Histogram

Ying Nian Wu

Department of Statistics, UCLA, Los Angeles, CA, USA

Definition

Histogram is a graphical display of the distribution of observed values of some random variable.

Theory and Applications

Histogram was introduced by Karl Pearson. In a histogram, the range of the observed values is divided into a number of bins of equal length. A rectangle is erected on top of each bin so that the area of the rectangle equals the frequency that the observed values fall into this bin. A histogram is a more detailed summary of a distribution than mean and variance. It can be considered a nonparametric estimate of the probability density function of the random variable.

In image analysis and computer vision, histograms are often obtained by spatial pooling and they serve as image features. For a texture image, histograms of responses from a bank of filters are pooled over the image domain, and these histograms serve as features that characterize the texture pattern. Histograms can also be pooled within local windows as local texture features. Heeger and Bergen [3] proposed an algorithm for texture synthesis by matching histograms of filter responses. Zhu, Wu, and Mumford [7] proposed a Markov random field model for stochastic textures. The model is the maximum entropy distribution that matches observed marginal histograms of filter responses. The spatially pooled histograms discard the position information. This is appropriate for characterizing texture patterns, which are spatially stationary.

The local orientation histograms of image intensity gradients are key components of two of the most successful image features, namely, SIFT (scale-invariant feature transform) [5] and

HoG (histogram of oriented gradients) [2]. Such histograms are pooled within local cells, where each pixel contributes a weighted vote to the histogram bin that corresponds to the orientation of the intensity gradient at this pixel. The weight can be the magnitude of the gradient or some nonlinear transformation of it. Such histograms are very informative descriptions of local image patches, and they are partially invariant to local geometric distortions or shape deformations, because they are spatially pooled within local cells where information about the exact positions of the gradients is discarded.

A more general version of histogram is also used in the bag-of-words method for image classification [1]. The basic idea is to obtain a code-book of “words” by quantizing local image features via clustering. The histogram is in the form of the frequencies of the occurrences of the code-words. The histogram can be pooled over the entire image. One can also divide the image into subregions and pool the histograms within these subregions [4]. Such histograms can then be used for image classification, usually by SVM with histogram intersection kernel [4, 6]. Again, because the spatial pooling of the histograms discards the exact position information, such histograms are invariant to shape deformations.

Definition

Human pose estimation is the process of estimating the configuration of the body (pose) from a single, typically monocular (While the problem of human pose estimation can be formulated from simultaneous observations from multiple camera views (or one or more RGBD cameras), which can result in higher-fidelity results or alleviate annotation [46], such formulations are substantially less common, as they require cumbersome hardware setups, making them inappropriate for many applications.), image or video. The pose can be expressed in variety of ways (e.g., joint positions/keypoints or angles between body parts) in either the image (2d) or the world (3d) coordinate frame.

Background

Human pose estimation is one of the key fundamental problems in computer vision that has been studied for well over 20 years. The reason for its importance is the abundance of applications that can benefit from such a technology. For example, human pose estimation allows for higher-level reasoning in the context of human-computer/human-robot interaction and activity recognition; it is also one of the basic building blocks for marker-less motion capture (MoCap) technology. MoCap technology is useful for applications ranging from character animation, in film and games, to clinical analysis of gait pathologies.

Despite many years of research, however, pose estimation remains a very difficult problem. Among the most significant challenges are (1) variability of human visual appearance in images, (2) variability in lighting conditions, (3) variability in human physique, (4) partial occlusions due to self-articulation and layering of objects in the scene, (5) complexity of human skeletal structure, (6) high dimensionality of the pose, and (7) the loss of 3d information that results from observing the pose from 2d planar image projections. Despite these challenges,

however, there has been enormous progress in the field, and recent approaches that utilize forms of custom-designed neural architectures are able to produce impressive, albeit not perfect, results in challenging cluttered scenarios with multiple, sometimes partially occluded and interacting, persons.

Theory and Application

In earlier days, the human pose estimation was typically formulated probabilistically to account for ambiguities that may exist in the inference (though there were notable early exceptions, e.g., [24]). In such cases, one is generally interested in estimating the posterior distribution, $p(\mathbf{x}|\mathbf{z})$, where \mathbf{x} is the pose of the body and $\mathbf{z} = g(\mathcal{I})$ is a feature set derived from the image. The key modeling choices that affect the inference are:

- The representation of the output pose – \mathbf{x} .
- The nature and encoding of image features – $\mathbf{z} = g(\mathcal{I})$.
- The inference framework required to estimate the posterior – $p(\mathbf{x}|\mathbf{z})$.

More recently, with the advent of convolutional neural networks (CNNs), the image encoding is being learned as part of the CNN architecture, rather than hand-designed. As an artifact, the explicit encoding of image features has been replaced by distributed and hierarchical feature representations learned and tuned for the pose estimation task within CNNs. The more recent models, while sometimes still can be interpreted probabilistically, are more often than not formulated as direct estimates. As a result, these CNN architectures are designed to learn a functional mapping $\mathbf{x} = f_{\Theta}(\mathcal{I})$ between an image, \mathcal{I} , and the depicted pose, \mathbf{x} . This sometimes involves intermediate semantic representations (e.g., in the form of the 2d joint heatmaps) that can be used either directly or indirectly to arrive at the final pose \mathbf{x} . Note the inherent assumption that the image contains only a single person; we will

address this later in the chapter. The main modeling choices in such formulations are:

- The representation of the output pose – \mathbf{x} .
- The design of the CNN architecture (e.g., number, form, and connectivity of the layers), i.e., parametrization of the function $f_{\Theta}(\mathcal{I})$.
- The formulation of, one or more, loss function(s) that serve as proxy measure(s) for evaluating performance of the model on the training data and are used to backpropagate the error and learn parameters Θ of $f_{\Theta}(\mathcal{I})$.

Next, the primary lines of research in pose estimation with respect to these modeling choices are reviewed. It is worth noting that these modeling choices are not always independent. For example, some inference frameworks and neural architectures are specifically designed to utilize a given representation of pose. In what follows we describe older historical algorithmic trends, as well as recent advances, to put the problem of human pose estimation in perspective.

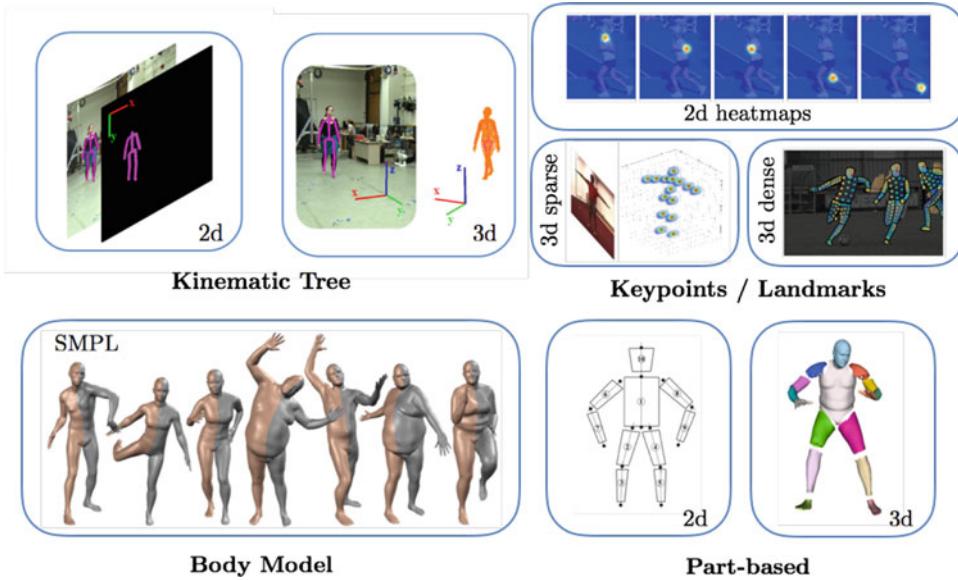

Representation The configuration of the human body can be represented in a variety of ways. The most direct and classic representation is obtained by parameterizing the body as a *kinematic tree* (see Fig. 1), $\mathbf{x} = \{\tau, \theta_{\tau}, \theta_1, \theta_2, \dots, \theta_M\}$, where the pose is encoded using position of the root segment (to keep the kinematic tree as short as possible, the pelvis is typically used as the root segment), τ , orientation of the root segment in the world, θ_{τ} , and a set of relative joint angles, $\{\theta_i\}_{i=1}^M$, that represent the orientations of body parts with respect to their parents along the kinematic tree (e.g., the orientation of the thigh with respect to the pelvis, shin with respect to the thigh, etc.).

Kinematic Tree Representations The kinematic tree representation can be obtained for 2d, 2.5d, and 3d body models. In 3d, $\tau \in \mathbb{R}^3$ and $\theta_{\tau} \in SO(3)$: $\theta_i \in SO(3)$ for spherical joints (e.g., neck), $\theta_i \in \mathbb{R}^2$ for saddle joints (e.g., wrist), and $\theta_i \in \mathbb{R}^1$ for hinge joints (e.g., knee), representing

the pose of the body in the world. Note that the actual representation of the rotations in 3d is beyond the scope of this entry but can involve Euler angles, quaternions, and exponential maps. It is worth noting that in terms of the skeletal model, the kinematic tree representation of this form is perhaps the most anatomically accurate. It also allows easy modeling of certain anatomic constraints (e.g., limb proportions, joint ranges and limits). In 2d, $\tau \in \mathbb{R}^2$ and $\theta_{\tau} \in \mathbb{R}^1$; $\theta_i \in \mathbb{R}^1$ corresponds to pose of the cardboard person in the image plane. The 2.5d representations are the least common and are extensions of the 2d representation such that the pose, \mathbf{x} , is augmented with (typically discrete) variables encoding the relative depth (layering) of body parts. In all cases, be it in 2d or 3d, this representation results in a high-dimensional pose vector, \mathbf{x} , in $\mathbb{R}^{30} - \mathbb{R}^{70}$, depending on the fidelity and exact parameterization of the skeleton and joints.

H

Body Model Representations Kinematic tree representation defines a skeletal articulation of the body. Sometimes, however, it is useful to augment this representation in order to build a full-pledged *body model*. A body model is a parametric, typically mesh-based, representation of the human body outer surface. While the focus of human pose estimation is clearly on pose, the shape of the body may also be of interest and, more importantly, may be necessary to estimate for accurate pose recovery (e.g., in a generative framework). Formally, the body model is a function $\mathcal{M}(\mathbf{x}, \mathbf{s}) : \mathbb{R}^K \rightarrow \mathbb{R}^{3N}$ which maps the articulated pose, \mathbf{x} , and the shape parameters, \mathbf{s} , to the deformations of vertices of a reference triangular mesh with predefined human topology (N is the number of vertices). In other words, by modifying pose and shape parameters, using $\mathcal{M}(\mathbf{x}, \mathbf{s})$, one can generate a complete 3d mesh representation of a person in any pose and of any identity/physique (Fig. 1 bottom). Various functional forms for $\mathcal{M}(\mathbf{x}, \mathbf{s})$ have been explored, but perhaps the most widely used to date are SCAPE and SMPL [29, 32]. Both SCAPE and SMPL decompose body shape into person-dependent shape and nonrigid pose-dependent shape deformations;

Human Pose Estimation, Fig. 1 Pose Representations: Illustration of the 2d and 3d kinematic tree representation is in the (top-left). Various forms of keypoint/landmark representations are illustrated in (top-right). The 2d keypoint representation is illustrated in terms of heatmaps. (Figure is reproduced from [57]). The 3d keypoint representations are illustrated in terms of *sparse* joints and *dense* body mesh locations. (Figures are

reproduced from [40] and [3], respectively). SMPL body model representation is illustrated in (bottom-left) by a sample of poses produced with different pose and shape parameters. (Figure is reproduced from [32]). Finally, part-based representations in 2d and 3d are illustrated in (bottom-right). (Figures are reproduced from [49] and [68], respectively)

both deformations are learned from 3d human scans of multiple subjects in variety of poses.

Keypoint/Landmark Representations Alternatively, one can parameterize the pose of the body by 2d or 3d *keypoints/landmarks* that most often correspond to locations of the major joints [9]. Some keypoint representations are augmented to also include other fiducial markers (e.g., facial features [11] or even dense keypoints defined on the surface of the body [2, 3], i.e., mesh vertices in the body model described above). Taken simply, $\mathbf{x} = \{\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_M\}$, where \mathbf{p}_i is the joint location/keypoint in the world, $\mathbf{p}_i \in \mathbb{R}^3$, or in an image, $\mathbf{p}_i \in \mathbb{R}^2$. The keypoint-based representations are somewhat impoverished, as modeling joints independently make it more difficult to encode structural constraints of the body (e.g., preserve limb lengths and left-right body symmetries and rule out impossible pose configurations). Also, note that while the

kinematic tree can be converted to keypoints (2d or 3d) uniquely, using forward kinematics, the opposite conversion from keypoints to kinematic tree is not unique (e.g., twist of a limb could be lost). However, at the same time, keypoint representations have significant benefits, which make them the representation of choice for many recent CNN-based formulations. Mainly, the independence of representation makes it easy to estimate each joint separately, without the need to reason about the body as a whole. In other words, the inference or regression over pose can be reduced to M -independent inference/regression problems (one for each joint) in a much lower and unstructured 2d, or less frequently 3d, space.

Part-Based Representations Finally, one can model the body as a set of parts (The subtle difference with keypoints is that parts are traditionally assumed to have spatial extent, i.e., are themselves identifiable in the image,

whereas keypoints do not have spatial extent and are only identifiable through contextual region around them. That said, this difference has been progressively blurred in the literature, and, in more recent formulations, the two could be used almost interchangeably.), $\mathbf{x} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M\}$, each with its own position and orientation in space, $\mathbf{x}_i = \{\tau_i, \theta_i\}$, that are connected by a set of statistical or physical constraints that enforce skeletal (and sometimes image) consistency. Because this *part-based* parameterization is redundant, it results in an even higher-dimensional representation. However, it does so in a way that makes it efficient to infer the pose, as will be discussed in a later section. Methods that utilize such a parameterization are often called part-based. As in kinematic tree models, the parts can be defined in 2d [4, 7, 15, 17, 24, 43] or in 3d [50], with 2d parameterizations being significantly more common. In 2d, each part's representation is often augmented with an additional variable, γ_i , that accounts for uniform scaling of the body part in the image, i.e., $\mathbf{x}_i = \{\tau_i, \theta_i, \gamma_i\}$ with $\tau_i \in \mathbb{R}^2$, $\theta_i \in \mathbb{R}^1$ and $\gamma_i \in \mathbb{R}^1$. Each part can also be endowed with learned, or predefined, geometric primitives, resulting in a part-based body model (see Fig. 1 bottom-right).

Discussion Generally speaking, there is a significant benefit to 2d parameterizations over the 3d ones, mainly in that (1) they are lower dimensional and (2) are typically directly observable in an image and hence are less ambiguous to estimate. At the same time, 3d pose estimates are practically more useful, enabling a much broader range of applications. As a consequence, in most recent frameworks, 2d joint location/keypoint pose estimation is either the final output or, in the very least, an intermediate stage. The more advanced architectures that predict 3d pose are then often conditioned on these intermediate 2d estimates.

Image features Performance of any pose estimation approach depends substantially on the observations, or image features, that are chosen to represent salient parts of the image with respect to

the human pose. A related and equally important issue is one of how these features are encoded.

Hand-Crafted Representations Early approaches to human pose estimation engineered feature representations and the encodings. Over the years, many features have been proposed by various authors. The most common features included image silhouettes [1], for effectively separating the person from background in static scenes; color [43], for modeling un-occluded skin or clothing; edges [43], for modeling external and internal contours of the body; and gradients [8], for modeling the texture over the body parts. Less common features include shading and focus [35]. To reduce dimensionality and increase robustness to noise, these raw features were often encapsulated in image descriptors, such as shape context [1, 4, 9], SIFT [9], and histogram of oriented gradients [8]. Alternatively, hierarchical multilevel image encodings can be used, such as HMAX [25], spatial pyramids [25], and vocabulary trees [25]. The effectiveness of different feature types on pose estimation has been studied in the context of several inference architectures; see [4] and [25] for discussions and quantitative analyses.

Neural and CNN Representations More recently, with computer vision transitioning to learned feature representations that are integrated with the end-to-end neural architecture designs, typically taking the form of CNNs, the burden of engineering has shifted from features to architectural designs of the networks. Starting from AlexNet [58], there have been important advances in CNN designs, including a general trend toward stacks of reusable blocks (e.g., pooling and upsampling layers which resemble an hourglass [37]) and residual connections (e.g., ResNet [21]). Such advances in CNN designs have broadly improved the performance of computer vision systems. Beyond traditional CNN architectural advances, two architectural designs seem to be particularly well tailored to the task of pose estimation: (i) use of encoder-decoder architectures with a bottleneck, e.g., constructed using convolution and deconvolution layers [37, 61],

and (ii) multi-resolution architectures that, for example, use multi-scale fusion from parallel multi-resolution subnetworks [54].

Inference Given an image representation (hand-crafted or neural), inference over the pose can be formulated in hundreds of different ways. Here we will restrict ourselves to discussion of four broad classes of inference methods, highlighting representative works and designs in each category. We start by discussing (1) *classic regression* models, where a simple functional mapping (e.g., linear, kernel, etc.) is learned in order to map image features to the pose. Similar in nature, (2) *deep learning and CNN-based* models learn a much more complex hierarchical and nonlinear mapping functions while simultaneously learning the feature representations themselves. Both of the aforementioned classes of methods can be regarded as *discriminative*, owing to the input-output inference nature that attempts to characterize and learn relationship between features (\mathbf{z}) and pose representation (\mathbf{x}). In stark contrast, (3) *generative* methods define a generative process that underlines image formation with specific body model and then attempt to recover the parameters of the body, often through optimization, that give rise to the observed image or image features. Finally, (4) *part-based* models rely on distributed body representations to facilitate inference. The ability to represent the body as a collection of body parts is convenient as it allows one to express inference over the high-dimensional pose of the body, in terms of series of lower-dimensional inferences for more rigid components (limbs or joints) loosely connected by (local) statistical or geometric relations.

