eye calibration problem first appeared and got its name from the robotics community, where a camera (eye) was mounted on the gripper (hand) of a robot. The camera was calibrated using a calibration pattern. Then the problem of identifying the unknown transformation from the camera to the hand coordinate system is known as the hand-eye calibration.

Background

There is a strong need for an accurate hand-eye calibration. The reasons are twofold: (i) to map sensor-centered measurements into the robot-world coordinate and (ii) to allow for an accurate prediction of the pose of the sensor on the basis of the arm motion – in fact these

are often complementary aspects of the same problem [1].

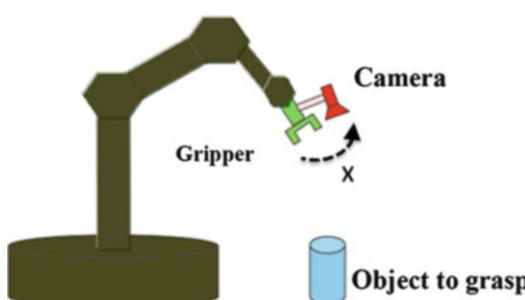

Theory

A typical hand-eye structure is shown in Fig. 1, where a camera is rigidly mounted on the gripper of the robot. In Fig. 1, \mathbf{X} , a 4×4 matrix, denotes the Euclidean transformation between the hand coordinate system and the camera coordinate system, i.e., the hand-eye calibration. Roughly speaking, the hand-eye calibration methods can be divided into two categories: one is to decompose the matrix \mathbf{X} into its rotational and translational parts then optimize the rotation at first, followed by an optimization for the translational part. The other is to optimize the rotation and translation simultaneously.

The standard approach to hand-eye calibration relies on (i) a known reference object and (ii) the possibility to reliably track points on this reference object in order to obtain corresponding points between pairs of images. As shown in Fig. 2, \mathbf{A} , \mathbf{B} , \mathbf{C} , and \mathbf{D} are Euclidean transformation matrices between different coordinate systems, which can be represented by a 4×4 homogeneous matrix as

$$\begin{bmatrix} \mathbf{R} & \mathbf{t} \\ \mathbf{0}^T & 1 \end{bmatrix} \quad (1)$$

where \mathbf{R} is a 3×3 rotation matrix and \mathbf{t} is a 3×1 vector. Matrix \mathbf{A} denotes the transformation between the first and second position of the robot

Hand-Eye Calibration, Fig. 1 A camera (eye) mounted at the gripper (hand) of a robot

hand (also known as tool center point motion, TCP motion), which could be read out from the robot controller. Since the camera is calibrated beforehand, the transformation matrices \mathbf{C} and \mathbf{D} are assumed known, then the motion of the camera, \mathbf{B} , can be expressed as

$$\mathbf{B} = \mathbf{CD}^{-1} \quad (2)$$

From this we have the basic equation of the hand-eye calibration as

$$\mathbf{AX} = \mathbf{XB} \quad (3)$$

H

A number of approaches have been proposed for the determination of the hand-eye calibration matrix \mathbf{X} from Eq. (3). Here is a brief historical development of the approaches.

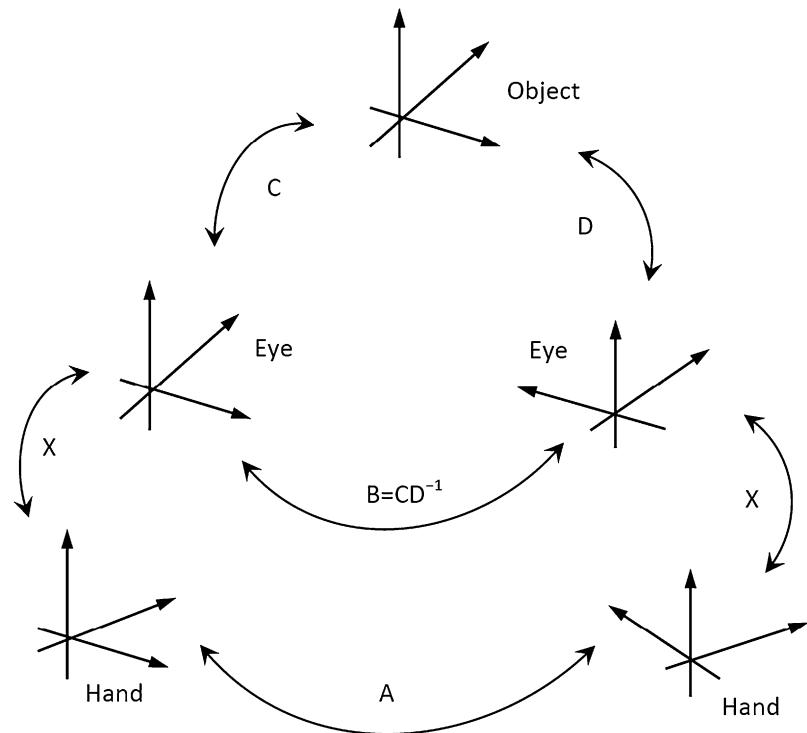

1980s

Early solutions decoupled the rotational part of \mathbf{X} from the translational one, yielding some simple, fast, but error-prone formulations, since rotation estimation errors could propagate to the translational part. Shiu et al. [2] used angle-axis representation and least-squares fitting to calculate the rotation then the translation. Tsai et al. [3] gave a closed-form solution using a more efficient linear algorithm. The number of unknowns in their method is unchanged no matter how many measurements are available. Wang [4] compared [2, 3] with real data and showed that [3] is slightly better than [2].

1990s

Zhuang et al. [5] extended and simplified part of the results in [2] by reformulating the solutions for the rotational part of the homogeneous transform equation as a quaternion equation. Chou et al. [6] presented another quaternion-based approach where a closed-form solution is obtained using the generalized inverse method with singular value decomposition (SVD). Based on the concept of *screw motion*, Chen [7] did not decouple rotational and translational terms for the first time. Zhuang et al. [8] applied

Hand-Eye Calibration,
Fig. 2 Standard approach
of hand-eye calibration

nonlinear optimization directly for \mathbf{X} estimation by minimizing a similar expression to the Frobenius norms of homogeneous matrices of transformation errors. Park et al. [9] performed nonlinear optimization in the same way but again under the decomposed formulation. Lu et al. [10] introduced the eight-space formulation based on quaternions and derived a closed-form least-squares solution using Schur decomposition and Gaussian elimination. Horaud et al. [11] solved simultaneously for rotation and translation using Levenberg–Marquardt technique. Ma [12] gave a linear approach for camera self-calibration and head–eye calibration by controlling the camera platform to undertake at least three orthogonal motions. It is the first approach to combine both camera self-calibration and hand-eye calibration based on active vision concept. Wei et al. [13] nonlinearly minimized algebraic distances and performed a fully automatic hand-eye and camera calibration. Daniilidis [14] introduced the dual quaternions – an algebraic representation of the screw theory to describe motions, which makes

it possible to find a fast SVD-based joint solution for rotation and translation.

2000s

Bayro-Corrochano et al. [15] gave an SVD-based linear solution of the coupled problem by the use of motors within the geometric algebra framework. Andreff et al. [16] combined structure from motion with known robot motions for the calibration. They did not enforce the nonlinear orthogonality constraint by increasing the dimensionality of the rotational part and managed to formulate the problem as a single homogeneous linear system. Fassi et al. [17] investigated the standard equation using a geometrical approach and gave some new properties of the equation. Fassi et al. highlighted the reason of over-constrained system when multiple instances of the equation are to be solved simultaneously. Schmidt et al. [18] presented a calibration approach which, in contrast to the standard method, does not require a calibration pattern for determining camera position and orientation.

Application

Hand-eye calibration is useful in many industrial applications, for instance, grasping objects, visual servoing, robot navigation, et al. For example, in robot-assisted endoscopic surgery [19], the hand-eye transformation has to be estimated every time when the camera head is mounted anew on the endoscope optics, which is done before each operation because it has to be sterilized. Therefore, an automatic and robust hand-eye calibration algorithm is both desirable and welcome.

Hashing for Face Search

Svebor Karaman and Shih-Fu Chang
Columbia University, New York, NY, USA

Synonyms

[Binary coding for face retrieval](#)

Definition

Hashing is the process of compressing a given input real-valued feature representation into a binary code of a relatively small number of bits. For the application of face search with deep features, it corresponds to encoding a feature extracted from a deep learning-based face recognition model into a binary representation with the

goal of maintaining most of the retrieval ability of the original representation.

Background

The state-of-the-art face recognition methods represent a face image as a high-dimensional real-valued feature, obtained using a deep network. However, comparisons of this high-dimensional feature can be computationally expensive. Furthermore, when dealing with large face images database, this representation can lead to prohibitive storage requirements. Thus, the goal of hashing for face search is mainly to:

- Lower the memory consumption: hashing is a way to produce a compact representation, and thus a larger face database can be stored on a single machine;
- Speed-up the comparison: Hamming distance computation directly over the binary codes can be performed very efficiently thanks to low-level instructions;
- Reduce the cost of transmission of the features over bandwidth constrained networks like wireless.

There has been comprehensive surveys of compact hashing for large-scale retrieval [1], but they did not address the unique challenges of face recognition. Recently, [2] has explored the problem of hashing a face, and some of the discussions reported in this article are based on this work. A face search application with hashing is illustrated in Fig. 1.

Hashing a face representation is especially challenging as the problem of face recognition can be seen as a fine-grained recognition problem, as all faces share similar structure and the difference between two identities can be very subtle. Besides, different face images of the same individual can exhibit very high level of variations due to change of pose or viewing angle, lighting condition, variations of expressions, etc. A face image can be a partial observation, with

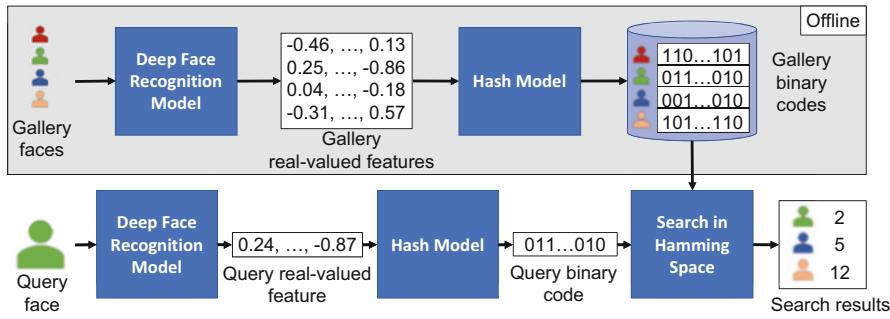

parts of the face being occluded by other persons or objects in the scene. These face images can be captured as a single shot but also as a video, therefore inducing motion blur and other capture artifacts.

Thus, recent face image representations tend to be highly specialized and discriminative features, often heavily learned and optimized from a large amount of data. As intra-class variations may be larger than interclass differences, the face recognition problem creates very challenging conditions to learn a hashing model that is able to produce a compact binary representation that is still effective for the face search task. We therefore assume here that the face representation is highly discriminative, and our goal is to train a hashing model, given a set of face features but no identity labels that can produce medium length (128 to 1024 bits) binary hash codes to maintain a face search performance similar to that obtained with the original features.

Theory

The task of hashing a face representation can be formalized as follows. A dataset \mathcal{S} is composed of N faces samples $\{s_i\}_{i=1\dots N}$. We denote the d -dimensional feature representation of the face sample s_i as the row vector $\mathbf{x}_i \in \mathbb{R}^d$, and $\mathbf{X} \in \mathbb{R}^{N \times d}$ is the feature matrix of all samples. A hashing model H with parameters Θ maps \mathbf{x}_i to a binary code of length b , i.e., $H(\mathbf{x}_i, \Theta) = \mathbf{h}_i \in \mathbb{B}^b$ and the full feature matrix to $H(\mathbf{X}, \Theta) = \mathbf{H} \in \mathbb{B}^{N \times b}$. The binary space \mathbb{B} can technically be either $\{0, 1\}$ or $\{-1, 1\}$ for different methods, but there is obviously a strict equivalence between these two choices. We can see the hash model H as a set of b hash functions, i.e., $H = \{f_j\}_{j=1\dots b}$ each having a set of parameters Θ_j . The j^{th} bit h_{ij} of \mathbf{h}_i is obtained by applying the j^{th} hash function f_j of H to the feature, i.e., $h_{ij} = f_j(\mathbf{x}_i, \Theta_j)$.

Many different strategies can be employed to estimate the hashing model parameters Θ . We briefly review in the next few paragraphs the most relevant hashing methods of the literature for the application of face search. We refer the reader to

Hashing for Face Search, Fig. 1 Illustration of a face search application with hashing. Offline, given a gallery of face images, their features are computed with a deep model and compressed into binary codes with a hash model. At test time, given a query face image, its feature

is extracted and compressed, and the search is performed by comparing the binary codes in the Hamming space to retrieve the most relevant samples (with smallest distances as shown above) from the database

the survey [1] for a more complete overview of learning-based hashing methods in general and to [2] for more detailed discussions on hashing for face verification and search.