Inference (classic regression models) Characterizing the posterior distribution, $p(\mathbf{x}|\mathbf{z})$, can be done in a number of ways. Perhaps the most intuitive is to define a parametric [1, 9, 25] or nonparametric [36, 48, 52, 59] form for the conditional distribution $p(\mathbf{x}|\mathbf{z})$ and learn the parameters of that distribution from a set of training exemplars. This class of models is more widely known as discriminative methods, and they have been shown to be very effective for pose estimation. Such

methods directly learn $p(\mathbf{x}|\mathbf{z})$ from a labeled dataset of poses and corresponding images, $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{z}_i)\}_{i=1}^N$, which can, alternatively, be produced artificially using computer graphics software packages (e.g., Poser) [1, 25, 48]. The inference takes a form of probabilistic regression. Once a regression function is learned, a scanning window approach is typically used at test time to detect a portion of the image (bounding box) where the person resides; $p(\mathbf{x}|\mathbf{z})$ is then used to characterize the configuration of the person in that target window. The simplest method in this category is the one of linear regression [1], where the body configuration, \mathbf{x} , is assumed to be a linear combination of the image features, \mathbf{z} , with additive Gaussian noise:

$$\mathbf{x} = A[\mathbf{z} - \mu_z] + \mu_x + \nu; \quad \nu \sim \mathcal{N}(0, \Sigma);$$

$\mu_x = \frac{1}{N} \sum_{i=1}^N \mathbf{x}_i$ and $\mu_z = \frac{1}{N} \sum_{i=1}^N \mathbf{z}_i$ are means over samples used to center the data. Alternatively, this can be written as:

$$p(\mathbf{x}|\mathbf{z}) = \mathcal{N}(A[\mathbf{z} - \mu_z] + \mu_x, \Sigma). \quad (1)$$

The regression coefficients, A , can be learned easily from paired training samples, $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{z}_i)\}_{i=1}^N$, using the least squares formulation (see [1] for details).

Parametric vs. Nonparametric Parametric discriminative methods [1, 9, 25] are appealing because the model representation is fixed with respect to the size of the training dataset \mathcal{D} . However, simple parametric models, such as linear regression [1] or relevance vector machine [1], are unable to deal with complex nonlinear relationships between image features and poses. Nonparametric methods, such as nearest neighbor regression [48] or kernel regression [48], are able to model arbitrary complex relationships between input features and output poses. The disadvantage of these nonparametric methods is that the model and inference complexity are both functions of the training set size. For example, in kernel regression:

$$p(\mathbf{x}|\mathbf{z}) = \sum_{i=1}^N \mathcal{K}_x(\mathbf{x}, \mathbf{x}_i) \frac{\mathcal{K}_z(\mathbf{z}, \mathbf{z}_i)}{\sum_{k=1}^N \mathcal{K}_z(\mathbf{z}, \mathbf{z}_k)} \quad (2)$$

where $\mathcal{K}_x(\cdot, \cdot)$ and $\mathcal{K}_z(\cdot, \cdot)$ are kernel functions measuring the similarity of the arguments (e.g., Gaussian kernels) and the inference complexity is $\mathcal{O}(N)$ (where N is the size of the training dataset). More sophisticated nonparametric methods, such as Gaussian Process Latent Variable Models (GPLVMs), can have higher complexity; GPLVMs have $\mathcal{O}(N^3)$ learning and $\mathcal{O}(N^2)$ inference complexity. In practice, nonparametric methods tend to perform better but are slower.

Dealing with Ambiguities If one assumes that $p(\mathbf{x}|\mathbf{z})$ is unimodal [1], conditional expectation can be used to characterize the plausible configuration of the person in an image given the learned model. For example, for linear regression in Eq. (1), $\mathbb{E}[\mathbf{x}|\mathbf{z}] = A[\mathbf{z} - \mu_z] + \mu_x$; for kernel regression in Eq. (2):

$$\mathbb{E}[\mathbf{x}|\mathbf{z}] = \sum_{i=1}^N \mathbf{x}_i \frac{\mathcal{K}_z(\mathbf{z}, \mathbf{z}_i)}{\sum_{k=1}^N \mathcal{K}_z(\mathbf{z}, \mathbf{z}_k)}. \quad (3)$$

In practice, however, most features under standard imaging conditions are ambiguous, resulting in multimodal distributions. Ambiguities naturally arise in image projections, where multiple poses can result in similar, if not identical, image features (e.g., front- and back-facing poses yield nearly identical silhouette features). To account for these ambiguities, parametric mixture models were introduced in the form of mixture of experts [9, 25]. Nonparametric alternatives, such as Local Gaussian Process Latent Variable Models (LGPLVMs) [59], cluster the data into convex local sets and make unimodal predictions within each cluster or search for prominent modes in $p(\mathbf{x}|\mathbf{z})$ [36, 52].

Learning Obtaining the large datasets that are required for learning discriminative models that can generalize across motions and imaging conditions is challenging. Synthetic datasets often do not exhibit the imaging characteristics present

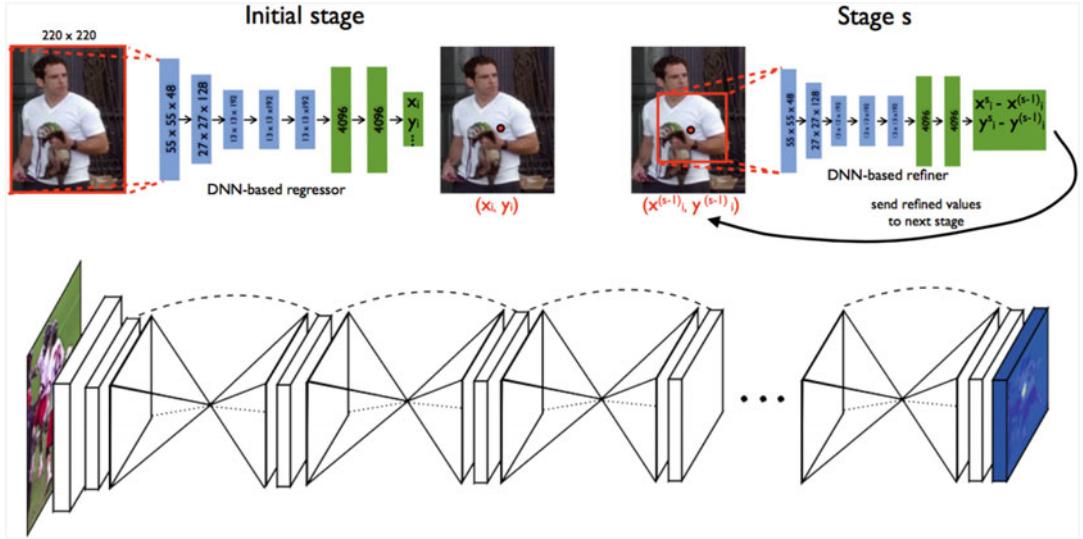

in real images, and real fully-labeled datasets until relatively recently have been difficult to collect. Furthermore, even with large datasets, learning standard regression models described above, from vast amounts of data, is not a trivial task [9]. To address this issue, two solutions were introduced: (1) learning from small datasets by discovering an intermediate low-dimensional latent space for regularization [36, 52] and (2) learning in semi-supervised settings, where a relatively small dataset of paired samples is accompanied by a large amount of unlabeled data [25, 36, 52].

Inference (deep learning and CNNs) Most recent pose estimation systems, starting from around 2014, have adopted convolutional neural networks (CNNs) as their building blocks. CNNs and deep neural networks can be thought of as *ultimate* parametric regression models (see above). They are, provably, able to learn arbitrarily complex functional mappings and learn feature representations appropriate for the task (and specific data). This has led to significant performance improvements on the standard benchmark datasets, leading to results that are now becoming commercially feasible for many applications.

The first successful CNN-based architecture for pose estimation was DeepPose [58] illustrated in Fig. 2 (top). DeepPose adopted a standard AlexNet CNN backbone, initially proposed for image classification, replacing the last fully connected layer with the one of output dimension of $2M$, where M is the number of pose keypoints. The input to the network is directly an RGB image patch of size $L \times L$ containing a person ($L = 220$), e.g., obtained using a person detector. In effect, the network defines a functional mapping from the image \mathcal{I} to the keypoint-encoded pose of the body \mathbf{x} :

$$\mathbf{x} = \{\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_M\} = f_\Theta(\mathcal{I}) : \mathbb{R}^{3 \times L \times L} \rightarrow \mathbb{R}^{2M}. \quad (4)$$

The parameters Θ include all parameters of involved convolutional and fully connected layers and were optimized to minimize prediction error, which, in non-probabilistic form, can be expressed directly as a L_2 loss optimized over

Human Pose Estimation, Fig. 2 Sample CNN architectures for 2d pose estimation: Architecture of Deep-Pose [58] is illustrated on top and architecture of stacked hourglass [37] in the bottom. The major difference is

that [37] produces heatmaps, one per joint, as the output, while [58] produces the joint estimates directly. See text for more details. (Figures are reproduced from [58] and [37] top-to-bottom, respectively)

all joints and annotated examples in the dataset $\mathcal{D} = \{(\mathbf{x}_i, \mathcal{I}_i)\}_{i=1}^N$,

$$\arg \max_{\Theta} \sum_{i=1}^N \sum_{j=1}^M \|\mathbf{p}_{i,j} - f_{\Theta}(\mathcal{I}_i)_j\|_2^2. \quad (5)$$

In addition, the idea of iterative (or cascaded) refinement that has permeated the future CNN formulations was first introduced in [58]. The idea is simple; at the first stage, the cascade starts off by estimating an initial pose $\mathbf{x}^{(0)} = \{\mathbf{p}_1^{(0)}, \mathbf{p}_2^{(0)}, \dots, \mathbf{p}_M^{(0)}\}$ using Eq. (4). At subsequent stages, additional CNN refinement regressors are trained, one per joint, to predict a displacement from the predicted joint location from previous stage to the true location. Each such refinement regressor takes the same form of the AlexNet with input being a crop around a predicted joint position: $\mathcal{I}[\mathbf{p}_j^{(s-1)} \pm \frac{W}{2}]$, where $W \times W$ is the size of the crop. In other words,

$$\begin{aligned} \mathbf{p}_j^{(0)} &= f_{\Theta}(\mathcal{I})_j; \quad \mathbf{p}_j^{(s)} = \mathbf{p}_j^{(s-1)} \\ &+ \underbrace{f_{\Theta_{\text{ref},j}} \left(\mathcal{I} \left[\mathbf{p}_j^{(s-1)} \pm \frac{W}{2} \right] \right)}_{\text{refinement}}, \end{aligned} \quad (6)$$

where $s > 0$ is the stage of refinement and $\mathbf{p}_j^{(s)}$ is the estimate for the joint j at that stage. The parameters of the refinement networks $\Theta_{\text{ref},j}$, one for each joint j , are different from those at the initial stage $0 - \Theta$. Notably, conceptually similar iterative refinement estimation for the pose, shape, and camera parameters was employed in [26] to estimate the SMPL body model; we will discuss this later.

However, direct regression of joints, or body parameters, has generally proven difficult. Doing so requires architectures that typically involve fully connected layers that are parameter heavy, making networks more difficult to train and generalize. More recent human pose estimation approaches transform the formulation to one of estimating M heatmaps, $\{\mathbf{H}_1, \mathbf{H}_2, \dots, \mathbf{H}_M\}$, one for each joint. A heatmap \mathbf{H}_j is a (lower resolution) one-channel “image” which at each pixel encodes probability, or confidence, of keypoint/joint j occurring. For training, a keypoint representation can be trivially converted to the heatmap by quantizing (x, y) annotated keypoint positions to a courser grid of the heatmap; in practice, for robustness and to avoid heatmaps with only one nonzero entry, a 2d

Gaussian kernel centered around (x, y) is used to generate target heatmaps. In inference, prediction for the joint j can simply be taken as:

$$\mathbf{p}_j = \arg \max_{(x,y)} \mathbf{H}_j(x, y). \quad (7)$$

The benefit of architectures that output heatmaps is that they can easily be formulated, without fully connected layers, using, typically, only convolutional and pooling (downsampling) operations. More recent architectures use a combination of convolutional pooling (downsampling) and deconvolutional (upsampling) layers. The exact form of the neural functional mapping,

$$\begin{aligned} \{\mathbf{H}_1, \mathbf{H}_2, \dots, \mathbf{H}_M\} &= f_\Theta(\mathcal{I}) : \mathbb{R}^{3 \times L \times L} \\ &\rightarrow \mathbb{R}^{M \times L' \times L'}, \end{aligned} \quad (8)$$

encoded into the architectures varies significantly from paper to paper. Parameters Θ are typically learned with respect to a mean squared error loss between the predicted and ground truth heatmaps.

Perhaps the first instance of the heatmap-based architecture is [57], which generalized the idea of (two-stage) cascade/refinement from [58] to heatmaps. Similar to [57, 58] used cropped feature maps, centered on coarsely predicted joints, for refinement of the heatmap predictions. However, unlike [57, 58] utilizes parallel multi-resolution convolutional feature maps and fusion in order to improve quality of predictions. The concept of multi-resolution features/subnetworks has since been adopted into many architectures, including the latest state-of-the-art HRNet [54]. Convolutional Pose Machines (CPM) [60] have similar motivation to [57] and also use a progressive cascade/refinement over a number of stages. The first stage predicts heatmaps, while subsequent stages refine them using image as context. Importantly, later stages use progressively larger kernels, which has an effect of producing progressively larger receptive fields. This, implicitly, allows learning of long range spatial interactions between joints, giving the model ability, at least in principle, to reason about limb length and other structural constraints of the body. Convolutional Pose Machines are

fully differentiable, effectively taking a form of a large CNN with intermediate supervision (loss is computed after each stage), which can be trained end-to-end.

Important to note that CPM was a precursor to OpenPose [11] framework, which is among the most widely used pose estimation systems to date. OpenPose uses the general CPM architecture of [60] but in addition to heatmaps also predicts Part Affinity Fields (PAF) – a 2d vector field that, for each body part, at each pixel, predicts position and orientation of the limb (e.g., for a left shoulder joint the vector field would extend from the shoulder to the corresponding elbow joint). See illustration of the OpenPose and PAF in Fig. 4. The benefit of PAF is that it makes it easy to associate joints and combine them into a coherent pose; one must simply follow the estimated vector field to arrive at the next joint along the kinematic chain. Association is trivial when an image contains only one person and heatmaps output a peak at the correct joint position but becomes problematic when multiple overlapping persons are present or images are complex, producing spurious peaks in the heatmaps. The use of PAF and robust associate procedure allows OpenPose to robustly estimate pose of multiple, interacting, people in the same image.

An interesting departure from [57, 60] is the work of [37], which introduces a stacked hourglass model. The intuition of this model is simple, unlike its predecessor architectures that effectively rely on progressively larger receptive fields, resulting from convolutions in deeper levels, to capture context for keypoint refinement; [37] uses repeated bottom-up and top-down processing in combination with intermediate supervision (also utilized in [60] and others). The resulting stacked hourglass network consists of identical blocks chained together, each of which comprising of pooling and upsampling layers (hence the name). The pooling has an effect of bottom-up (high-resolution to low-resolution) and upsampling of top-down (low-resolution to high-resolution) processing. Skip connections preserve spatial information. The stacked hourglass model achieved new state of the results

on a number of benchmarks and popularized the use of auto-encoder like architectures for pose estimation. This idea has further been explored in [61], which has introduced a much simplified architecture consisting of effectively a standard downsampling backbone (ResNet) and a few upsampling (deconvolution) layers at the end. Without requiring skip connections and despite a much simplified architecture, approach was able to produce higher accuracy results.

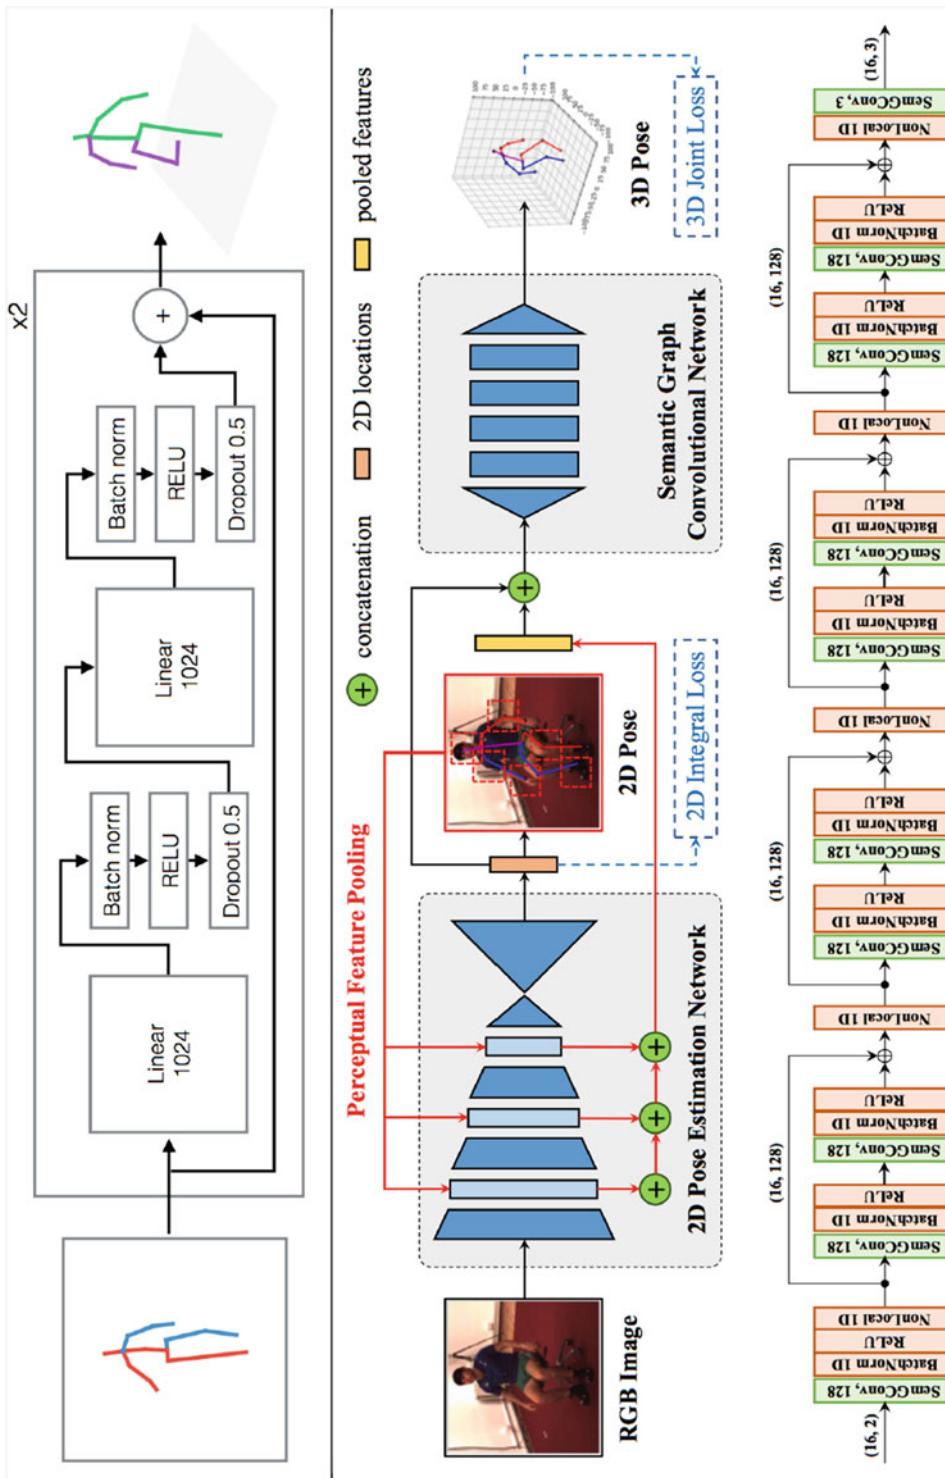

It is worth noting that the aforementioned approaches can easily be adopted to reason about joint occlusions by applying a threshold on the heatmaps. If no pixel in the heatmap for a joint is above a certain probability/confidence threshold, that joint can be assumed to be missing or occluded in the image. This is a useful strategy that has been applied in many state-of-the-art works.

Lifting Notably, all of the CNN architectures discussed above produce 2d keypoint representations as the output. While architectures such as DeepPose [58] are able to regress 3d poses and heatmap approaches are able to be extended to 3d volumes [40], this has generally proven less effective in practice. Instead, a number of effective *lifting* approaches were proposed. Lifting is the process of taking a 2d pose and regressing a 3d pose based on it. A number of neural approaches of this form have been proposed that leverage variety of architectures from stacks of fully connected layers [33] to forms of graph neural networks [67]; the most recent approach uses local-to-global architecture with graph pooling and upsampling [10]. While lifting networks can be trained separately from 2d pose-estimation pipelines by utilizing 2d-3d pose correspondences, better results are often achieved by combining the two pipelines and training them jointly with supervision at 2d and 3d level. In this way, the 2d keypoints effectively serve as intermediate supervision for the final 3d keypoint task. See Fig. 3 for illustrations (Fig. 4).

Multi-person Pose Estimation Briefly, it is worth mentioning that estimating pose of multiple, potentially interacting people is a substantially

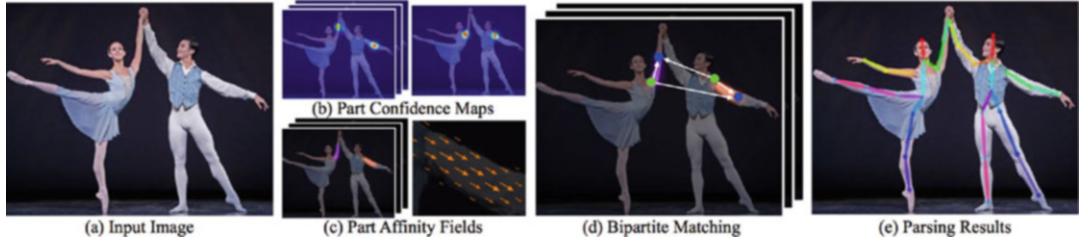

more difficult task. A simple way to address the problem is to apply person detection, extract person regions using those detections, and then apply any of the pose detection approaches discussed, independently, on each region. The premiere approach to mention in this context is Mask-RCNN [22] that uses a single integrated two-stage end-to-end network with multiple prediction “heads.” The first stage is used to predict image regions likely to contain people/objects. The second stage extracts a feature representation from each region and applies three neural “heads” to (i) classify presence/absence of the person, (ii) predict the corresponding segmentation, and (iii) keypoint-based representation of the pose. Because everything is integrated and trained end-to-end, Mask-RCNN doesn’t suffer from some of the typical issues that older two-stage frameworks have encountered. Mask-RCNN, and other similar approaches, tends to work well when person instances in the image or video are well separated or lightly occluded.

It becomes consistently more difficult to deal with cases where person instances are significantly occluding one another. Notably such challenging scenarios make it difficult to detect person instances robustly in the first place. In general, robust multi-pose estimation requires more detailed reasoning which involves association of joints to individual pose instances. One approach for doing this was discussed above in the context of OpenPose [11]; however, many other alternatives exist [16, 42]. In [11] person detection is avoided by producing heatmaps and PAF for the entire input image, irrespective of the number of persons present, and then formulating optimal keypoint association as a maximum weight bipartite graph matching problem which is solved using Hungarian algorithm. Alternatively, [42] formulate the association as an instance of an integer linear program, implicitly performing non-maximum suppression on the set of part candidates, in a part-based formulation, and grouping them to form configurations of body respecting geometric and appearance constraints. Approaches of this form typically fall into category of part-based

Human Pose Estimation, Fig. 3 Lifting: Two instances of 2d-to-3d lifting architectures are illustrated. On top is the illustration of the simple architecture introduced in [33] which comprises of $\times 2$ blocks, each containing two fully connected/linear layers with ReLU activations. Bottom is the more sophisticated network introduced in [67], which composes of an integrated 2d heatmap-based estimation pipeline and the semantic graph convolutional network, illustrated in the very bottom, responsible for lifting 2d pose estimates to 3d; intermediate 2d and final 3d losses are combined and the network is trained end-to-end

part/keypoint detection and (c) Part Affinity Fields for part association. The parsing step (d) performs a set of bipartite matchings to associate body part candidates into body poses (e). (Figure is reproduced from [11])

models which we will discuss later; a more detailed discussion is beyond the scope of this chapter.

Inference (generative) Alternatively, one can take a generative approach and express the desired posterior, $p(\mathbf{x}|\mathbf{z})$, as a product of a likelihood and a prior:

$$p(\mathbf{x}|\mathbf{z}) \propto \underbrace{p(\mathbf{z}|\mathbf{x})}_{\text{likelihood prior}} p(\mathbf{x}) \quad (9)$$

Characterizing this high-dimensional posterior distribution is typically hard; hence, most approaches rely on a posteriori (MAP) solutions that look for the most probable configurations that are both typical (have high prior probability) and can explain the image data well (have high likelihood):

$$\mathbf{x}^* = \arg \max_{\mathbf{x}} p(\mathbf{x}|\mathbf{z}). \quad (10)$$

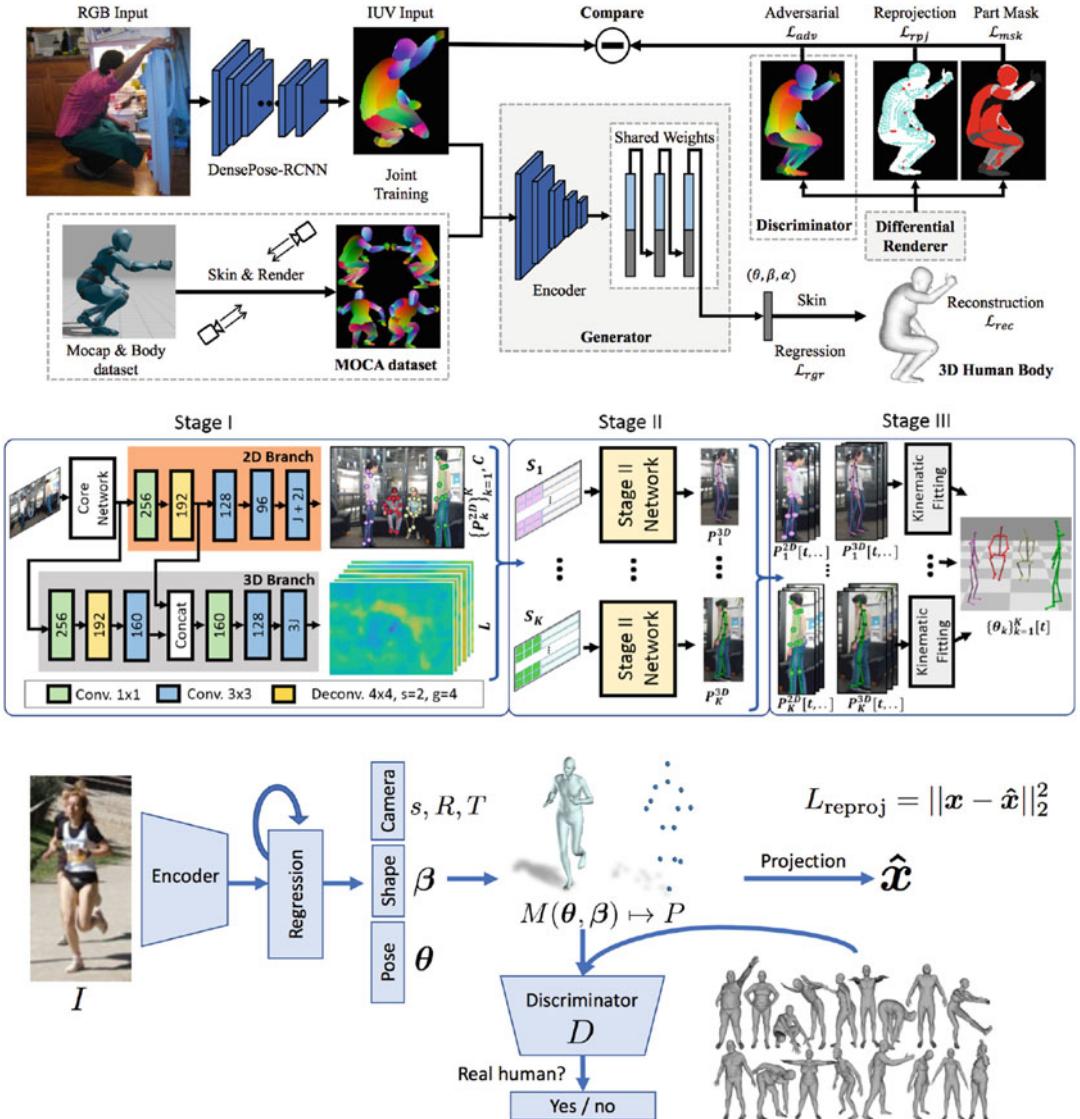

Classically, search for such configurations, in the high-dimensional (40+) articulation space, has been challenging with most approaches frequently get stuck in local optima. Global stochastic hierarchical search methods, such as annealed particle filter [19] or hybrid MCMC, have shown some promising results for simple skeletal configurations, where body is mostly upright and when observations from multiple cameras are available (Fig. 5).

More recently, the advancements in differentiable renderers allowed direct gradient-based optimization [62] with respect to the desired

image-matching objectives (e.g., joint reproduction, silhouette and part-mask projections). For example, [34] uses a three stage pipeline that first regresses 2d keypoints, using approach similar to OpenPose [11], then lifts the 2d keypoints to 3d, using a set of fully connected layers, and then finally estimates the 3d kinematic pose using a gradient-based optimization procedure which involves forward kinematics. The quality of estimates being generated by CNN-based regression algorithms is also able to provide good initial starting points for optimization itself that are much more likely to converge to global optima (or close to it). In particular, a number of recent approaches (e.g., [26, 29]) take the form of initial neural network regression of the 3d body pose (\mathbf{x}), body shape (\mathbf{s}), and camera parameters (C) and then optimize the objective that encompasses the likelihood and the prior:

$$\begin{aligned} & \{\mathbf{x}^*, \mathbf{s}^*\} \\ &= \arg \max_{\mathbf{x}, \mathbf{s}} \underbrace{E_{rep}(\mathbf{x}, \mathbf{s}; C, \mathbf{J}_{2d}) + \lambda_{3d} E_{3d}(\mathbf{x}, \mathbf{s}; \mathbf{J}_{3d})}_{\text{likelihood}} \\ &+ \underbrace{\lambda_x E_p(\mathbf{x}) + \lambda_s E_s(\mathbf{s})}_{\text{prior}}; \end{aligned} \quad (11)$$

the \mathbf{J}_{2d} , in the above, are typically 2d pose keypoint estimates produced by a CNN-based network and $E_{rep}(\cdot)$ is an L_2 [29, 34] or L_1 [26] error between the projected keypoints of the body model $\mathcal{M}(\mathbf{x}, \mathbf{s})$ (or equivalent) and the predicted 2d joints; notably, ground truth estimates can also be used instead for \mathbf{J}_{2d} if those are available. The second likelihood term measures L_2 similarity

Human Pose Estimation, Fig. 5 Generative models: Illustrated are three different recent generative architectures for 3d pose (and shape [26, 62]) estimation. While approaches share some architectural design principles,

they differ significantly in details. See discussion in the text for explanation. Worth noting is that [34] is real time. (Figures are reproduced from [62], [34], and [26] top-to-bottom, respectively)

between the keypoints derived from the predicted model, through forward kinematics and/or body model mesh generation and the corresponding ground truth markers \mathbf{J}_{3d} . Some methods add additional supervision on the body model parameters themselves, in terms of predicted and ground truth vectors $\{\mathbf{x}, \mathbf{s}\}$ directly [26, 29, 66].

The λ_x and λ_s are the weighting factors for corresponding pose and shape priors. The prior

terms take different forms. For example, in [34], $E_p(\cdot)$ takes the form of explicit (soft) joint limit constraints encoded using L_2 regularizer which activates when the joint is beyond a prescribed limit; [29] further adds a mixture of Gaussians pose prior to this, trained with SMPL body shapes fitted on marker data, and a quadratic penalty on the shape coefficients for $E_s(\cdot)$. An interesting departure is [26] which introduces a factorized

adversarial prior (using a GAN-like discriminator). The approach of [26] also utilizes iterative refinement, through error feedback, using a formulation similar to [12], made popular by CNN-based keypoint regression methods.

Discussion The latest generative models have produced truly impressive results. However, such approaches come with significant challenges. As can be noted from above, they often optimize combinations of multiple objectives with a variety of choices being employed for both architectural components and the terms in the objective itself. As a result, while some are able to utilize standard gradient-based optimization, others require multistage optimization procedures. Further, often datasets with different granularity of annotation need to be combined to train the final model. This stems from the fact that data that contains accurate 3d annotations typically comes from simplified environments (e.g., captured in the lab with specialized equipment such as 3d scanners), while in-the-wild data is often annotated with only 2d keypoints. Combination of the two sources of data typically is needed to train systems that are both accurate and able to generalize across complex imagery.

Inference (part-based models) Let us briefly review; regression models (classic or CNN-based), discussed so far, generally predict a set of 2d or 3d joints independently. This is efficient but lacks the ability to preserve structure between joints, at least potentially, resulting in pose configurations that are impossible or implausible. Generative models address this issue, since they typically search for a solution within the space of plausible pose configurations, but can result in expensive inference that may involve high-dimensional optimization at test time. Part-based models are a set of traditional approaches to pose estimation that are specifically designed to address both of those challenges through a distributed but loosely coupled representation of the body and the corresponding derived graphical model-based inference.

Part-based methods originate in the object recognition community with formulation of Fis-

chler and Elschlager (1973) and assume that a body can be represented as an assembly of parts that are connected by constraints imposed by the joints within the skeletal structure (and, sometimes, by the image “constraints” imposed by projections onto an image plane that account for occlusions). This formulation reduces the inference complexity because likely body part locations can be searched for independently, only considering the nearby body parts that constrain them, which significantly prunes the total search space.

Among the earliest successes along this line of research is the work of Lee and Cohen [30]. Their approach focused on obtaining proposal maps for the locations of individual joints within an image. These proposal maps were obtained based on a number of features that were computed densely over the image. For example, face detection was used to obtain hypotheses for the location of the head; head-shoulder contour matching, obtained using a deformable contour model and gradient descent, was used as evidence for shoulder joint locations; elliptical skin regions, obtained using skin-color segmentation, were used to determine the locations of the lower arms and lower legs. In addition, second-derivative (ridge) observations were used as evidence for other limbs of the body. Given proposals for the different joints, weighted by the confidence of corresponding detectors, a data-driven Markov chain Monte Carlo (MCMC) approach was used to recover 3d configurations of the skeleton. This inference relied on direct inverse kinematics (IK) obtained from 2d proposal maps. To further improve the results, a kinematic jump proposal process was also introduced. The kinematic jump proposal process involves flipping a body part or a set of parts (i.e., the head, a hand, or an entire arm) in the depth direction around its pivotal joint.