One popular hashing method is locality-sensitive hashing (LSH) [3] which is data-independent with interesting asymptotic theoretical guarantees. The idea of LSH is to define a family of hash functions that ensures that “similar” samples are more likely to be mapped to the same hash code. One common strategy is to sample random projections and thresholds to define the hash functions. LSH approaches often require long hash codes and potentially multiple hash tables to produce reasonable retrieval performance.

To overcome these limitations, more recent hashing methods learn the hash functions from the data. The iterative quantization (ITQ) method [4] minimizes the quantization error obtained when directly encoding the sign of a principal component analysis (PCA)-based projection. The optimization process seeks a rotation matrix that minimizes the quantization error of the projected features. ITQ has been shown to be competitive, especially compared to other PCA-based hashing methods. However, it is limited to produce binary codes no longer than the original features dimension.

Learning the hash functions from the data can enable selecting more effective hash functions. However, any hashing method relying on the sign

of linear projections will have limited discriminative ability. Therefore, several hashing methods have been proposed that rely on nonlinear hash functions. Specifically, one common idea of such methods is to sample the feature space to obtain a set of “pivot” or “anchor” points. Then, similarities or distances with regard to these pivots are exploited to define the hash functions.

The Neighbor-Sensitive Hashing [5] (NSH) method aims to avoid using hash bits to capture the distances between samples that are far apart. The key element of the NSH approach is what the authors call a Neighbor-Sensitive Transform (NST) that is a continuous and monotonic function that produces “larger gaps” in a given range of distances. The hash functions are learned as random orthogonal projections in the embedded space induced by NST functions applied to the distances between a sample and the pivot points.

The spherical hashing (SpH) method introduced in [6] proposes to define hashing functions not as hyperplanes but as hyperspheres, based on a set of pivots as centers of the hyperspheres and associated distance thresholds. The optimization aims to get independent and balanced hashing functions, by iteratively optimizing the hypersphere centers position in space and the threshold values. The theoretical advantage of using hyperspheres for hashing is that matched hash codes can correspond to closed regions with tight distance bounds.

Finally, the Unsupervised Rank Preserving Hashing (URPH) method [7] aims to optimize the hash model to produce hash codes that preserve the ranking obtained using the original features. A shallow neural network is optimized with a gradient descent approach to minimize a ranking loss and regularization losses. The optimization is therefore directly targeting the final usage of the hash codes, i.e., being able to properly rank the samples using the binary codes.

Application

The task of face search is of, given a query face image, finding the most similar face images in a large database of face images. One of the typical use cases would be a watch list situation, where the database holds a list of missing or wanted persons, and queries are face images of persons of interest.

If some query images do not have a match in the gallery, the task is named an open-set identification. In that case, a good face recognition system should still retrieve the most similar samples from the gallery, but they should have a low similarity score. Thus, a filtering approach based on the similarity score should enable flagging the probe as having no match in the gallery.

Experimental Results

IJB-C Dataset The IJB-C [8] dataset was developed with the goal of pushing the limits of face recognition, especially targeting the unconstrained setting. It contains 31,334 images and 11,779 videos of 3,531 subjects. This data has been collected with the goal of covering a wide set of occupations and geographic origins. This dataset has two gallery sets containing 1,772 and 1,759 subjects, respectively, with a template of about 5 images defined for each subject. There is a probe set of 19,593 templates, build from both still images and video frames, and one subject may have multiple probe templates. There is no pre-defined training set, and we rely on the UMD faces [9] dataset, which is composed of

a distinct set of identities, to train all hashing models.

Experimental Settings We use the RAG1 feature that is extracted from the bottleneck layer of a resNet-101 network as detailed in [10]. This model is trained on a dataset containing over 5 millions of images of about 58,000 subjects. Furthermore, the RAG1 feature is embedded into a real-valued 128-dimensional space using the Triplet Probabilistic Embedding (TPE) approach [11]; we will refer to this embedded version as ERAG1. The features are extracted and embedded with TPE for each face image in a template, face images coming from different frames of the same video are first averaged into a media-averaged feature, and then all media-averaged features and still images features are averaged to define the template feature. The features are L2-normalized. In the following, we will compare the performance of the NSH, SpH, and URPH methods. We report the search performance averaged over the two galleries.

Face Search Results We compare the search results on the IJB-C dataset in Table 1, with the best hashing results in bold. For each probe sample, a ranked list of the most similar samples (estimated based on the Hamming distance for hashing methods) in the gallery is retrieved. We compute the retrieval rate as the portion of probe samples for which we have correctly retrieved a matching gallery sample within a given rank. We report the original features performance (using the Euclidean distance to rank the samples) in the last line of the table for reference. We can observe that the original continuous-valued ERAG1 feature achieves a very high level of face search performance, with retrieval rates of 0.945 and 0.975 at rank 1 and 10, respectively. The SpH [6] method needs at least 512 bits to achieve a retrieval rate of 90% at rank 1. Limited improvements are observed when further increasing the hash code length to 1024 bits. The NSH [5] methods obtain a better performance with a retrieval rate of 90% at rank 1 using only 256 bits. With 1024 bits, NSH achieves a retrieval rate of 0.933 at rank 1 and 0.961 at rank 5 which

Hashing for Face Search, Table 1 Face search results on IJBC.

| Method | # bits | Retrieval rate at rank # | | | | | | |

is very close to 0.968 using the original features. The URPH [7] method performs the best of all hashing methods, obtaining retrieval rates that are very close to the original features performance when using 1024 bits. The retrieval rate at rank 1 with just 128 bits is almost 90%. This confirms by direct optimization for the retrieval task that a hashing method such as URPH can achieve highly effective performance.

Open Problems

Recently, small-world graph-based indexing methods [12] have gained popularity due to their high level of performance and close to logarithmic complexity when solving the approximate nearest neighbors (ANN) search problem. Thus, studying the combination of hashing with advanced graph-based indexing scheme is an interesting problem. The authors of [7] explore the use of rank-preserving hashing combined with small-world graph-based indexing, demonstrating that this combination can achieve excellent performance in terms of search speed and accuracy while enabling storing a large number of database samples thanks to the compression induced by the use of hashing.