Other part-based approaches tried to assemble regions of an image into body parts and successively construct those parts into a body. Prime examples of such methods are introduced by Mori et al. [35] and Ren et al. [44]. In [35], super-pixels were first assembled into body parts based on the evaluation of low-level image cues, including contour, shape, shading,

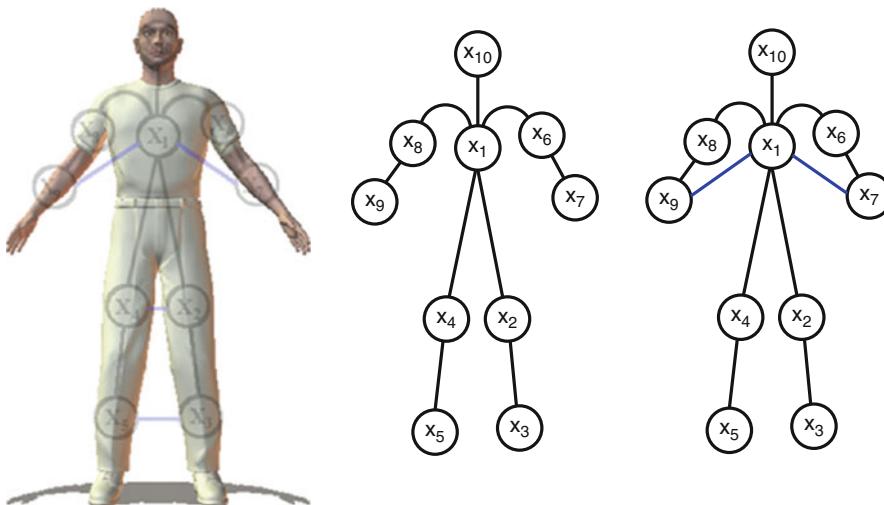

and focus. The part-proposals were then pruned and assembled together using length, body part adjacency, and clothing symmetry. A similar approach was taken in [44], but line segments were used instead of assembling super-pixels. Parallel lines were assembled into candidate parts using a set of predefined rules, and the candidate parts were in turn assembled into the body with a set of joint, scale, appearance, and orientation consistency constraints. Unlike [35], the search for the most probable body configurations was formulated as a solution to an integer quadratic programming (IQP) problem. More recent approaches rely on much more sophisticated body part detectors obtained using state-of-the-art object detection approaches (e.g., faster RCNN [42]) and formulate search over configurations of multiple persons using integer linear programming [42].

The most traditional approach, however, is to represent the body using a Markov random field (MRF) with body parts corresponding to the nodes and constraints between parts encoded by potential functions that account for physical and statistical dependencies (see Fig. 6). Formally, the posterior, $p(\mathbf{x}|\mathbf{z})$, can be expressed as:

$$p(\mathbf{x}|\mathbf{z}) \propto p(\mathbf{z}|\mathbf{x})p(\mathbf{x})$$

$$\begin{aligned} &= p(\mathbf{z}|\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M\})p(\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M\}) \\ &\approx \underbrace{\prod_{i=1}^M p(\mathbf{z}|\mathbf{x}_i) p(\mathbf{x}_i)}_{\text{likelihood}} \underbrace{\prod_{(i,j) \in E} p(\mathbf{x}_i, \mathbf{x}_j)}_{\text{prior}}. \end{aligned} \quad (12)$$

In this case, pose estimation takes the form of inference in a general MRF network. The inference can be solved efficiently using message-passing algorithms, such as belief propagation (BP) [28]. BP consists of two distinct phases: (1) a set of message-passing iterations are executed to propagate consistent part estimates within a graph, and (2) marginal posterior distributions are estimated for every body part [4, 17, 43]. A typical formulation looks at the configuration of the body in the 2d image plane and assumes discretization of the pose for each individual part, e.g., $\mathbf{x}_i = \{\tau_i, \theta_i, s_i\}$ where $\tau_i \in \mathbb{R}^2$ is the location and $\theta_i \in \mathbb{R}^1$ and $s_i \in \mathbb{R}^1$ are orientation and scale of the part i (represented as a rectangular patch) in the image plane. As a result, the inference is over a set of discrete part configurations $\mathbf{l}_i \in \mathbb{Z}$ (for part i), where \mathbb{Z} is the enumeration of poses for a part in an image (\mathbf{l}_i could be a discretization of \mathbf{x}_i). Notably, if a part is assumed to be parametrized by location only, i.e., $\mathbf{x}_i = \{\tau_i\}$, the representation is no different from a keypoint, and the part-based

Human Pose Estimation, Fig. 6 Pictorial structures model: Illustrated is the depiction of the ten-part tree-structured pictorial structures model (middle) and a non-

tree-structured (loopy) pictorial structures model (right). In the non-tree-structured model, additional constraints encoding occlusions are illustrated in blue

model would simply find a set of consistent keypoints that result in a plausible pose. With an additional assumption of pairwise potentials that account for kinematic constraints, the model forms a tree-structured graph known as the tree-structured pictorial structures (PS) model. An approximate inference with continuous variables is also possible [49, 50].

Inference in the tree-structured PS model first proceeds by sending recursively defined messages of the form:

$$m_{i \rightarrow j}(\mathbf{l}_j) = p(\mathbf{l}_i, \mathbf{l}_j) p(\mathbf{z}|\mathbf{l}_i) \sum_{k \in A(i) \setminus j} m_{k \rightarrow i}(\mathbf{l}_i), \quad (13)$$

where $m_{i \rightarrow j}$ is the message from part i to part j , with $p(\mathbf{l}_i, \mathbf{l}_j)$ measuring the compatibility of poses for the two parts and $p(\mathbf{z}|\mathbf{l}_i)$ the likelihood and $A(i) \setminus j$ is the set of parts in the graph adjacent to i except for j . Compatibility, $p(\mathbf{l}_i, \mathbf{l}_j)$, is often measured by the physical consistency of two parts at the joint or by their statistical (e.g., angular) co-occurrence with respect to one another.

Once all of the message updates are complete, the marginal posteriors for all of the parts can be estimated as:

$$p(\mathbf{l}_i | \mathbf{z}) \propto p(\mathbf{z}|\mathbf{l}_i) \prod_{j \in A(i)} m_{j \rightarrow i}(\mathbf{l}_i). \quad (14)$$

Similarly, the most likely configuration can be obtained as a MAP estimate:

$$\mathbf{l}_{i,MAP} = \arg \max_{\mathbf{l}_i} p(\mathbf{l}_i | \mathbf{z}). \quad (15)$$

One of the key benefits of the pictorial structures (PS) paradigm is its simplicity and efficiency. In PS exact inference is possible in the time linear in the number of discrete configurations a given part can assume. Because of this property, implementations [4] can handle the pixel-dense configurations of parts that result in millions of potential discrete states for each body part. The linear complexity comes from the observation that a generally complex non-Gaussian prior over neighboring parts, $p(\mathbf{x}_i, \mathbf{x}_j)$, can be expressed as a Gaussian prior over the

transformed locations corresponding to joints, mainly $p(\mathbf{x}_i, \mathbf{x}_j) = \mathcal{N}(T_{ij}(\mathbf{x}_i); T_{ji}(\mathbf{x}_j), \Sigma_{ij})$. This is done by defining a transformation, $T_{ij}(\mathbf{x}_i)$, that maps a common joint between parts i and j , defined in the part i 's coordinate frame, to its location in the image space. Similarly, $T_{ji}(\mathbf{x}_j)$ defines the transformation from the same common joint defined in the j 's coordinate frame to the location in the image plane. This transformation allows the inference to use an efficient solution that involves convolution (see [17] for more details).

Performance The effectiveness of a PS model is closely tied to the quality of the part likelihoods [4]. Discriminatively trained models [43] and more complex appearance models [4] outperform models defined by hand [17]. A more recent discriminative formulation of PS model allows joint learning of part appearances and model structure [63] using structural support vector machine (SVM).

Part-Based CNN Variants The latest approaches rely on deep learning formulations for both part likelihoods and inference. Recent work has shown that a typical formulation of PS can actually be expressed exactly as a CNN [20]. The construction involves formulating part detection using a CNN architecture and implementing unrolled inference in the MRF using a set of carefully constructed CNN layers. Some variants of this formulation include ability to learn compatibility functions between parts at the same time as the remaining parameters of the neural network. Alternatives formulate approximate inference in the conditional random field (CRF), instead of MRF, using a form of mean field algorithm, implemented using a recurrent neural network [14]. The latest variants, while not always explicitly making the connection to PS, utilize graph neural networks (GNNs) for inference [65]. GNNs effectively implement message passing needed for inference and do not require specific topology (tree-structure) of the underlying CRF/MRF. While GNN-based architectures typically cannot guarantee that the result is consistent with a specific form of a

marginal distribution, they do effectively carry out inference in a graph of the required topology making them uniquely appropriate for the task. Variants of such methods include [10, 67].

Non-tree-Structured Extensions Although tree-structured PS models are computationally efficient and exact, they generally are not sufficient to model all the necessary constraints imposed by the body. More complex relationships among the parts that fall outside of the realm of these models include non-penetration constraints and occlusion constraints [49]. Incorporating such relationships into the model adds loops corresponding to long-range dependencies between body parts. These loops complicate inference because (1) no optimal solutions can be found efficiently (message-passing algorithms, like BP, are not guaranteed to converge in loopy graphs) and (2) even approximate inference is typically computationally expensive. Despite these challenges, it has been argued that adding such constraints is necessary to improve performance [7]. To alleviate some of the inference complexities with these non-tree-structured models, a number of competing methods have been introduced. Early attempts used sampling techniques from the tree-structured posterior as proposals for evaluation of a more complex non-tree-structured model [15]. To obtain optimality guarantees, branch-and-bound search was recently proposed by Tian et al. [55], with the tree-structured solutions as a lower bound on the more complex loopy model energy.

Datasets No discussion of pose estimation would be complete without some mention of the common datasets and benchmarks that have driven performance on the task. The COCO dataset [31] and the corresponding COCO Keypoint Detection Challenge, which has been running since 2016, require localization of person keypoints in challenging, uncontrolled conditions. The task requires simultaneous detection of people and their pose. The COCO train, validation, and test sets contain more than 200,000 images and 250,000 person instances labeled with keypoints. A similar benchmark, but

focusing on videos, was proposed as part of MPII Human Pose dataset [6]. The dataset includes approximately 25,000 images, taken from YouTube videos, containing over 40,000 people with annotated body joints. Interestingly, the collection procedure in [6] utilized established taxonomy of everyday human activities, resulting in hierarchical activity labels that accompany the videos. Both COCO and MPII datasets provide 2d annotated poses in complex imaging conditions: community photographs with single and multiple subjects exhibiting diversity of poses, clothing, and backgrounds. These challenges and abundance of annotations made these datasets popular choices for benchmarking advances in 2d pose estimation.

Collection of 3d pose datasets is significantly more challenging and, in general, requires specialized equipment. To this end, Human3.6M [23] dataset was introduced in 2014. Human3.6M contains multi-view video hardware synchronized with 3d poses obtained using commercial marker-based motion capture system. As implicit in the name, dataset contains 3.6 million frames and corresponding poses of actors performing variety of pre-scripted everyday activities. While the dataset spans a good variety of poses, the image complexity, in terms of background and clothing of the subjects, is limited due to requirements of the setup that limits capture to an instrumented indoor environment. Nevertheless, Human3.6M continues to be one of the most widely used datasets for benchmarking 3d pose estimation and 2d-to-3d lifting approaches.

Open Problems

Human pose estimation is an active area of research with algorithms evolving quickly over the last couple of years. Performance of 2d keypoint-based, and corresponding 3d lifting, architectures continues to increase with development of more sophisticated neural models. The use of graph-based neural networks (GNNs) [10, 67], in this context, appears particularly promising as a way to add structure into the predictions. These trends of improving

performance through better architectural designs is likely to continue at least for the next couple of years. Further, there is significant evidence suggesting that successfully estimating pose independently at every frame is a very ill-posed problem. Spatiotemporal models that aggregate information over time [10, 66] are emerging as a way to regularize performance and smooth out the noise in the estimates. Some of such models, e.g., [41], are starting to leverage physics-based modeling and reasoning to improve plausibility of both poses and recovered dynamics; this appears to be a promising future direction. Much more work is also needed to build realistic human avatars, by recovering not only body pose and shape in the form of realistic body models (e.g., SCAPE or SMPL) but also clothing and texture.

Speaking more broadly, and longer term, one needs to integrate multi-person models and start to reason about pose in the context of the environments and objects that subject is interacting with. This is a very challenging task that will require integration of multi-person pose estimation with other techniques in computer vision (e.g., object detection, segmentation, and scene understanding). Finally, nearly all work in pose estimation assumes passive cameras and capture environments. Very recent approaches are starting to experiment with active capture setups [27], where, for example, a camera is able to follow the subject and capture the images/video in service of recovering the pose from opportune angles. This direction not only opens up a broader set of applications (i.e., capturing poses that are part of extreme mobile activities, e.g., skiing, riding horses, etc.) but also enables opportunities for positioning the cameras in a way that actually simplifies the task and reduces pose ambiguities.

Finally, nearly all of the approaches discussed in this chapter are learning-based and require large datasets of images/videos with annotated poses to learn from. One would argue that current approach are, at least, as limited by the data as they are by algorithmic innovations. While this challenge is not unique to pose estimation and is broadly applicable to problems across the computer vision, it is exacerbated by the complexity of required pose annotations (especially

when considering poses in 3d). As such, the trend of unsupervised learning widely regarded as the next frontier for scaling neural architectures is also starting to exhibit itself in pose estimation domain, with initial successes shown by [13] and [45]. One would expect this trend to only grow over the next couple of years.

Definition

Hyperspectral imaging (HSI) is a newly developing technique combining the advantages of optical imaging and spectroscopy to simultaneously collect spatial and spectral information from a scene. A set of monochromatic images at almost continuous hundreds of wavelengths can be acquired by HSI.

Background

The light emitted from illumination sources or reflected from scene objects generally spans a broad range of wavelengths [13]. The vision of the human eye is dependent on three basic color (red, green, and blue) bands, which means the human eye is only able to see a limited part of the electromagnetic spectrum and distinguish between objects based on their different spectral responses in that narrow spectral range. Though trichromatic sensing suffices for the human visual system in many circumstances, hyperspectral imaging collects image data with a greater number of spectral channels than traditional trichromatic sensors, thus providing spectral information about the captured scene and objects at a higher level of detail. In HSI, each pixel of the image contains spectral information which is added as a third dimension of values to the two-dimensional spatial image, generating a three-dimensional data cube. A simple, well-known example of a three-dimensional data cube is the common RGB image, where each pixel only has three bands (red, green, and blue) of the visible spectrum. The three bands are limited to observing scenes and usually not able to

obtain enough information about the external or internal components of the material. Hyperspectral data cubes contain continuous narrow bands ($<10\text{ nm}$) across the electromagnetic spectrum and can provide absorption, reflectance, or fluorescence spectrum data for each image pixel. The additional spectral information contained with the continuous hyperspectral image can be utilized to more accurately analyze and understand micro- and nanoscale spectral features, which are not feasible by the discrete RGB imaging with only three bands (Fig. 1).

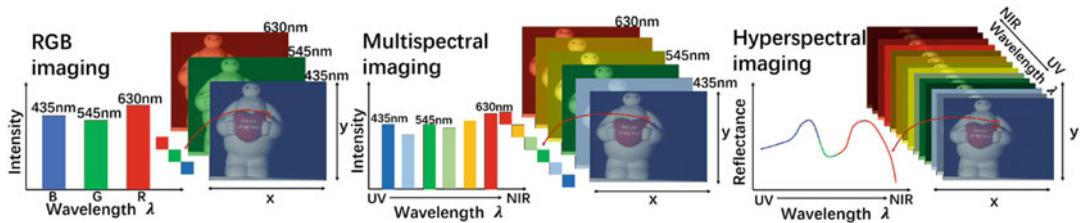

Multispectral imaging (MSI) acquires data in a small number of spectral bands. As the superset of multispectral imaging, HSI consists of a larger number of spectral bands (i.e., having a higher spectral resolution) and generates continuous spectral bands.

H

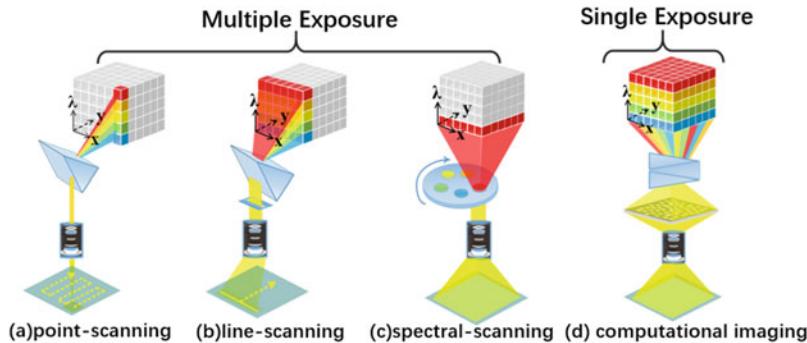

Theory

In the past few decades, various methods have been developed for acquiring hyperspectral data $S(x, y, \lambda)$ which has two spatial dimensions (x, y) and one spectral dimension (λ). Since hyperspectral data cubes $S(x, y, \lambda)$ are of a higher dimensionality than the two-dimensional (2D) camera detector arrays currently available, the design of hyperspectral imaging methods trades off either temporal resolution or spatial resolution. There are mainly two types of methods, namely, the scanning-based methods (multiple exposure) and the computational imaging methods (single exposure) (Fig. 2).

The scanning-based methods The development of the scanning-based methods has gone through three stages: the point-scanning methods, the line-scanning methods, and the spectral-scanning methods. The point-scanning methods [18] capture the spectrum of a single spatial location at each time instant and thus require substantial time to obtain an entire 3D data cube. Rather than a pinhole aperture, the line-scanning methods [28] employ a slit aperture aligned with one of the two spatial dimensions (either x or y), and the spectrometer is translated

Hyperspectral/Multispectral Imaging, Fig. 1 The comparison of RGB imaging, multispectral imaging, and hyperspectral imaging

Hyperspectral/Multispectral Imaging, Fig. 2 The portions of the data cube collected during the hyperspectral imaging process for the scanning-based methods (multiple exposure) and the computational imaging

methods (single exposure). (Figure is modified from [39].) (a) Point-scanning. (b) Line-scanning. (c) Spectral-scanning. (d) Computational imaging

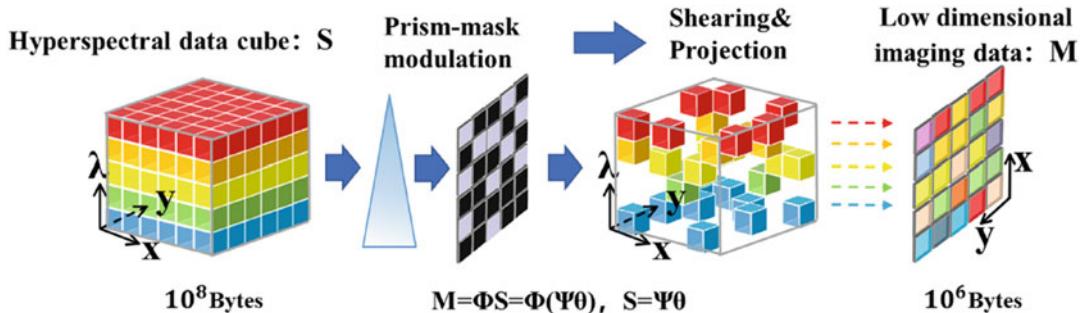

along the other direction, providing much lower latency than the point-scanning methods. Both the line-scanning methods and the point-scanning methods utilize a dispersive component to expand the spectral information of the incoming signals in spatial dimension, and the exposure time can be lengthened to increase signal intensity. Nevertheless, they also involve more mechanical and calibration complexity in practice. The spectral-scanning methods record a sequence of images using different narrowband filters in the optical path of an imaging device, which effectively samples a set of full spatial resolution images over the spectral range at the expense of temporal resolution. For instance, Schechner and Nayar [30] attached a spatially varying color filter rigidly to a movable camera – as the camera moves, it senses each pixel in the scene multiple times, each time in a different spectral band. Different from the traditional scanning methods, acousto-optic tunable filter

[17] (AOTF) and liquid crystal tunable filter [1] (LCTF) are based on the principle of polarized light and have a very fast scanning speed. In addition to passive spectral-scanning methods, Nayar et al. [19] proposed the multiplexed illumination scheme which employs active illumination to sweep from band to band. There are also other scanning methods such as Fourier transform spectral imaging methods which scan one mirror of a Michelson interferometer in order to obtain measurements at multiple optical path difference (OPD) values – the Fourier domain equivalent of a tunable filter camera [11]. Agile spectrum imaging [29] uses a diffraction grating to disperse the rays into different colors and introduce a slot-like mask in the optical path to modulate the spectrum. Over the past 30 years, scanning techniques have witnessed an impressive improvement, but the underlying technology and concepts have not changed significantly. Most of these

systems trade off temporal resolution for spectral resolution and are thus unsuitable for video acquisition. Since the scanning-based methods cannot capture dynamic scenes, technology for collecting high-dimensional spectral data cubes in a single exposure appears.

The computational imaging methods To overcome the limitation of the scanning-based methods, several snapshot methods have been developed in the past few decades. From the 1930s to the 1960s, to be applied in astronomy, the most common approaches to snapshot imaging spectrometry are the integral field techniques (based on mirror arrays, fiber arrays, and lenslet arrays: IFS-M [6], IFS-F [21], and IFS-L [10]) – so-called because each individual measurement of a data cube voxel results from integrating over a region of the field. In the 1970s, multispectral beamsplitting methods [33] are brought up which make use of multiple beamsplitters to split incident light into several color bands. A more conceptually simple approach – multiaperture filtered camera [32] (MAFC 1994) – uses an array of imaging elements and places a different filter at each element in order to collect portions of the full spectral band. In the tunable echelle imager [2] (TEI 2000), the output from an imaging Fabry-Perot interferometer is cross-dispersed by a grism in one direction and dispersed by an echelle grating in the perpendicular direction. This forms a mosaic of different narrowband images of the same field on a detector. Though with the capability of multispectral acquisition at a snapshot, these methods are still insufficient in spatial resolution or spectral resolution. The advent of large-format (4 megapixel) detector arrays, some 20 years ago, brought with the capability to measure millions of voxels simultaneously, which makes snapshot spectral imaging practical and useful [20]. Techniques based on computed tomography imaging spectrometry (CTIS [12], 1995) have been presented for multispectral imaging in a single snapshot. Inspired by tomographic medical imaging, Descour and Dereniak [12] introduced the approach of reconstructing a 3D data cube

with two spatial and one spectral dimension from a set of simultaneously captured 2D projections that integrate spectral signals from different scene positions on the detector. A major advantage of the CTIS approach is that the system layout can be made quite compact, but a major disadvantage has been the difficulty in manufacturing the kinoform dispersing elements. Moreover, since its inception, CTIS has had to deal with problems surrounding its computational complexity, calibration difficulty, and measurement artifacts. Though video imagery could potentially be acquired via CTIS, the computationally intensive reconstruction, requiring up to 20–30 min per frame for a $100 \times 100 \times 100$ data cube, makes tomographic approaches unsuitable for real-time video applications at that time. Coded aperture snapshot spectral imager (CASSI [8], 2006) is the first spectral imager attempting to take advantage of compressive sensing theory for snapshot measurement which estimates a spectral image from fewer measurements than data cube entries. The underdetermined data cube is solved by assuming sparsity in a multiscale wavelet basis, a common property of natural scenes. As illustrated in Fig. 3, The whole under-sampling process of the compressive sensing [4] theory can be regarded as a sensing matrix (Φ) for the high-dimensional spectral data. The hyperspectral data cube $S(x, y, \lambda)$ is coded through a prism-mask modulation and mapped to a low-dimensional imaging matrix M ($M = \Phi S$). S can have a sparse representation of a spectral vector orthonormal basis Ψ and a sparse coefficient θ ($S = \Psi\theta$). When the sensing matrix Φ and the orthonormal basis Ψ have smaller coherence, fewer measurements are needed for complete reconstruction, and the sensing system has higher sampling efficiency; therefore, the high-precision reconstruction from the low-dimensional imaging data M to the original hyperspectral data cube S can be realized. A dual disperser (DD) CASSI [16] and a single disperser (SD) CASSI [37] were later proposed to improve spatial and spectral resolving power. Compressive spectral imaging systems are much more compact and flexible in various application fields and have a lower cost. Nevertheless, limitations still exist in the

Hyperspectral/Multispectral Imaging, Fig. 3 Schematic of the prism-mask modulation based system (CASSI[8,16, 37]; PMVIS [9,13])

coded aperture-based imaging systems, whereby (1) the reconstruction error is unavoidable due to the sparsity assumption for a natural scene and (2) the computational complexities of the reconstruction algorithms, such as TWIST [5], ADMM [7], and HS dictionary learning plus sparse-constraint computational reconstruction algorithms [25], are not satisfying, and the high-dimensional spectral data cannot be reconstructed in real-time. In order to overcome the above disadvantages, Wang et al. [38, 40] proposed a dual-camera imaging system based on complementary observations, and a hyperspectral image reconstruction algorithm combining the data and prior knowledge is developed. Cao et al. [9, 13] proposed the prism-mask multispectral video imaging system (PMVIS, 2011) which can be constructed with the low-cost off-the-shelf optical components and is much simpler to calibrate in practice. Additionally, PMVIS can generate high-dimensional spectral videos in real-time. Considering that spectral resolution has been the short board in many machine vision applications, snapshot hyperspectral imaging Fourier transform spectrometer [22] (SHIFT, 2010), multispectral Sagnac interferometer [23] (MSI, 2010), and image mapping spectrometer [15] (IMS, 2010) were proposed to trade the high spatial resolution of a camera for a higher spectral resolution. Following this, Manakov et al. [27] proposed a reconfigurable camera add-on (2013) that enables plenoptic imaging based on a physical copying mechanism, which multiplies a sensor image into a number of identical copies

and recovers the desired information via different optical filters.

New trends In the past years, the spatial and spectral resolution achieved by the computational imaging systems have become sufficient that the devices are now commercially viable (XIMEA, Specim, Pixelteq, ALPhANOV, LinkSquare, etc. [41]). More recently, with the rapid development in big data science and semiconductor device fabrication, some newly developed imaging systems have been emerging. As a substitute for traditional dispersive elements, e.g., prism and grating over hundreds of years, micro-nano fabrication allows wavelength-level modulation on chip such as the colloidal quantum dot spectrometer [3] (CQD, 2015) and the Imec's on-chip filter technology, the latter providing high spatial (up to 7Mpx) and spectral (150+bands) resolution in a compact, lightweight, and mass-manufacturable design. In addition, metasurfaces [35,42,43] based on resonant subwavelength photonic structures enable novel ways of wavefront control and light focusing, underpinning a new generation of flat-optics devices. In conclusion, the computational imaging methods have demonstrated considerable potential than the scanning methods in various applications because of the remarkable efficiency in dynamic spectrum capture and simple low-cost system configurations. Meanwhile, several limitations exist in different spectral imaging systems, which must account for further combinations of optical principles, compressive sensing theory, machine learning

algorithms, and semiconductor device fabrication technologies.

Application

Since various material and object properties can be inferred from detailed spectrum, acquisition systems for precise spectral measurements can be effective tools for scientific research and engineering applications. HSI has been applied to numerous applications including environmental monitoring [34], military defense [31], art conservation and archeology [24], medical diagnosis [26], food quality control [14], and mineralogical mapping of earth surface [36].

Open Problems

The rapid increase of possible HSI applications requires the availability of better hyperspectral imaging methods with a much higher speed in acquisition speed, smarter data elaboration, new set-ups, and new ideas. The increase number of spectral bands will result in lower signal-to-noise ratio (SNR) per band, and the varying illumination can be a challenging condition for HSI. How to obtain hyperspectral images with higher spatial resolution and higher spectral resolution stably at a lower time cost is still a problem worthy of study.

- ▶ [Color Constancy](#)
- ▶ [Incident Light Measurement](#)

Definition

The purpose of illumination estimation is to determine the direction and intensity of the lighting in a scene. In contrast to direct measurement of lighting, the illumination information is inferred from visual cues within the scene, without the use of a special probe.

Estimating the illumination color of a scene may also be referred to as illumination estimation. This research problem is commonly termed as *color constancy*, which is described in another entry of this encyclopedia.

Background

The appearance of objects and scenes can vary considerably with respect to illumination conditions. In [1], differences in face appearance due to lighting were found to be greater than those due to identity. Since such appearance variations can affect the performance of certain computer vision algorithms, much research has focused on illumination estimation, so that lighting can be accounted for in image understanding.

To simplify inference, methods for illumination estimation typically assume that the illumination originates from distant light sources. With this assumption, the illumination can be considered to be uniform across the scene, such that only a single global lighting condition needs to be estimated. Most techniques perform this estimation on a single input image, as this allows for wider applicability.

Early Methods

Early methods generally infer illumination from a particular lighting effect within an image. Several techniques categorized by lighting cue are described in the following.

Shading

Many methods for illumination estimation are based on an analysis of shading over the surface of an object. They typically utilize the relationship between shading and lighting described by

the Lambertian reflectance model:

$$I(x) = \rho(x)N(x) \cdot L$$

where x indexes the shaded image pixels, I denotes image intensity (shading), ρ is the albedo, $N(x)$ is the surface normal, and L is the light vector that encodes the direction and magnitude of illumination. To solve for L , shading-based techniques often assume the surface of interest to have a uniform albedo and a known geometry. If the absolute albedo value is unknown, then L can be estimated only up to an unknown scale factor.

While some methods focus on recovering just the direction of a single illuminant [2, 3], most address the more common scenario of multiple illumination sources. Hougen and Ahuja [4] solve a set of linear equations to determine light intensities from a set of sampled directions. Yang and Yuille [5] use image intensities and known surface normals at occluding boundaries to constrain illuminant directions. Ramamoorthi and Hanrahan [6] compute a low-frequency illumination distribution from a deconvolution of reflectance and lighting. Zhang and Yang [7] estimate lighting directions from critical points which have surface normals perpendicular to an illuminant direction. Based on this, Wang and Samaras [8] segmented images into regions of uniform lighting and then performed estimation by recursive least-squares fitting of the Lambertian reflectance model to these regions.

Illumination may alternatively be estimated by uncalibrated photometric stereo [9], without the need for known albedos and surface normals. This approach requires a set of images taken under different lighting conditions as input.

Cast Shadows

Several techniques analyze cast shadows for illumination estimation. For an object of known shape, the shadows that it casts provide constraints on the lighting directions and their corresponding intensities. Sato et al. [10–13] formulated these constraints as a system of equations in terms of observed brightness values within shadows and a set of sampled lighting directions

at which source intensities are to be solved. These methods require a single input image for objects that cast shadows onto a uniform-colored surface; two images are needed to cancel out the effects of color variation for surfaces with texture. This approach was extended by Okabe et al. [14] to a lighting representation of Haar wavelets. Kim and Hong [15] later proposed a single-image method that handles surface texture by incorporating regularization and some user-specified information.

Specular Reflections

Some methods consider specular reflections in estimating illumination. From the locations of specular reflections on an object of known shape, these techniques compute the corresponding light source directions according to the mirror reflection property. This approach was used by Nishino et al. [16] to obtain an initial approximation of the illumination distribution, which is then refined using a more sophisticated model of reflectance. Illumination cues from specular reflections are combined with those from shading and shadows by Li et al. [17] to minimize the effects of scene texture on lighting estimation. Without needing explicit object shape recovery, Nishino et al. [18] and Wang et al. [19] proposed to estimate lighting from specular reflections on human eyes, which are highly reflective and have a similar shape from person to person.

Recent Techniques

Over the past decade, methods for illumination estimation have tended to consider image appearance more holistically, rather than focus on specific lighting effects. Many also are designed to jointly estimate other appearance factors such as reflectance or shape in addition to illumination, thus avoiding the need for strong assumptions or measured data on these properties. Moreover, most recent methods are able to infer more general models of lighting, such as environment maps, and employ deep learning to take advantage of information from large datasets.

These techniques can be classified according to the locality of the scene area they process.

While some estimate lighting from the appearance of an individual object, others utilize the partial view of a scene that is visible within an image.

Object-Based Estimation

Some methods for estimating illumination from a single object perform optimization over multiple appearance factors. These works must address ambiguities that exist among these factors, where a change in one can be offset by a corresponding change in another to yield the same object appearance. To deal with this problem, constraints based on prior knowledge have been imposed on the appearance factors, such that they conform to typical illumination conditions, reflectance properties, or object shapes. Given a known object shape, Lombardi and Nishino [20, 21] solve for illumination and reflectance by Bayesian joint estimation. Priors on illumination include it being of low entropy and having a heavy-tailed gradient distribution derived from natural image statistics. For reflectance, the estimates are bounded within a space of natural reflectances measured from real-world materials. Barron and Malik [22] estimate all three factors of shape, illumination, and reflectance. Among the priors employed are that the reflectance is piecewise constant and has a sparse palette, that the shape is smooth and has an isotropic distribution of surface orientations, and that the illumination fits a multivariate Gaussian model of low-order spherical harmonics.

More recently, methods for object-based illumination estimation have utilized convolutional neural networks. Many of these works specifically address the case of human faces, which are common in images and for which prior knowledge about face shape and appearance can be incorporated. From facial appearance, illumination has been estimated in the form of sun and sky models [23], directional lighting [24], spherical harmonics [25–27], and non-parametric environment maps [28, 29].

For more general objects, neural networks have been designed to estimate an environment map from an image given certain additional information or assumed object properties. Georgoulis et al. [30] addressed the case of

homogeneous specular objects with unknown shape, where a reflectance map is first estimated and then factorized into parametric reflectance and an environment map. They additionally presented a method to deal with piecewise constant materials given approximate surface normals [31]. This approach also estimates an intermediate reflectance map, but does so for each surface material and uses them jointly to estimate illumination. With known object geometry and reflectance, Weber et al. [32] estimate a low-dimensional model of indoor lighting learned from a dataset of indoor illumination environments. For the case of RGBD images, Wei et al. [33] take advantage of physical principles from inverse rendering to constrain illumination estimates while also utilizing neural networks to expedite the more computationally expensive portions of its processing.

A benefit of estimating illumination from individual objects is that this naturally allows for spatially varying lighting to be recovered, since different local illumination conditions can be inferred at different object locations within an image. However, a local object region may contain less information for illumination estimation than a more global scene area.

Scene-Based Estimation

In estimating the lighting from a view of the scene, several works utilize illumination models specific to outdoor environments. Lalonde et al. [34] combine cues from cast shadows, shading, and sky appearance with a data-driven prior to estimate a probability distribution of the sun position and parameters of a sky model. Hold-Geoffrey et al. [35] train a CNN to predict parameters of a low-dimensional outdoor illumination model by using image crops of outdoor panoramas as input and obtaining the ground truth by fitting the model to the panorama's sky regions. This work is extended by Zhang et al. [36] to handle different weather conditions. A separate network is trained to regress the parameters of a high dynamic range (HDR) outdoor illumination model from a low dynamic range (LDR) panorama, and this network is then used to label

a training set for the main illumination estimation network. In contrast to these methods based on analytical sky models, Hold-Geoffrey et al. [37] learn a data-driven sky model jointly with illumination estimation in an end-to-end manner.

Numerous other techniques have been presented instead for indoor settings. Some follow an approach of directly regressing illumination from scene appearance. Among them are a method by Gardner et al. [38] that trains a network to estimate light directions from a large set of LDR panoramas, where rectangular crops are taken as input images and the ground-truth lighting directions are derived from the panoramas. A small set of HDR panoramas is then used to fine-tune the network for predicting light intensities. This panorama-based approach is extended by Gardner et al. [39], who simplify the inference task by estimating illumination as a set of discrete light sources rather than as a general environment map. The 3D geometric and photometric parameters of the lights are regressed from a single image by a deep neural network. Different from these methods, Garon et al. [40] estimate spatially varying illumination, in the form of spherical harmonics at different image locations. For improved training and prediction, they employ multi-task learning where low-frequency depth, albedo, and shading are jointly learned as auxiliary subtasks together with the illumination estimation.