For some applications it may be interesting to combine multiple features to achieve the best performance. Therefore, the question of how to fuse multiple features in a hashing framework

is worth investigating. Three strategies could be explored: (i) an early fusion where the features are concatenated and hashed as if they were just one feature; (ii) an intermediate fusion strategy, especially applicable to pivot-based hashing methods, where the distances or similarities between a sample and the pivots in the different feature spaces are aggregated; and (iii) a late fusion strategy where each feature is hashed independently, but the hamming distances obtained in each binary space, induced by each hash model, are combined for the final task.

Definition

High dynamic range (HDR) imaging comprises a range of techniques for capturing, storing, editing, transmitting, and displaying images and video with an extended range of values between black and white, compared with traditional imaging techniques. This means that HDR images can be better representations of real scenes than conventional photographs, bringing associated enhanced realism and visual quality.

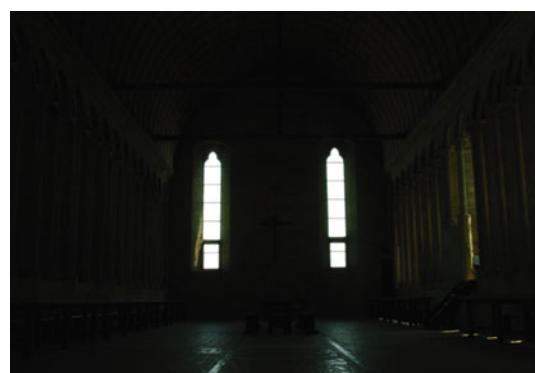

Introduction

Light levels to which humans are routinely exposed range from dim starlight to bright sunlight. While human vision cannot resolve detail over this enormous range simultaneously, through adaptive processes active in the visual system, humans can interpret and navigate through scenes that range from 10^{-6} to 10^8 cd/m^2 [1]. This represents a range of illumination spanning around 14 orders of magnitude (log units). At any one time, the human visual system can resolve detail over a range of about 3.7 orders of magnitude [2].

Conventional technologies for capturing, processing, and displaying images are more limited, in that they typically use image data spanning no more than 2 orders of magnitude of range between black and white. Such technologies, referred to as low dynamic range (LDR) or standard dynamic range (SDR) imaging, typically represent pixel data with a

bit depth of 8 nonlinearly encoded bits. This has several practical implications. First, it is easier to build sensors and display devices. Second, the demands on storage and transmission are limited.

On the other hand, SDR images do not match the capabilities of human vision. As a consequence, there is room for improvement, which is the *raison d'être* of HDR imaging. The aim of the latter is to represent a larger range of luminance values. It is often combined with employing a wide color gamut such as defined in ITU-R Recommendation BT.2020 [3], so that the range of chroma values is also increased. HDR images often look significantly more realistic than corresponding SDR images. Some researchers have remarked that HDR images, when viewed on an HDR display, evoke a sensation of realism that is not present in SDR images, akin to looking through a window [4]. Thus, HDR imaging offers a real enhancement in image quality over SDR imaging. As an example, Fig. 1 (left) shows an image taken from a scene using standard digital photographic techniques. The image on the right shows the same scene, obtained with HDR capture techniques, and subsequently tone mapped. This image is arguably a better representation of the scene than the image on the left. HDR technologies have reached a level of maturity sufficient for market introduction.

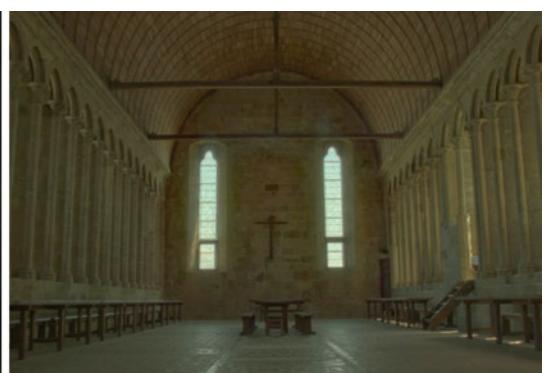

High Dynamic Range Imaging, Fig. 1 Left: a single capture of a challenging scene, whereby most pixels are either under- or overexposed. Right: an image captured

History

The first digital images originated from scanning photographs. One of the first such images is shown in Fig. 2, where multiple binary scans were merged to obtain a digital grayscale image. By 1968, scanning technology was able to produce 12-bit images directly [5], even if the resulting images were stored in a logarithmic format while keeping the 9 most significant bits. At the time, these images could be exponentiated to control a vector graphics display with 8-bit precision [5]. Note that in this case, the difference between capture and display bit depth is 4 bits. Thus, to be able to display the images, their dynamic range had to be reduced: in essence, removing the n least significant bits can be seen as an early form of dynamic range reduction, which is also known as tone mapping or tone reproduction (see the section on “Tone Management” below).

From that moment, a trickle of research papers emerged that broadly addressed the problem of tone reproduction, starting in 1972 [6]. In 1984, this topic was used to introduce computer graphics to the field of lighting design [7]. Computer graphics became a fertile ground for research on HDR imaging, as rendering algorithms naturally produce high dynamic range images which require tone mapping prior to display [8]. The Radiance rendering software, for example, [9], which was first released in 1987, included a HDR image file format which was used widely.

with HDR techniques and subsequently processed for display. This image resembles the actual scene much more accurately

High Dynamic Range Imaging, Fig. 2 One of the first digital photographs, scanned by Russell Kirsch at the National Institute of Standards and Technology (NIST) in 1957. (From https://en.wikipedia.org/wiki/Russell_A._Kirsch; this image is in the public domain)

Due to limitations in sensor design, digital photography was not able to natively produce HDR images. However, multiple image captures from the same vantage point, while varying the exposure time, allow an extended range to be captured. In a post-processing step, the individual captures are merged to form the final HDR image [10]. This has broadly solved the problem of image capture of static scenes without the need for upgrading capture hardware. With this method, however, scenes with movement are difficult to capture without additional processing, as outlined in the “Capture” section below.

The availability of HDR image data has then opened up the possibility to use that data inside a renderer as complex spatially varying illuminants [11]. The visual quality of computer-generated imagery has thus greatly improved, paving the way for a large array of special effects.

Research into HDR imaging picked up pace dramatically in 2002, when a batch of papers once again addressed the problem of tone reproduction [12–15].

Direct display of HDR imagery became a reality in 2003 when the first HDR display system was demonstrated [16]. HDR camera systems followed in 2001 [17]. The first standards governing HDR video transmission appeared in 2014, paving the way for HDR broadcast systems [18–20]. HDR cinema projection systems have been demonstrated [21], while HDR movie cameras are now a reality. For those wishing to experiment with HDR images and videos, there are several resources available online, including the HDR Photographic Survey [22], a database of cinematic HDR video sequences [23] and a dataset of test materials for the assessment of picture quality [24].