Indoor illumination has also been estimated in a geometric manner via 3D scene reconstruction. Song and Funkhouser [41] employ a neural network to infer scene geometry from the image, and then a partial environment map for any scene position is reconstructed through reprojection of the image pixels via the predicted geometry. The rest of the environment map is completed using a generative network, and then a third model is applied to infer HDR light intensities from the LDR image colors. Srinivasan et al. [42] instead predict a volumetric scene representation from a narrow-baseline stereo pair of images, where a novel view near the stereo pair and an environment map captured within the scene are provided as rendering targets for the loss function. From

the estimated volume, an environment map at a queried 3D location is generated by casting rays along the directions sampled in the environment map.

In addition to scene geometry, the reflectance properties of surfaces and their effects on light transport within a scene are accounted for in methods based on differentiable rendering. A differentiable renderer generates image appearance from scene attributes, namely, illumination, geometry, and reflectance, while explicitly retaining gradients of the rendered image with respect to these attributes. With these gradients, a neural network can be trained to estimate lighting as well as other scene attributes by minimizing the difference of its rendered images and the corresponding observed scenes. Azinovic et al. [43] present a differentiable Monte Carlo path tracer for estimating reflectance properties and lighting given 3D scene geometry and several images as input. Environment lighting, albedos, and surface normals are jointly estimated in the work of Sengupta et al. [44], which introduces a residual appearance renderer trained to model complex appearance effects not captured by rendering of direct illumination. Li et al. [45] employ a differentiable rendering layer to more generally estimate spatially varying lighting and reflectance in addition to shape, with illumination modeled by a spherical Gaussian representation.

Applicable to both indoor or outdoor settings, the method of Cheng et al. [46] recovers a spherical harmonics model of lighting using paired photos from the front and rear cameras of a mobile device. Estimating from single-image input, LeGendre et al. [47] train a neural network on LDR videos that include spheres of various reflectivity at the bottom of the frame. The network learns to predict an HDR environment map from the background image that is consistent with the appearance of the spheres.

Applications

Illumination estimation has been employed in various applications based on appearance modeling. In [18], lighting estimates from eye

reflections are used for robust face recognition under varying illumination conditions. Estimates of scene illumination have also been used to realistically composite virtual objects into real images in an illumination-consistent manner [33, 34, 40, 42, 43, 45, 48, 49], to relight human faces [24, 27, 29], and to edit scene appearance, such as by replacing surface materials with others that have different reflectance properties [45] or by adjusting the lighting conditions [22, 49].

Image Decomposition: Traditional Approaches

Marshall F. Tappen

Amazon, University of Central Florida, Seattle,
WA, USA

Definition

An image decomposition is the result of a mathematical transformation of an image into a new set of images that represent different aspects of the input image or scene pictured in that image. The original image can typically be reconstructed from these new images.

Background

While images are primarily stored as an array of pixel values, an image can be represented in a number of different ways. For instance, an image can be easily transformed into two images, one containing the high-frequency variation in the input image and a second containing the low-frequency variation. This process decomposes the input image into two images, each of which expresses different information about the original image.

This process is useful when further processing will treat these two images differently. If the decomposition is chosen correctly, the image is decomposed into a set of images that can each be processed uniformly. Thus, the decomposition facilitates adaptive processing of the content of an image.

Theory

Image decompositions can be roughly divided into two different types of decompositions, image-based decompositions and intrinsic image decompositions. Image-based decompositions represent the image itself using new images, while the intrinsic image decompositions reflect

the content of the scene pictured in the image itself.

Image-Based Decompositions

Similar to the background example above, many image-based decompositions focus on representing multi-scale frequency content in the scene. The Gaussian pyramid is one of the most basic decompositions representing multi-scale content. The decomposition consists of a set of images of progressively smaller resolution, with each image being one level of the pyramid. Each level is created by filtering the image at the level below and then downsampling the result. This creates a multi-resolution set of images.

Depending on the application, the usefulness of the Gaussian pyramid may be limited because each level contains redundant information. This can be eliminated by modifying the pyramid creation process to create a Laplacian pyramid [1]. In the Laplacian pyramid, the input image is progressively downsampled. The image at level i in the Laplacian pyramid is computed by taking the difference between the i th level of the Gaussian pyramid and the upsampled version of level $i + 1$, which has been downsampled from the i th level of the Gaussian pyramid. Effectively, each level of the Laplacian pyramid expresses the image information at a particular scale. Figure 1 shows an example of the Laplacian decomposition of an image.

In [2], Simoncelli et al. extended this decomposition process to also separate orientation into different images, creating the steerable pyramid decomposition. Similar decompositions can also be generated by using a different process to separate the images. In [3], the bilateral filter is used to generate a two-image decomposition.

These decompositions are also connected to other image transformations, particularly wavelets. The connections are discussed in [2].

Intrinsic Image Decompositions

While image-based decompositions are focused on the pixel values themselves, intrinsic image decompositions create images that are based on the content of the scene. The intrinsic image decomposition is based on the

Image Decomposition: Traditional Approaches,

Fig. 1 These images are a Laplacian pyramid created from the well-known *Lena* image. Each image captures the variation at a specific scale

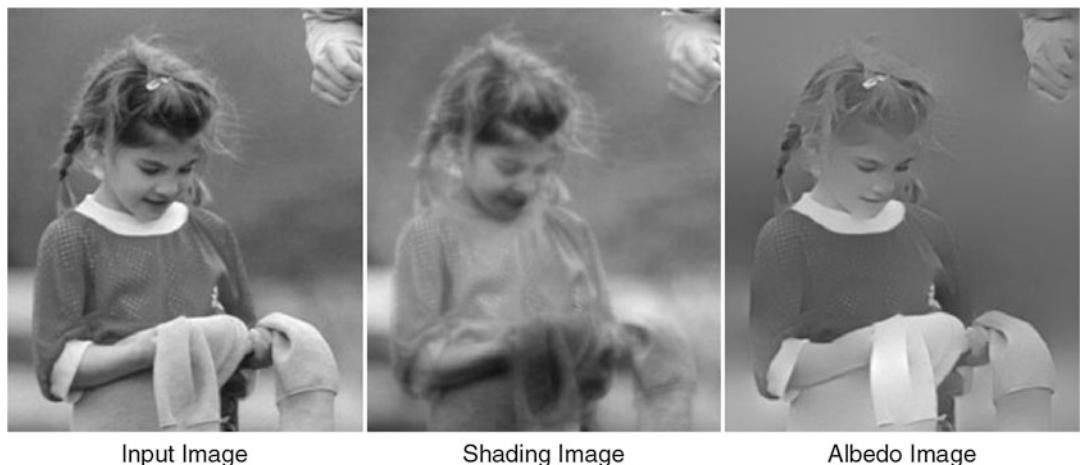

Image Decomposition: Traditional Approaches, Fig. 2 An example of an intrinsic image decomposition. The image on the *left* is decomposed into shading and albedo components

intrinsic image approach for representing scene characteristics. In this approach, each intrinsic characteristic of the scene is represented by a distinct image. These images are chosen to represent both intrinsic characteristics and image content.

In [4], Weiss uses video data to separate an image into illumination, or shading, and albedo components. In this decomposition, an input image pixel at location n , $I(n)$, is equal to the product of a shading image and an albedo image, or $I(n) = S(n) \times A(n)$. In [5] and [6], Tappen et al. show how the intrinsic image decomposition can be computed from a single

image. Figure 2 shows an example of an intrinsic image decomposition for the image on the left.

Application

Image decompositions are frequently used to generate images that process separately. In [7], Portilla et al. use the steerable pyramid to denoise images. Heeger and Bergen showed that texture can be generated by forcing the marginal histograms of the levels of a steerable pyramid to match those of a pyramid generated from a reference image [8]. More complete measures of

statistical similarity are used in [9], leading to improved synthesis results.

As mentioned earlier, the bilateral filter is used in [3] to separate the image into large- and fine-scale variations to combine images taken under different illumination. In [10], Bousseau et al. describe how user input can improve intrinsic image decompositions and demonstrate how they can be applied for graphics applications.

Traditionally, systems for creating image decompositions have been designed to separate different types of image causes by modeling the statistics of different contributors to surface appearance. Similar to many other areas of computer vision, these methods are now generally outperformed by deep learning methods.

Image Descriptors and Similarity Measures

Vincent Lepetit

ENPC ParisTech, Champs-sur-Marne, France

Definition

An image descriptor is a vector representing concisely the content of an image. A similarity measure is a function estimating the similarity between two objects, usually represented by vectors.

Background

Image descriptors are an ubiquitous tool in computer vision. By representing the content of an image or an image region in a compact and robust way, they make matching problems more efficient, as shown in Figs. 1 and 2. Typically, a descriptor is used to query a set of descriptors, looking for the most similar descriptor in the set. Efficient algorithms, such as hashing, can be used to make this search extremely fast, even for large databases, when the Euclidean distance can be used as similarity measure. Applications range from simultaneous localization and mapping (SLAM) and Structure from Motion (SfM) to image retrieval and object recognition.

Many different approaches were proposed over the years, and as almost any computer vision topic, deep learning has also changed the way descriptors could be computed. We describe below the most representative approaches to computing descriptors, as well as similarity measures, as these two concepts are closely related.

Image Descriptors and Similarity Measures, Fig. 1 Affine regions represented as ellipses matched across two images using their local descriptors. (Images from [1])

Image Descriptors and Similarity Measures, Fig. 2 By using the NetVLAD image descriptors, one can match images despite strong perspective and light changes. (Images from [2])

Local Image Descriptors

Early Developments and SIFT

A local descriptor is a vector of scalar values characterizing a region of an image, in a way that is as invariant as possible to factors such as illumination or perspective while being distinctive. For example, simply using pixel intensities for the descriptor's values would not be robust as they change when light or perspective change.

Since the descriptor is “local,” in the sense that it describes only a region of the image, one has first to choose the size and shape of this region. For many problems, the region is centered on “feature points,” which are detected using some automated method (SIFT, Harris, FAST detectors, etc.). The size can be manually specified or selected automatically. For example, the choice of size for the region can be based on the

scale-space theory: The size is then taken as a function of the standard deviation that maximizes the normalized Laplacian of Gaussian. It has been shown that this results in a region stable to scale changes [3].

An early description method depends on the image derivatives L_{ij} at the region center \mathbf{x} , computed by convolutions with Gaussian derivatives:

$$L_{ij}(\mathbf{x}) = \left(\left(\frac{\partial^i}{\partial u^i} \frac{\partial^j}{\partial v^j} G \right) * I \right) (\mathbf{x}), \quad (1)$$

where G is a Gaussian kernel and I denotes the image. The set of derivatives L_{ij} has been called “local jet” by Koenderink and van Doorn. It is possible to define a descriptor that is invariant to rotations based on them [4]:

$$\mathbf{d} = [L_{00}, L_{01}^2 + L_{10}^2, 2L_{10}L_{11}L_{01}, L_{20} + L_{02}, \dots]^T. \quad (2)$$

Note that the first coordinate is the weighted average intensity, the second one is the square of the intensity gradient magnitude, and the fourth one is the Laplacian of Gaussian of the intensities. Such descriptor can also be made to be invariant to scale changes. However, it is not invariant to perspective transformations. Its distinctiveness is also very limited, as it is made of only eight values.

Many other descriptors were proposed in the 1990s, based on various heuristics and images cues, such as color histograms, color moments, Gabor filters, etc., but the SIFT descriptor [5] introduced by Lowe was a clear breakthrough. This descriptor is based on multiple histograms of image gradient orientations, as shown in Fig. 3a. While it is not per se invariant to deformations or perspective transformations, it achieves a remarkable robustness to significant local deformations. The region is divided into several, typically 4×4 , subregions, and the contents of each subregion are summarized by an eight-bin histogram of gradient orientations. The descriptor is then a vector of 128 dimensions, built by concatenating the different histograms. Finally, this vector is normalized to unit length to reduce the effects of illumination changes.

The idea of building the descriptor from histograms of image gradients was key to achieve robustness to deformations and was motivated by the theory of Hubel and Wiesel on V1, the first layer of the mammals' visual cortex. In this theory, some neurons, called "simple cells," perform operations similar to oriented gradient detection. Other neurons, called "complex cells," collect the output of the simple cells with similar orientations but with slightly different receptive fields. Creating histograms of gradients is an efficient way to implement the functionality of the simple and complex cells.

GLOH is another keypoint extraction and description method [6], close to SIFT, the main difference being that the region has a foveal structure (Fig. 3b). SURF [7] is also closely related to SIFT. Even if it does not build explicitly histograms of gradients, it also computes sums of gradient magnitudes for several directions. The sums are computed using integral images,

which makes the SURF descriptor very efficient to compute, for a very good discriminative power. Implementations of SIFT on GPU also exist. The DAISY descriptor is also based on histograms of gradients [8], where the histogram regions form a foveal shape, and the histograms are computed by applying Gaussian smoothing to maps of oriented gradients. The advantage of DAISY is that it can be computed for each image location efficiently, which can be useful for dense image alignment, for example.

Invariance to Rotations and Affine Transformations

To achieve more invariance, an orientation can also be assigned to the region. Such orientation is also computed based on heuristics. For example, in SIFT, it is taken to be the one corresponding to a peak in the histogram of the gradient orientations within a region around the keypoint location. This method appears to be quite stable under viewpoint changes in practice. The image region is then rotated according to the estimated orientation, before computing the local descriptor.

Lindeberg and Garding [9], Baumberg [10] and Mikolajczyk and Schmid [1] showed that it is possible to estimate, from the pixel intensities of the region to describe, an affine transformation that varies with geometric transformations applied to this region. More exactly, the matrix of this affine transformation can be taken as the square root of the second moment matrix of the intensities and is defined up to a rotation. This missing rotation can however be estimated by the method described in the previous paragraph.

Such rectification techniques can be applied to any description method, even though a public implementation combining rectification and description from different authors is not always available.

Binary Local Descriptors

The descriptors described above are made of floating point values, which makes them relatively slow to compute and match. This can substantially affect real-time applications such as SLAM. Binary descriptors, which are binary

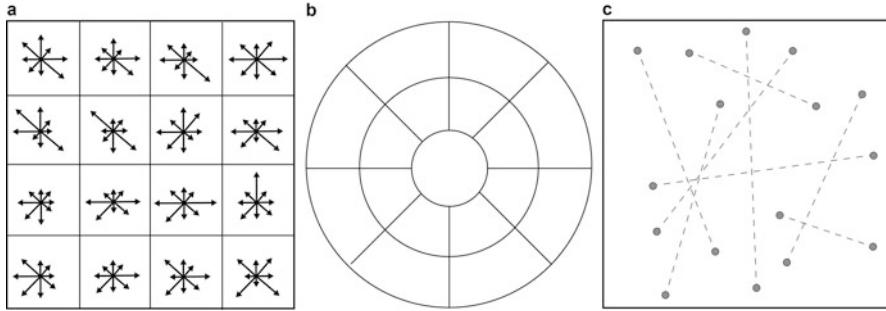

Image Descriptors and Similarity Measures, Fig. 3

Some local descriptors. (a) The SIFT descriptor is computed from eight-bin histograms of the image gradient directions for several subregions. (b) The GLOH descrip-

tor prefers a foveal shape for the subregions. (c) The BRIEF descriptor is computed by comparing image intensities at locations randomly selected

strings rather than vectors of floating point values, were invented for speeding up these operations.

An early local binary descriptor, called “census transform,” was motivated by stereo reconstruction [11], to make point matches robust to the presence of occluding contours and illumination changes. The census transform can be defined as

$$\mathbf{d} = \sum_i 2^i \tau(I, \mathbf{x}, \mathbf{y}_i), \quad (3)$$

where I denotes the image, \mathbf{x} the center of the local region, \mathbf{y}_i the image locations in this region, and τ a binary test:

$$\tau(I, \mathbf{x}, \mathbf{y}_i) = \begin{cases} 1 & \text{if } I(\mathbf{x}) < I(\mathbf{y}_i), \text{ and} \\ 0 & \text{otherwise.} \end{cases} \quad (4)$$

Locally Binary Patterns (LBPs) also build a bit string where the neighborhoods are taken to be circles of fixed radius [12]. Unlike census, however, LBPs usually translate the bit strings into its decimal representation and build a histogram of these decimal values. The concatenation of these histogram values has been found to result in stable descriptors. Extensions are numerous.

The BRIEF descriptor [13] generalized the census transform approach and considers the binary string:

$$\mathbf{d} = \sum_i 2^i \tau(I, \mathbf{y}_i, \mathbf{z}_i), \quad (5)$$

where the $(\mathbf{y}_i, \mathbf{z}_i)$ are pairs of pixel locations taken randomly. Rublee et al. [14] proposed to optimize these locations. Other schemes have been proposed to sample the image intensities. Usually, 128- or 256-bit descriptors are used.

The advantages of using a binary string for descriptor are multiple, even if they are often not as discriminative. First, they are typically very fast to compute while being robust to large illumination changes. Second, the similarity between descriptors can be measured by the Hamming distance, which can be done extremely fast on modern CPUs that often provide instructions to perform the XOR and bit count operations to implement the Hamming distance, as is the case in the SSE and NEON instruction sets. Locality-sensitive hashing (LSH) can also be used for efficient matching in case of large numbers of descriptors. Binary descriptors are also memory efficient as they can be stored using only a few bytes.

Deep Learning Methods

The methods described above are *ad hoc*, but other methods also aimed at *learning* to compute descriptors. Different approaches have been proposed, but the most suitable approach is based on siamese networks. As this is an approach that is not limited to local descriptors, we describe it below, at the end of the section on “Similarity

Measures.” More recent works such as LF-Net and SuperPoint learn together the methods for detecting the regions and computing their local descriptors.

Several surveys and evaluations have been published on the topic of local image descriptors, and the interested reader is invited to refer to them as well [15].

Image Descriptors

Image descriptors describe the whole content of an image and can be used for image retrieval and localization for example. However, they are usually not suitable for semantic tasks such as object recognition.

Bags-of-Words

Image descriptors can be created from local descriptors. An early successful image descriptor is the bag-of-words (BOW) representation [16]. This representation was motivated by text retrieval techniques. To apply such techniques, an equivalent to the concept of words but for images is required. This is done by quantizing the space of local descriptors. This quantization is obtained by clustering a large set of local descriptors, and the cluster centroids are called “visual words.” In practice, thousands or even millions of visual words are used, from local descriptors computed on affine regions. A local descriptor can then be replaced by its most similar visual word.

An image is then described by a descriptor $\mathbf{d} = [t_1, \dots, t_k]^\top$ of the frequencies of its visual words. More exactly, the term “frequency-inverse document frequency,” or tf-idf, is used rather than the mere frequency, and is defined as

$$t_i = \frac{n_i}{n} \log \frac{1}{T_i}, \quad (6)$$

where n_i is the number of occurrences of visual word i in the image, n is the number of local descriptors extracted from the image, and T_i is the prior frequency of visual word i , estimated on a large set of images. $\frac{n_i}{n}$ is the frequency of visual word i in the image, weighted by $\log \frac{1}{T_i}$,

which downweights words that appear often and are therefore not discriminative.

It can be seen that the image locations of the visual words do not influence the final descriptor. While some information is thus lost, this approach still performs remarkably well.

VLAD

The VLAD descriptor [17], for Vector of Locally Aggregated Descriptors, was later introduced to improve search accuracy and speed and memory footprint. VLAD first computes the sums of differences between the local descriptors and their closest visual word:

$$\mathbf{v}_i = \sum_{\mathbf{d}^L \mid \text{NN}(\mathbf{d}^L)=i} \mathbf{d}^L - \mathbf{w}_i, \quad (7)$$

where the sum is over the local descriptors \mathbf{d}^L of the image that are associated to visual word \mathbf{w}_i . The VLAD is then $\mathbf{d} = [\mathbf{v}_1^\top, \dots, \mathbf{v}_k^\top]^\top$, after power normalization and L2 normalization. Power normalization acts as a robust estimator and here reduces the influence of repetitive visual elements in the image. Jégou et al. [17] shows that this process is an approximation of computing the Fisher vector of the local descriptors. The Fisher vector captures higher-order statistics, providing a finer representation than the BOW vector.

Without further processing, the size of the VLAD representation would be $k \times s$ scalar values, where k is the number of visual words and s the dimension of the local descriptors. Long descriptors, however, are not desirable as they have a bigger memory footprint, and search in high-dimensional space does not perform very well.

To reduce this size, a first dimensionality reduction is applied to the local descriptors using PCA, before computing the VLAD. A second PCA dimensionality reduction is performed on the full descriptor after normalization. The descriptor is then quantized, meaning that it is assigned a discrete value, which can be seen as a binary string for convenience. This is done by relying on the same k-mean-based strategy as for assigning local descriptors to a finite number of visual words. However, directly clustering

VLAD representations is not tractable, as they are still highly dimensional. The key idea is then “product quantization”: The vector is first split into smaller vectors, $\mathbf{d} = [\mathbf{d}_1^\top, \dots, \mathbf{d}_d^\top]^\top$, and each vector \mathbf{d}_i is quantized independently. This results in a remarkably short descriptor of a few tens of bits yet very discriminative. Note that the search can be performed using an asymmetric distance, where the descriptors in the database are quantized but not the query descriptor. This limits the degradation of the distance computations due to the quantization.

NetVLAD

NetVLAD introduces a “VLAD layer” that is appended to a Convolutional Neural Network and mimics the computation of the VLAD representation on the image features extracted by the network [2]. Since the network and the VLAD layer are trained jointly using a Siamese network framework as described at the end of this chapter, the visual words in the VLAD layer can be optimized for better retrieval performance, instead of simply taking them as cluster centroids as it was done with the original VLAD.

To make end-to-end training possible, the VLAD layer has to be differentiable, even though the computation of the original VLAD is not. This computation, already presented in Eq. (7), can also be written as

$$\mathbf{v}_i = \sum_{\mathbf{d}^L} a_i(\mathbf{d}^L)(\mathbf{d}^L - \mathbf{w}_i), \quad (8)$$

where $a_i(\mathbf{d}^L) = 1$ if the closest visual word to \mathbf{d}^L is \mathbf{w}_i and 0 otherwise. This is clearly not differentiable, and NetVLAD changes it into

$$\mathbf{v}_i = \sum_{\mathbf{d}^L} \frac{e^{\mathbf{a}_i^\top \mathbf{d}^L + b_i}}{\sum_i' e^{\mathbf{a}_{i'}^\top \mathbf{d}^L + b_{i'}}} (\mathbf{d}^L - \mathbf{w}_i), \quad (9)$$

where the $\{\mathbf{a}_i\}_i$, $\{b_i\}_i$, and $\{\mathbf{w}_i\}_i$ are sets of parameters learned by minimizing a loss function similar to the one in Eq. (17) described above and the \mathbf{d}^L are here local image features extracted by the CNN. NetVLAD demonstrates impressive retrieval performance, even in presence of

day-night differences between the database and the query image.

Similarity Measures

Ad hoc Measures

The Euclidean distance $\|\mathbf{d}_1 - \mathbf{d}_2\|$ between two descriptors \mathbf{d}_1 and \mathbf{d}_2 is often used to estimate their similarity. Alternatively, the cosine $\frac{\mathbf{d}_1^\top \mathbf{d}_2}{\|\mathbf{d}_1\| \|\mathbf{d}_2\|}$ can also be used and is equivalent to the Euclidean distance if the descriptors are normalized.

Since the SIFT descriptor can be seen as a histogram, [18] suggests using the Hellinger kernel, also known as the Bhattacharyya’s coefficient. It is a similarity measure more suitable to histograms and has the following form:

$$H(\mathbf{d}_1, \mathbf{d}_2) = \sum_{i=1}^n \sqrt{\mathbf{d}_1^{(i)} \mathbf{d}_2^{(i)}}. \quad (10)$$

This can be implemented efficiently by normalizing the SIFT descriptors using L1 normalization and replacing each element by its square root. After this transformation, which results in what the authors call “RootSIFT descriptors,” comparing two descriptors can still be done using the Euclidean distance, as it became equivalent to using the Hellinger kernel: $\|\sqrt{\mathbf{d}_1} - \sqrt{\mathbf{d}_2}\| = 2 - 2H(\mathbf{d}_1, \mathbf{d}_2)$. This is shown to significantly improve the similarity estimation.

For binary descriptors, as mentioned above, the Hamming distance is used. The Hamming distance between two binary strings is defined as the number of bits for which the strings differ, but is actually equivalent to the square of the Euclidean distance if the descriptors are considered like scalar value vectors.

Unsupervised Metric Learning

The Mahalanobis distance

$$\sqrt{(\mathbf{d}_1 - \mathbf{d}_2)^\top \Sigma^{-1} (\mathbf{d}_1 - \mathbf{d}_2)}, \quad (11)$$

where Σ is the covariance matrix of descriptors, is also often used. This distance gives more

weight to directions in the descriptor space with less variances, so that all directions have similar influences in the distance value. This distance can be computed efficiently by pre-multiplying the descriptors by matrix $\mathbf{P} = \sqrt{\Sigma^{-1}}$ and using the Euclidean distance on the resulting descriptors. Note that when PCA is used to reduce the dimensionality of the descriptors, the Euclidean distance in the eigenspace is also an approximation of the Mahalanobis distance in the original space.

Supervised Metric Learning

The covariance matrix Σ involved in the Mahalanobis distance is estimated in an *unsupervised* way, in the sense that it needs no additional information besides a set of descriptors large enough to empirically estimate Σ . Other metrics can be learned in a *supervised* way.

Such supervised metric learning methods rely on two training sets \mathcal{S} and \mathcal{D} of pairs of examples that are known to be similar and dissimilar, respectively:

$$\begin{aligned}\mathcal{S} &= \{(\mathbf{d}_1, \mathbf{d}_2) \mid \mathbf{d}_1 \text{ and } \mathbf{d}_2 \text{ are similar}\}, \text{ and} \\ \mathcal{D} &= \{(\mathbf{d}_1, \mathbf{d}_2) \mid \mathbf{d}_1 \text{ and } \mathbf{d}_2 \text{ are dissimilar}\}.\end{aligned}\quad (12)$$

Here, \mathbf{d}_1 and \mathbf{d}_2 can be local descriptors for local regions that correspond or not to the same 3D physical point or VLAD representations for images of the same landmark or not. A third training set with relative constraints is sometimes also used:

$$\begin{aligned}\mathcal{R} &= \{(\mathbf{d}_1, \mathbf{d}_2, \mathbf{d}_3) \mid \mathbf{d}_1 \\ &\text{ is more similar to } \mathbf{d}_2 \text{ than to } \mathbf{d}_3\}.\end{aligned}\quad (13)$$

The advantage of learning a metric in that way is that it can adapt the distance between descriptors to the problem at hand. However, creating the training sets \mathcal{S} , \mathcal{D} , and possibly \mathcal{R} in order to do so can be difficult in practice.

Distances of the form $d_{\mathbf{M}}(\mathbf{d}_1, \mathbf{d}_2) = \sqrt{(\mathbf{d}_1 - \mathbf{d}_2)^T \mathbf{M} (\mathbf{d}_1 - \mathbf{d}_2)}$, which are sometimes called (pseudo) Mahalanobis distances, and where \mathbf{M} is a positive semi-definite

matrix can be learned based on \mathcal{S} and \mathcal{D} . For example, LDAHash [19] estimates a matrix \mathbf{P} that minimizes

$$\alpha \frac{1}{|\mathcal{S}|} \sum_{(\mathbf{d}_1, \mathbf{d}_2) \in \mathcal{S}} d_{\mathbf{P}^T \mathbf{P}}(\mathbf{d}_1, \mathbf{d}_2) - \frac{1}{|\mathcal{D}|} \sum_{(\mathbf{d}_1, \mathbf{d}_2) \in \mathcal{D}} d_{\mathbf{P}^T \mathbf{P}}(\mathbf{d}_1, \mathbf{d}_2), \quad (14)$$

where α is a weight balancing the two terms. It is shown that matrix \mathbf{P} can be estimated in closed form, using Linear Discriminant Analysis.

For another example, the MMC method learns a matrix \mathbf{M} by solving the problem:

$$\max_{\mathbf{M}} \sum_{(\mathbf{d}_1, \mathbf{d}_2) \in \mathcal{D}} d_{\mathbf{M}}(\mathbf{d}_1, \mathbf{d}_2) \quad (15)$$

$$\text{such that } \sum_{(\mathbf{d}_1, \mathbf{d}_2) \in \mathcal{S}} d_{\mathbf{M}}^2(\mathbf{d}_1, \mathbf{d}_2) \leq 1,$$

under the constraint that \mathbf{M} is a positive semi-definite matrix.

The interested reader can also refer to the [20] survey for more metric learning methods.

Siamese Networks

The methods described above assume that a description method is already available and apply a simple linear transformation to the descriptors to learn a better distance than the Euclidean distance.

It is also possible to learn a distance that directly estimates the similarity between two raw inputs, which would be in our case image regions or complete images. While machine learning methods such as boosting have been used to this aim, deep networks are usually more powerful. A network predicting the similarity between two inputs can be trained by minimizing, for example:

$$\begin{aligned}\mathcal{L}(\Theta) &= \sum_{(I_1, I_2) \in \mathcal{S}} f^2(I_1, I_2; \Theta) + \\ &\sum_{(I_1, I_2) \in \mathcal{D}} \max(0, m - f(I_1, I_2; \Theta))^2,\end{aligned}\quad (16)$$

over parameters Θ of network f , where training sets \mathcal{S} and \mathcal{D} are now made of pairs of images or image regions. $m > 0$ is an arbitrary constant.

However, this approach is not optimal as the network has to be invoked every time the similarity between two images has to be computed, which prevents the use of efficient data structures for fast query. Instead, a deep network can be used for computing descriptors from raw input, while the Euclidean distance is used for evaluating the similarity between descriptors for fast query. This idea is actually not new, as the main technique, Siamese networks, was introduced in [21]. A network computing descriptors from raw data can be trained by minimizing

$$\begin{aligned} \mathcal{L}(\Theta) = & \sum_{(R_1, R_2) \in \mathcal{S}} D(R_1, R_2, \Theta)^2 \\ & + \sum_{(R_1, R_2) \in \mathcal{D}} [\max(0, m - D(R_1, R_2, \Theta))]^2 \end{aligned} \quad (17)$$

with $D(R_1, R_2, \Theta) = \|g(R_1; \Theta) - g(R_2; \Theta)\|$.

Such a loss function is called a contrastive loss. The name “Siamese network” comes from the fact that the same network appears twice when computing the distance between descriptors. Hard negative mining is necessary when minimizing Eq. (17) for good performance, as many pairs in \mathcal{D} may not contribute to the gradient of the loss function if their distance is already larger than m . More sophisticated losses can also be considered, for example, triplets as in \mathcal{R} can also be used.

This approach blends the boundary between descriptor computation and metric learning, as the descriptors are optimized according to the desired similarities. The interested reader can refer to [22] for an empirical study of such approaches for local descriptors.

Definition

Image enhancement and restoration is a procedure that attempts to improve the image quality

by removing the degradation while preserving the underlying image characteristics.

Background

Image quality is often deteriorated during acquisition, compression, and transmission. Typical degradations include image blur introduced by lens out-of-focus, resolution downgrade due to acquisition equipment pixel limitation, noise spots introduced at high ISO, and JPEG block artifact, as illustrated in Fig. 1. Image enhancement and restoration is a procedure that attempts to improve the image quality by removing the degradation while preserving the underlying image characteristics. For some specific degradations as mentioned above, image enhancement and restoration is also known as deblurring, super-resolution zooming, denoising, and deblocking. While jointly addressed here and in most of the literature, *restoration* often refers to the case where one attempts to mathematically invert the degradation (e.g., invert the blurring filter), and *enhancement* refers to the improvement of the overall image quality without explicit mathematical inversion of the degradation process.

Theory

The problems of image enhancement and restoration are ill posed since they amount to recovering some image information that has been eliminated during the degradation. Solving these problems must therefore rely on some prior knowledge of the image, or in mathematical terms *image models*, to regularize the solution. Mathematically, let f denote an ideal image, U a linear degradation operator, w an additive noise, and

$$y = Uf + w \quad (1)$$

the degraded (observed) image. While this model does not cover all possible degradation scenarios, it is very popular and useful, and serves to illustrate the underlying image enhancement and

Image Enhancement and Restoration: Traditional Approaches, Fig. 1 From *left to right*. Ideal image, image degraded by out-of-focus, resolution downgrade, noise spots, and JPEG block artifact

restoration key concepts. Modern image enhancement and restoration estimates the underlying image f from the degraded observation y by, for example, minimizing a functional of the form

$$\hat{f} = \arg \min_h \left(\|y - Uh\|^2 + \varphi(h) \right), \quad (2)$$

where the first term ensures that the restored image \hat{f} and the degraded image y agree with the image degradation Eq. (1), and the second term $\varphi(h)$ regularizes the solution via a certain image model. The technology of image enhancement and restoration thus has been developed hand in hand with a better understanding of image modeling.

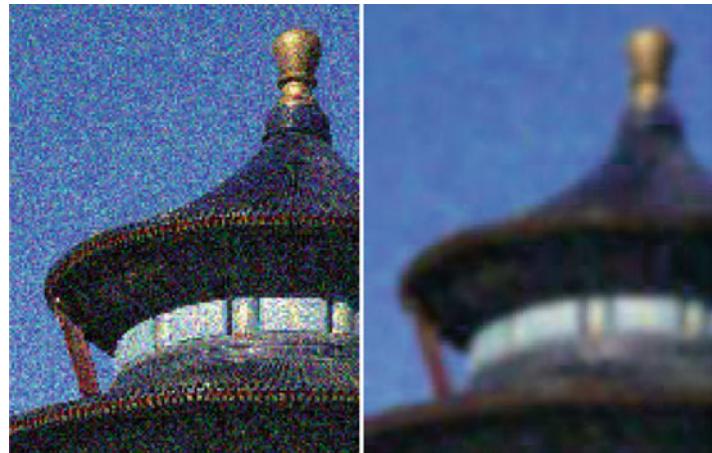

The most classic image model that dated from the 1960s assumes that image content is uniformly smooth [1]. This model results in a number of well-known image enhancement and restoration algorithms, including Gaussian smoothing for denoising, bicubic interpolation for zooming, and Wiener filter for deblurring [2]. All these algorithms are implemented with *linear* filtering uniformly applied over the image, typical isotropic local filters smoothing out the image. While the uniformly smooth assumption holds on regular image regions such as sky or a blackboard, that typically dominates a natural image, it is obviously oversimplified on other important types of image transition structures, such as contours, that are smooth along one direction but not the other, and textures that are oscillatory patterns. As shown in Fig. 2, although image noise is attenuated, image contours

become blurred at the end of restoration when this simple uniformly smooth model is assumed.

Anisotropic image models attempting to address this problem came into the scene in the early 1990s (with some works dating to the 1960s as well, by Gabor). As opposed to the uniformly smooth assumption, the anisotropic models assume that an image is piecewise smooth, in other words, smooth inside each sub-region, and that at a contour or boundary of the regions where the image intensity sharply changes, the smoothness holds only along the contour direction but not in the perpendicular direction. These models give clearly a better image description and have been elegantly formulated in some partial differential equation frameworks such as anisotropic diffusion [3, 4] and total variation [5]. The resulting algorithms implement *nonlinear* filtering adaptive to the image content, uniformly smoothing inside each image sub-region, and smoothing only along the contour direction on the region boundaries. Therefore, image contours are better preserved.