Capture

To capture a high dynamic range image, a common technique is to take several photographs from the same vantage point, usually by employing auto-bracketing, resulting in a sequence of SDR exposures obtained with different exposure times. The difference between each successive exposure may, for example, be 1 *f*-stop apart. The idea is that each part of the scene will be well exposed in at least one of the exposures.

In a post-process, the exposures are then combined into an HDR image [10]. This requires knowledge of the camera response curve, i.e., the nonlinear relationship between scene light and pixel value. Each exposure is first linearized by applying the inverse camera response curve and then scaled by its exposure time. A windowing function may then be applied to reduce the effect of noise in underexposed pixels and the lack of information in overexposed pixels. After that, the exposures are simply averaged to produce the HDR image.

In the presence of noise, further noise removal may be applied [25]. Image alignment may be required to account for movement of the camera [26], especially when the camera was handheld. If objects move while the exposures are taken, then the averaging process may result in ghosting. Detection and elimination of such ghosting

artifacts has proven to be a challenging problem [27, 28].

Alternatively, the exposures may be merged into an SDR image, albeit one with more detail and information than any of its constituent exposures. This is a process called exposure fusion [29].

Rather than recording several exposures one after the other, cameras may be constructed that divert light to multiple sensors using beam splitters [17]. Optical filters may optionally be applied to attenuate the light reaching each sensor differently. The advantage of such an approach is that no ghosting or alignment issues are present and that the achievable video frame rate is not reduced due to the capture of multiple exposures.

Tone Management

HDR and SDR technologies will coexist for the foreseeable future. This means that SDR content may be displayed on HDR displays, and HDR content may have to be displayed on SDR displays. A significant amount of research has been devoted to develop perceptually plausible algorithms that map HDR data to SDR levels [30] – a process known as tone mapping or tone reproduction. The mapping of SDR data to HDR levels is known as inverse tone mapping or inverse tone reproduction [31].

Tone reproduction often includes a nonlinear mapping which can be applied identically to all pixels of an image. By attenuating light pixels more than dark pixels, a range reduction can be achieved that matches human visual experience well [30]. Especially sigmoidal (s-shaped) tone mapping functions are close to the static behavior of photoreceptors [32].

In addition, spatially varying processing may be applied to locally increase contrast, although such procedures tend to be computationally much more costly. Spatially varying operators that relate to human visual perception include Retinex processing [33], image appearance models [34–36], and a display-adaptive tone reproduction operator [37].

A variety of other tone reproduction operators are known, including those based on bilateral filtering [13], gradient domain processing [14], and histogram adjustment [38].

Mapping SDR data to HDR levels, also known as inverse tone reproduction or inverse tone mapping, has proven to be a viable approach to creating HDR data. Color grading in post-production studios now routinely involves the creation of HDR grades, and these are often produced with the aid of inverse tone reproduction tools. A key requirement of such tools is that the processing is semiautomatic, so that the results can be adjusted or edited by the colorist.

H

Quality Assessment

Image quality assessment can either be accomplished through visual inspection, through carrying out a psychophysical experiment, or by applying metric. For HDR images and video, visible difference predictors [39] and quality assessment metrics are available [40, 41], allowing the automatic assessment of differences between images and quality of video, respectively.

Encoding, Compression, and Standards

Currently, HDR images are often stored as EXR files [42], a file format developed by Industrial Light & Magic (See <http://www.openexr.com/>). The JPG XT image compression standard [43] includes support for HDR images, while the aforementioned Radiance format is supported through the JPEG XR format [44].

In (movie) production and post-production, HDR is nowadays routinely employed, for example, through the ACES format (See <https://www.oscars.org/science-technology/aces/aces-documentation>). Guidelines for live production are available as well [45].

For the transmission and broadcast of HDR video, a current approach is to preprocess the HDR video data so that it can subsequently be

compressed with a standard codec, such as AVC or HEVC. To this end, each video frame is first passed through a compressive curve, known as an optoelectronic transfer function (OETF). Such curves are not unlike tone mapping curves, albeit that they are not necessarily optimized to match human visual perception, but to maximize compression efficiency of any subsequent encoder. In practice, such curves may still be based on insights from human visual perception. Curves currently in use are the Perceptual Quantizer [46] (PQ) and Hybrid Log-Gamma [47], as standardized by ITU-R, SMPTE, and ARIB [18–20].

A receiver such as a television or a set-top box may then decode the signal before applying an electro-optical transfer function (EOTF). This function may be the mathematical inverse of the corresponding OETF (PQ systems operate in this manner), but it may incorporate further processing to adapt the signal to the capabilities of a specific display (HLG systems work like this).

An alternative to encoding HDR video, while enabling backward compatibility, is to augment SDR video data with dynamic metadata that allows a receiver to reconstruct HDR video data [48]. Thus, a receiver not able to decode the metadata will simply display the SDR video, while an HDR-enabled television would be able to reconstruct HDR video and adapt it to its own capabilities. This approach is standardized by ETSI [49].

Provisions for the transmission of HDR are made in various other standards, including ATSC 3.0, DVB, and in China.

While broadcasters are implementing HDR broadcast channels, currently HDR video content can be enjoyed by consumers through streaming applications, as well as through Ultra HD Blu-ray disks, provided they have access to an HDR-capable television and Blu-ray player.

Discussion

High dynamic range imaging offers an improved range of light levels between black and white, creating a higher visual quality. Research has found solutions for most if not all of the problems

associated with high dynamic range imaging and video. Standardization and industry adoption are in an advanced state of progress, so that HDR will be broadly available soon.

Definition

The central objective of a computer vision task is to perceive visual data and develop a response. Various processes take place in the *data to decision* chain. High-performance computing refers to the capacity to achieve a computational task at the required fidelity with minimal resources including time and endurance. Recent explosive growth in video cameras and the resulting ubiquity of visual data broaden the scope of high-performance computer vision well beyond robotics and automation. It is difficult to crisply separate the processing and perception mechanisms underlying this chain. Inspired by neural information processing in the visual system, they are often broadly grouped as: low-level vision, intermediate-level vision, and higher-level vision. Low-level vision entails very simple computations applied at each pixel and its immediate neighborhood. Examples include edge detection, texture, order statistics, and optical flow. Intermediate-level analysis is concerned with local and regional consistencies including coherence. Examples include contour tracing, connected component labeling, and Hough transforms. These accumulative methods

do not fully capture certain evidence driven assimilative processes, where one or more salient features detected in the scene steer the evidence gathering low-level primitives over the rest of the image. Under special circumstances, the low-level and intermediate-level vision are coupled in an iterative style, giving rise to a recursive model of perceptive processing. Examples include, optimal placement of edges, deformable templates, subjective contours, and extraction plus grouping of gestalts. Higher-level processes are defined and analyzed from a broader perspective, facilitating a net perception sufficient to achieve detection, recognition, localization, association, prediction, etc. They drive complex applications such as super resolution, segmentation, reconstruction, object recognition, content-based image retrieval, tracking, etc.

Background

Abstract model of computation is comprised of an arithmetic and logic unit (ALU) to perform a primitive operation, an access mechanism to fetch or modify or the operands without imposing limit on the size of the data set or program, ability to concurrently maintain multiple independent intermediate results impacting the course of execution, and the richness of its instruction set. Parallel computing, pipelined processing, and application-specific hardware including heterogenous and reconfigurable processors have all been demonstrated as a means to achieve high performance. We will focus our discussion on approaches to achieve high performance in computer vision.

Distinct types of parallel computing models are used to characterize the overall computation required for computer vision: data level parallelism, cooperating concurrent processes, and competing concurrent threads with and without mutual preemption. Computations for low-level vision would follow data parallelism and are efficiently implemented using specialized designs including reconfigurable and pipelined processors to perform vector, block, and stream

operations. Modern general purpose graphic processing units (GPUs) and stream and vector processing CPUs are good at this. Intermediate vision processes are efficiently performed using concurrent/multi-threaded processing with multicore and multi-threaded processors and sufficient cache memory. Higher-level processes [1–3] are well suited for computing clusters consisting of super scalar processors with node level capabilities to efficiently process vector and regular gridded data. Most clusters employ message passing mechanisms to move data between processors; interconnection topologies such as bi-orthogonal linear buses, meshes, tori, trees, and hypercubes have all been tried in practice. The need for heterogeneous parallel computing for vision and all aspects of artificial intelligence were envisioned early on [4]. Low-level vision algorithms were developed to take advantage of early parallel processing architectures [5]. Parallel computing algorithms at all levels of the vision hierarchy have been adapted to suit prevailing architectures [6] including the modern CMOS image sensors [7]. Modern-day desktop computers make a powerful combination of heterogenous processors, multicore, and multi-processor systems more accessible and affordable. This has further broadened high- performance computing and shifted the focus on software methods, tools, and versatility of application scenarios.

Images acquired through physical cameras suffer a loss of depth. Computational methods aimed at recovering depth information involve iterative optimization of certain regularized functions which are compute-intensive. They are highly uniform, if not identical, across the entire image, making them a candidate for parallel processing. Vision algorithms are often designed to follow a divide and conquer approach. For example, the image is partitioned into four quadrants, each processed independently and the results grouped by a merging strategy. Each quadrant will in turn be recursively split into sub quadrants for further processing, until it is not necessary to split further. A problem-specific preprocessing or postprocessing step is used at the split and merge stages, respectively, and,

each partition can be processed independently in parallelized fashion. The computation is said to follow an adaptive quad-tree control structure. A seminal algorithm in computer graphics also known as the area subdivision (Warnock) algorithm, and a widely known quad-tree-based image segmentation algorithm (Pavlidis) follows this structure. Specific aspects of each computation will determine the type of data-flow: either top-down or bottom-up. Certain complex visual tasks involve bidirectional inferencing where one or more salient objects present in the scene steer the way the rest of the scene is processed. Such tasks will shift up and down the quad-tree in cyclical fashion. In general, they will include intra-block computations and adjacent-block data access to apply spatial operators. The interdependence between incremental computations is captured by a hybrid topological structure, a pyramid, which combines a quad-tree with a two-dimensional mesh. Basic computations such as convolution are performed as a systolic or vector operation across the mesh, using single instruction multiple data (SIMD) primitives [8]. They can also be achieved by carefully (de)composed sequence of partial sums and efficiently implemented (on a standard von-Neumann machine) as pipelined primitives [9] exploiting the order in which the pixels will be visited. Integral histograms are a powerful emerging low-level processing method for speeding up multi-resolution sliding window-based searching and other computer vision tasks using block-level pipelined computations. Multicore parallel implementations of integral histograms [9] can significantly scale up computation to large image and video collections.

Classic space filling curves such as Hilbert curves, Peano scans, and curves have been used as a locality preserving pixel organization [10, 11] and an alternative to the standard raster scan which scans the image left to right and top to bottom visiting each pixel exactly once. The spatially compact nature of space filling scans tends to cohere highly correlated pixels as maximal subsequences, producing a significant improvement on aggregative operators such as the run-length coding and compressive

sensing. A recent work on Z-trees combines the advantages of a binary tree control structure and spatially compact nature of Peano scans to achieve cache-oblivious computations [12] algorithms on sequential machines. Z-tree is built by inserting a Hilbert-curve scanned sequence of pixel at the terminal level of a binary tree and then building the tree upwards. Such a tree represents very large images as a collection of tiles, permitting mesh algorithms at any given level of the Z-tree and SIMD processing over two or more aligned tiles. Spatiotemporal visualization of gigapixel-sized images and videos has been implemented using such tiled representations [13–16].

Our understanding of human visual perception suggests multiple competing chains of evidence accumulation and incremental inferencing neural processes. The basic unit of such inferences is known as gestalts [17]. They cohere and coalesce into a candidate interpretation, which are indirectly influenced by context and cues about the scene. They account for subjective processes associated with observer expectations. Evidence gathered in one location across an image may at times add-to, concur-with, be neutral-to, or compete against the interpretation arising from elsewhere within the image. A consistent interpretation is achieved through a constraint propagation and resolution method known as relaxation labeling and belief propagation techniques [18]. Such methods have been studied thoroughly in the perception of line drawings of a complex scene of trihedral blocks. Animals that blend with the background such as the well-known Dalmatian dog camouflaged against a background of rocks are sometimes used to illustrate the inherent difficulties of separating foreground (the dog) from background based on local contrast or edge structures only. Any cue about the existence of a dog, immediately contributes to the coalescing of an otherwise disconnected set of patches into a meaningful grouping in the shape of dog. From a computational standpoint, two approaches have been proposed each with significant success [1].

Model-driven computations include hypothesize and verify methods following procedural models. In contrast, a collection of associations between physical scene/object situations and resulting observations across images are used effectively using rule-based computations to achieve one of more stable interpretations. These methods lend themselves to parallel computations. Light-weighted threads with carefully orchestrated spatial and feature space-based interdependencies will be required to efficiently implement these processes. Modern multi core heterogeneous processors are more suitable for this.

Recent advances in custom application-specific computing architectures have led to a class of high-performance computations to implement real-time computer vision systems based on neural networks. The general purpose graphic processing units (GPGPU), originally designed for video gaming and graphic visualizations have been useful to build and train very complex supervised learning of visual objects with deep learning neural networks [19]. Although the neural networks have been extensively researched in the 1990s, the use of GPGPUs has been catalytic [20]. The training process requires massive amount of samples to train with, and the resources required to compute the weights underlying the neural networks to be learned by a back propagation mechanism remain prohibitively high. The Systems of Neuromorphic Adaptive Plastic Scalable Electronics (SyNAPSE) processors pioneered by DARPA led to further advances. Spiking neural networks is another framework to build computer vision systems trained using supervised learning. These processors use signals that are made of three consecutive pulses to code the weights using pulse space modulation and offer very high integration density and energy efficiency. Both the IBM True North [21] and Intel Loihi [22] processors came out of the SyNAPSE program. These processors offer entirely new programming models.

From a computer engineering perspective, the granularity of the parallelism is of importance

for constructing high-throughput dedicated machines. However, from a computer science and computing architectures perspective, one will see that parallel computation for computer vision requires multiple architectures across scale and level of information processing. Topics not covered but deserving of further exploration are focal plane and light-field processing using optical parallel computing and quantum computing for vision algorithms. There is a diversity in the intrinsic parallelism that is seen at each stage of the data-to-decision chain.

Deep high-resolution representation learning;
Multi-resolution representation learning

Definition

High-resolution network (HRNet) is a deep convolutional neural network for visual recognition that learns semantically rich and spatially fine-grained representations by maintaining high resolution in the entire process.

Background

Most visual recognition tasks except image classification are position-sensitive. For example, semantic segmentation needs to assign a label to each pixel. Object detection needs to predict the position of an object. Human pose estimation needs to identify the positions of human joints. The key factor in deep learning approaches to position-sensitive tasks is to learn strong high-resolution representations.

Traditional two-stage frameworks first encode an input image as a low-resolution representation through a subnetwork that is formed by connecting high-to-low-resolution convolutions in series (e.g., AlexNet [5], VGGNet [13], GoogleNet [16], ResNet [3], and DenseNet [4]) and then recover the high-resolution representation from the encoded low-resolution representation. The process is depicted in Fig. 1. The typical approaches include Hourglass [9], SegNet [1], DeconvNet [10], U-Net [12], SimpleBaseline [18], and encoder-decoder [11].

High-resolution network, introduced in [15, 17], is able to learn strong high-resolution representations by maintaining high-resolution representations through the whole process. It starts from a high-resolution convolution stream, gradually adds high-to-low-resolution convolution streams one by one, and connects multi-resolution streams in parallel. The resulting network consists of several (typically 4) stages as depicted in Fig. 2, and the n th stage contains n streams corresponding to n resolutions. Together with repeated multi-resolution fusions that exchange information across parallel streams

over and over, the resulting high-resolution representation is semantically richer and spatially more fine-grained.

Approach

Architecture The HRNet architecture consists of two main components: parallel multi-resolution convolutions (Fig. 3a) and repeated multi-resolution fusions (Fig. 3b).

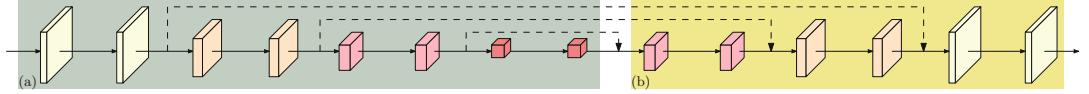

The network is formed by starting from a high-resolution convolution stream as the first stage, gradually adding high-to-low-resolution streams one by one to form new stages, and connecting multi-resolution streams in parallel. The resolutions for the parallel streams of a later stage consist of the resolutions from the previous stage and an extra lower one.

The example HRNet structure illustrated in Fig. 2 contains *four* parallel streams and is logically written as follows:

$$\begin{array}{ccccccc} N_{11} & \rightarrow & N_{21} & \rightarrow & N_{31} & \rightarrow & N_{41} \\ & & \searrow & & \searrow & & \\ & & N_{22} & \rightarrow & N_{32} & \rightarrow & N_{42} \\ & & & & \searrow & & \\ & & & & N_{33} & \rightarrow & N_{43} \\ & & & & & & \searrow \\ & & & & & & N_{44}, \end{array} \quad (1)$$

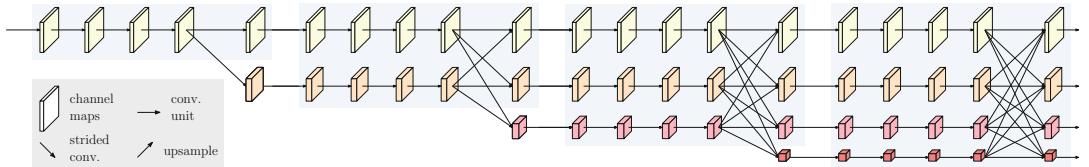

where N_{sr} is a sub-stream in the s th stage and r is the resolution index. The resolution index of the first stream is $r = 1$. The resolution of index r is $\frac{1}{2^{r-1}}$ of the resolution of the first stream. The widths of the convolutions of the four resolutions are C , $2C$, $4C$, and $8C$, respectively.

The across-resolution fusions are repeated several times for exchanging the information. Take fusing *three*-resolution representations as an example (Fusing *two* representations and *four* representations can be similarly derived.). There are three input representations: $\{\mathbf{R}_r^i, r = 1, 2, 3\}$, where r is the resolution index, and the associated output representations are $\{\mathbf{R}_r^o, r = 1, 2, 3\}$. Each output representation is the sum of the transformed representations of the three inputs: $\mathbf{R}_r^o = f_{1r}(\mathbf{R}_1^i) + f_{2r}(\mathbf{R}_2^i) + f_{3r}(\mathbf{R}_3^i)$. The fusion across stages (from stage 3 to stage 4)

resolution representation recovering subnetwork, which is formed by connecting low-to-high convolutions in series. (Figure courtesy of [17])

High-Resolution Network, Fig. 2 Example high-resolution network. There are four stages. The 1st stage consists of high-resolution convolutions. The 2nd (3rd,

4th) stage repeats two-resolution (three-resolution, four-resolution) blocks. (Figure courtesy of [17])

H

has an extra output: $\mathbf{R}_4^o = f_{14}(\mathbf{R}_1^i) + f_{24}(\mathbf{R}_2^i) + f_{34}(\mathbf{R}_3^i)$.

The choice of the transform function $f_{xr}(\cdot)$ relies on the input resolution index x and the output resolution index r . If $x = r$, $f_{xr}(\mathbf{R}) = \mathbf{R}$. If $x < r$, $f_{xr}(\mathbf{R})$ downsamples the input representation \mathbf{R} through $(r-s)$ stride-2 3×3 convolutions, for example, one stride-2 3×3 convolution for $2 \times$ downsampling and two consecutive stride-2 3×3 convolutions for $4 \times$ downsampling. If $x > r$, $f_{xr}(\mathbf{R})$ upsamples the input representation \mathbf{R} through bilinear upsampling followed by a 1×1 convolution for aligning the number of channels.

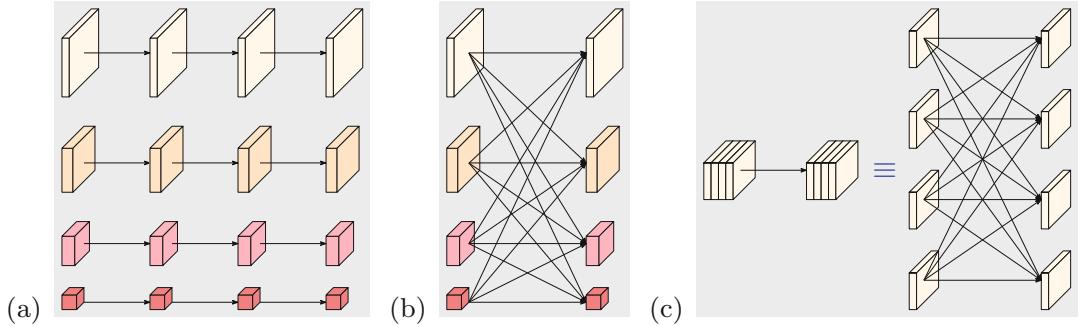

The representation of an image is computed by first feeding the image into a stem, which consists of two stride-2 3×3 convolutions decreasing the resolution to $\frac{1}{4}$, and subsequently the HRNet that outputs the representations with four resolutions $\frac{1}{4}, \frac{1}{8}, \frac{1}{16}$, and $\frac{1}{32}$.

Analysis The multi-resolution parallel convolution unit (shown in Fig. 3a) is similar to the group convolution. It divides the input channels into several subsets of channels with each subset corresponding to a different spatial resolution and performs a regular convolution on each subset, while in the group convolution, the resolutions are the same. This connection implies that

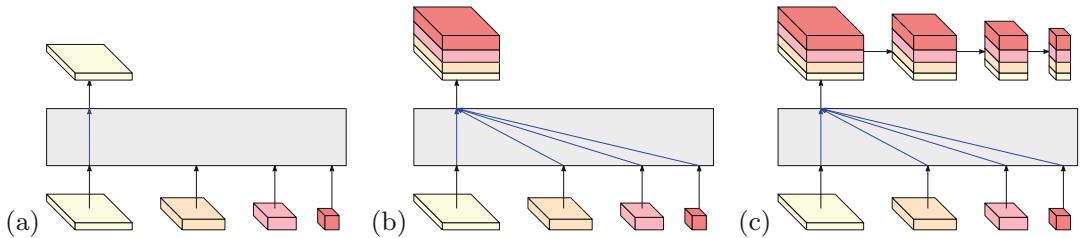

the multi-resolution parallel convolution enjoys a benefit similar to group convolution, e.g., reducing the redundancy by sparsifying the convolution kernel, and furthermore, it also reduces the spatial redundancy by applying convolutions on high and low resolutions.

The multi-resolution fusion unit (shown in Fig. 3b) is related to the multibranch full-connection form of the regular convolution, as illustrated in Fig. 3c. A regular convolution can be divided as multiple small convolutions as explained in [14, 19, 20]. The input channels are divided into several subsets, and the output channels are also divided into several subsets. The input and output subsets are connected in a fully connected fashion, and each connection is a regular convolution. Each subset of output channels is a summation of the outputs of the convolutions over each subset of input channels. The differences lie in that the connection in our multi-resolution fusion needs to handle the resolution change. Similar to multi-resolution parallel convolution, the multi-resolution fusion unit also enjoys the benefit of spatial redundancy reduction.

Advantages The high-resolution representations learned from HRNet are semantically

High-Resolution Network, Fig. 3 (a) Multi-resolution parallel convolution, (b) multi-resolution fusion. (c) A normal convolution (left) is equivalent to fully connected multibranch convolutions (right). (Figure courtesy of [17])

High-Resolution Network, Fig. 4 (a) Human pose estimation head: only output the representation from the high-resolution convolution stream. (b) Semantic segmentation head: concatenate the (upsampled) representations from all the resolutions. (c) Object detection and instance seg-

mentation head: form a feature pyramid from the representation by (b). The four-resolution representations at the bottom in each sub-figure are outputted from the network in Fig. 2. (Figure courtesy of [17])

High-Resolution Network, Fig. 5 Qualitative human pose estimation examples on the COCO dataset [7]. (Figure courtesy of [17])

richer and spatially more precise. There are two reasons. (i) The convolution streams from high resolution to low resolution are connected in parallel other than in series. It maintains high resolution instead of recovering high resolution from low resolution. Thus, the learned representation is potentially spatially more precise. (ii) HRNet repeats multi-resolution fusions to boost high-resolution representations with the help of low-resolution representations and vice versa. Consequently, the high-to-

low-resolution representations are semantically strong.

Application

HRNet is applicable to various visual recognition tasks, such as human pose estimation, semantic segmentation, face alignment, object detection, image style transfer, and so on. The heads for three example tasks, human pose estimation,

High-Resolution Network, Fig. 7 Qualitative object detection (top three) and instance segmentation (bottom three) examples on the COCO dataset [7]. (Figure courtesy of [17])

semantic segmentation, and object detection, are illustrated in Fig. 4. Qualitative results of human pose estimation, semantic segmentation, as well as object detection and instance segmentation are given in Figs. 5, 6, and 7, respectively. The codes are available at <https://github.com/HRNet>.

Empirical comparisons on many tasks presented in [17], such as human pose estimation, semantic segmentation, face alignment, as well as object detection and instance segmentation, demonstrate the superiority of HRNet in terms of accuracy, computation complexity, and parameter complexity over previous state of the arts, e.g., ResNet and VGGNet.