Since the boom of wavelets in the early 1990s, multi-resolution harmonic analysis has lead to considerable efforts and improvements on image modeling and restoration [2, 7]. Wavelet analysis models an image from multiple resolutions; at each resolution, translating local wavelet atoms oscillating at the corresponding scale are used. The wavelet response is typically high on image transition structures, such as contours and textures, and negligible on regular regions. As a result, it does not only implement *nonlinear* adaptive filtering, but also reveals the important

Image Enhancement and Restoration: Traditional Approaches, Fig. 2 *Left:* noisy image. *Right:* image denoised by Gaussian smoothing

concept of “sparse modeling”: wavelet analysis represents an image with only a few large wavelet coefficients that absorb most of the image energy, while the majority of wavelet coefficients quickly decay to zero. The wavelet’s sparsity as well as its performance in image enhancement and restoration have been later improved by geometric adaptive harmonic analysis such as curvelets [8] that include local directional atoms to catch the image contours.

In order to further promote the resulting sparsity relative to prefixed harmonic analysis dictionaries (Dictionary here means an ensemble of harmonic analysis atoms), such as wavelets or curvelets, *sparsifying learned dictionaries*, i.e., dictionaries that are learned from images of interest to yield sparse representations for that class of data, have emerged [9, 10], leading to further improved image enhancement and restoration performance [11].

Non-local image modeling is based on the observation that images typically contain repetitive local patterns (self-similarity). Since the pioneering work of the nonlocal means denoising algorithm [12] in 2005 (see also [13, 14]), non-local modeling has been extensively studied in image enhancement and restoration [15, 16].

Gaussian mixture models, a statistical model widely applied in machine learning, have been shown particularly effective for image enhancement and restoration [6]. The models assume that local image patches follow a mixture of

Gaussian distributions. The resulting *piecewise linear* algorithm is not only extremely fast, but also reveals some connections to sparse modeling and non-local modeling.

State-of-the-art image enhancement and restoration results are obtained with algorithms derived from the last three image models, namely, sparse modeling with learned dictionaries, non-local modeling, and Gaussian mixture models. Figure 3 illustrates some examples.

Open Problems

For image enhancement and restoration problems such as removing Gaussian white noise from an image and filling small holes at random positions in an image, it seems that the current performance is already acceptable, as illustrated in Fig. 4, and has arguably reached a quality boundary uneasy to go beyond. For other more difficult problems such as deblurring and zooming, although substantial visual quality improvement has been achieved with respect to classic algorithms such as Wiener filter and bicubic interpolation, objective performance improvement is relatively limited despite considerable efforts that have been devoted. Theoretical performance bounds of image enhancement and restoration remains to be understood. The recent very exciting compressive sensing theory [17] reveals the performance bounds of the sparse modeling approaches

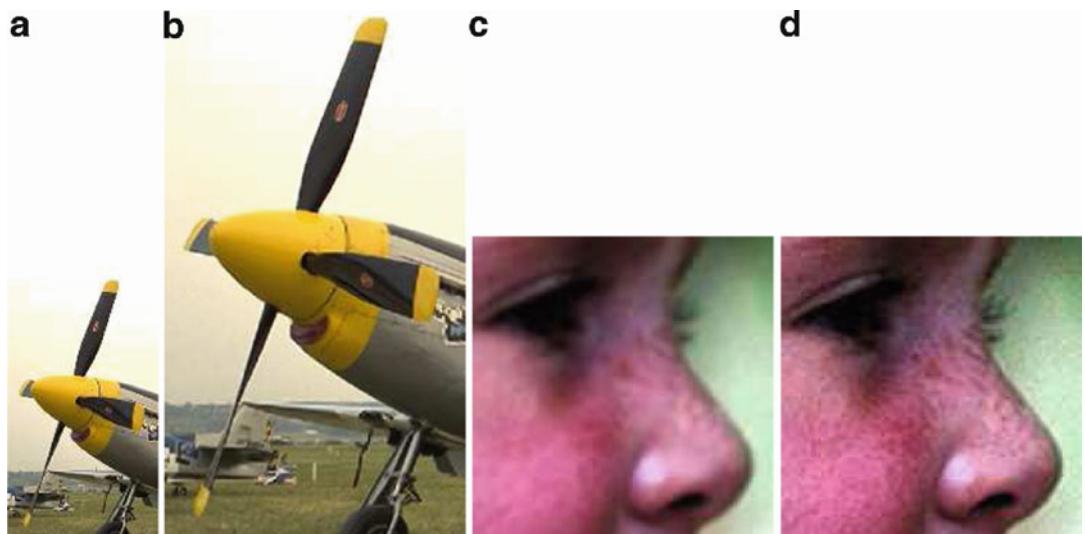

Image Enhancement and Restoration: Traditional Approaches, Fig. 3 Image enhancement and restoration examples. (a) and (b) Super-resolution zooming: Low-

resolution and zoomed images. (c) and (d) Deblurring: blurred and deblurred images. (Figures reproduced from [6])

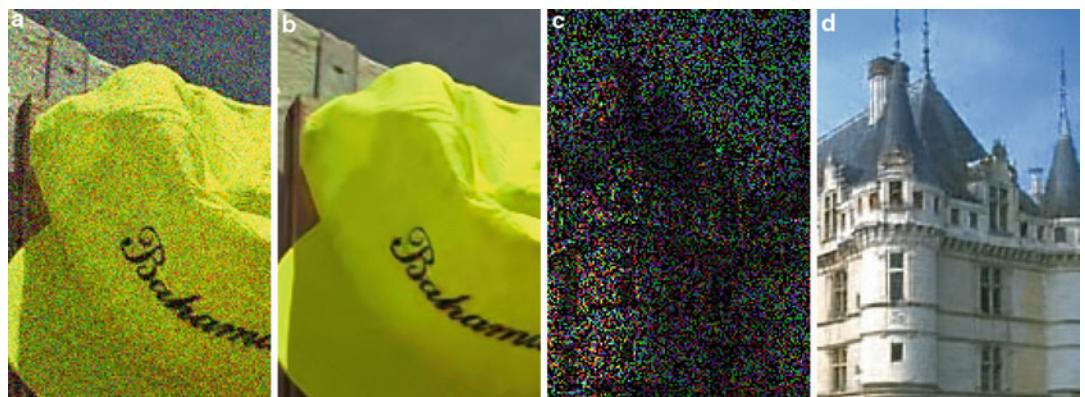

Image Enhancement and Restoration: Traditional Approaches, Fig. 4 Image enhancement and restoration examples. (a) and (b) Denoising: Noisy and denoised images. (c) and (d) Inpainting: image with 80 % random missing pixels and restore image. (This problem is related

to the task of reconstructing a color image from undersampled color channels, as present in most low/mid-end digital cameras.) The results are obtained following the technique in [6]

given some random degradation operations, but is inapplicable to typical degradations such as blurring and subsampling and to the most successful learned dictionaries. The extension of these results to more realistic image degradation scenarios and image models is among the current challenges of image restoration and enhancement.

Digital forensics; Image authentication

Definition

Image forensics refers to the analysis of an image to determine if it has been manipulated from the time of its recording. The techniques described here – so called passive techniques – operate in the absence of digital watermarks, signatures, or specialized hardware. Instead, these techniques analyze physical, geometric, optical, sensor, and file properties for inconsistencies that may arise from image manipulation.

Background

History has shown that many autocratic leaders had photographs manipulated in an attempt to rewrite history. These men understood the power of photography and that if they changed photographs they could change history. Cumbbersome and time-consuming darkroom techniques were required to alter the historical record on behalf of Stalin and others. Today, powerful and low-cost digital technology coupled with sophisticated rendering and synthesis techniques and the broad and rapid reach of social media have made it far easier to alter and disseminate digital content. The resulting fakes are often very difficult to detect and are having a significant impact in many different areas of society.

Doctored photographs are appearing in tabloid and fashion magazines, government media, mainstream media, social media, online auction sites, online dating sites, political ad campaigns, and scientific journals. More recently, the coupling of fake news with fake imagery has been used by individuals and state-sponsored entities to disrupt democratic elections, incite civil and political discord, and fuel horrific violence.

The technology that can distort and manipulate digital media is developing rapidly, and the implications of not authenticating content quickly and accurately are becoming more pronounced. The goal of the field of image (and video/audio) forensics is to develop techniques for quickly and accurately authenticating digital content.

At their foundation, most image forensic techniques rely on understanding the imaging pipeline, from the interaction of light with the physical 3-D world, the refraction of light as it passes through the camera lenses, the transformation of light to electrical signals in the camera sensor, to the conversion of electrical signals into a digital image file. This entry is organized according to this pipeline, with each section describing a representative set of forensic techniques built on understanding and modeling some aspect of the imaging process. Portions of this entry are adapted from [1].

Application

Physics-Based Forensics

A political ad shows a presidential candidate covertly meeting with a foreign agent. Is the image real or is it a composite created by splicing together two images? The lighting and reflections often hold the answer. Unless the candidate and agent were photographed under identical lighting conditions, there may be discrepancies in the shadows and lighting created by the light source and in the reflections of each actor on nearby shiny surfaces. This section describes a forensic technique for reasoning about the physical plausibility of shadows and reflections [2,3].

Shadows

Let's start with the simplest situation: A 3-D scene is illuminated by a single, small light source. Consider the scene depicted in Fig. 1a in which a box casts a shadow on the ground. For every point in this cast shadow, there must be a line to the light source that passes through the box. For every point outside the shadow, there must be a line to the light source that is unobstructed by the box. Consider now a line connecting the point at the corner of the shadow and its corresponding point at the corner of the box: Follow this line, and it will intersect the light.

Because straight lines in the physical scene are imaged as straight lines (assuming no lens distortion), the location constraint in the 3-D scene also holds in an image of the scene. Just as the shadow corner, the corresponding box corner, and the light source are all constrained to lie on a single line in the scene, the image of the shadow corner, the image of the box corner, and the image of the light source are all constrained to lie on a single line in the image. This idea is illustrated in Fig. 1a, which shows a line that connects a point on the edge of the shadow to the corresponding point on the box. In the image, the projection of the light source lies somewhere on this line. Now let's connect two more points on the cast shadow to their corresponding points on the box, as in Fig. 1b. We will continue to use the corners of the box because they are distinctive. These three lines intersect at a single point above the box. This intersection is the projection of the light source in the image.

The geometric constraint relating the shadow, the object, and the light holds whether the light source is nearby (a desk lamp) or distant (the sun). This constraint also holds regardless of the location and orientation of the surfaces onto which the shadow is cast. Regardless of the scene geometry, all of the constraint lines intersect at the same point.

The boundary of the image plane in Fig. 1b had to be extended to see the intersection of the three lines. This is because the light source is not visible in the original image of the scene. This will typically be the case, and, depending

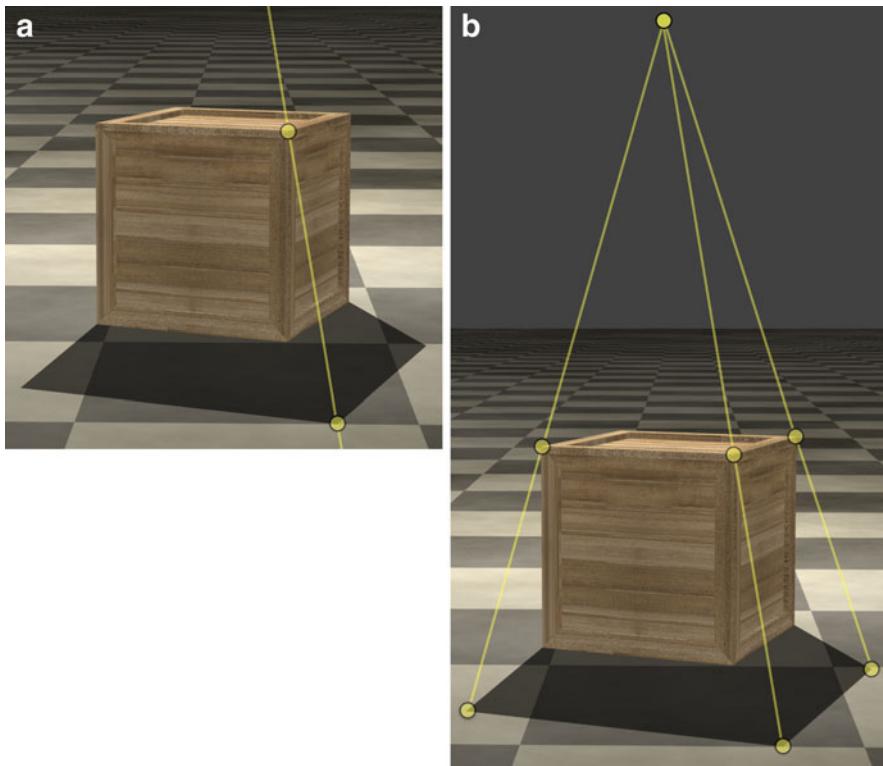

Image Forensics, Fig. 1 A cast shadow constraint connects (a) a point on the box’s shadow with the corresponding point on the box. Multiple such constraints (b) intersect at the projection of the light source

on where the light is, the lines may have to be extended beyond the image’s left, right, top, or (counterintuitively) bottom boundary.

If one or more of the cast shadow constraint lines in an image do not converge on a common intersection, the image may be a fake [3].

Reflections

Somewhat surprisingly, reflections in flat mirror surfaces lend themselves to the same type of analysis as cast shadows. The basic geometry of a reflection is shown in the bottom panel of Fig. 2. Shown on the left is a bird’s eye view of three boxes, and shown on the right is their mirror reflection, with the mirror shown in the middle. The reflections are equal in size and equal in distance from the mirror so that corresponding points on the virtual and real objects are connected by parallel lines.

This scene geometry changes when the scene is projected onto a camera sensor. Lines that

were parallel when viewed from the plane of the mirror are no longer parallel. Instead, due to perspective projection, these parallel lines converge to a single point, as shown in the top panel of Fig. 2. Because the lines connecting corresponding points in a scene and its reflection are always parallel, these lines should have a common intersection in the image.

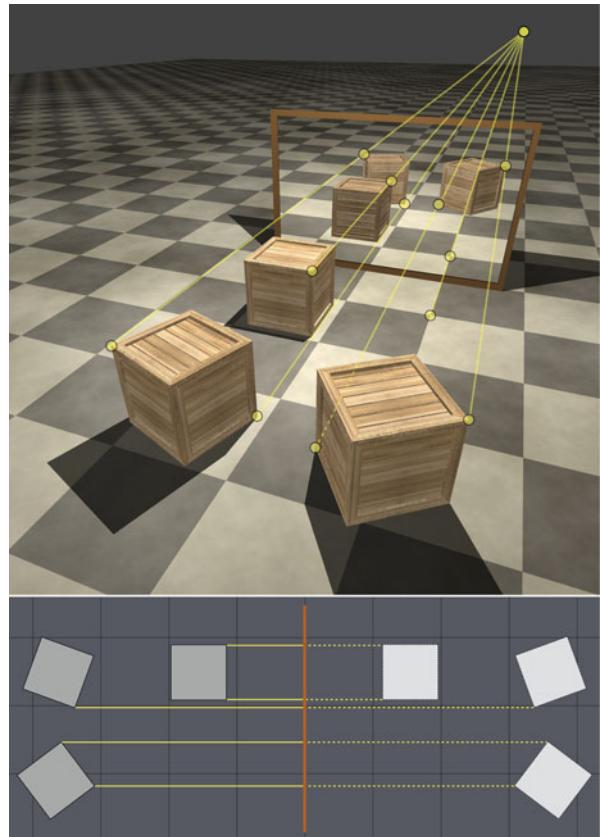

If one or more of the reflection constraint lines in an image do not converge on a common intersection, the image may be a fake [2].

Sensor-Based Forensics

Gun barrels are grooved to impart spin to a bullet for increased accuracy and range. Because these grooves introduce distinct markings to the bullet, ballistic techniques can link a bullet to a specific handgun. Similarly, photo forensic techniques can use the distinctive artifacts introduced by a camera’s sensor to link an image to a specific device. In addition, inconsistencies in

Image Forensics, Fig. 2

Three boxes are reflected in a mirror (top) and a virtual bird's eye view (bottom) of this scene with the boxes on the left, mirror in the middle, and reflection on the right. The yellow lines connect points on a box to their reflection. When such a scene is imaged under linear perspective projection, lines connecting any point in the scene with its reflection will intersect at a single point, as shown in the top panel

these artifacts can provide evidence of tampering. This section describes forensic techniques for estimating image artifacts introduced by camera sensors [4–6].

Color Filter Array

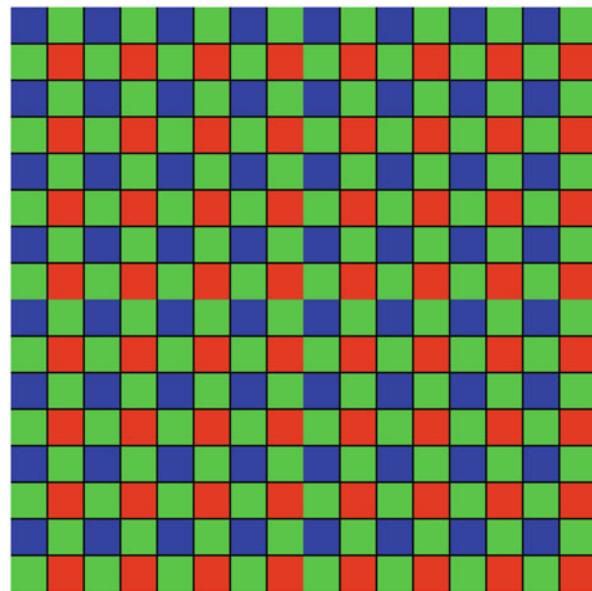

Modern digital cameras have three channels with different peak sensitivities: R (red), G (green), and B (blue). This means that each pixel in a digital image is represented as three values: R, G, and B. The camera sensor, however, is sensitive to all visible light. To measure the light in one color channel, it is, therefore, necessary to restrict the wavelength of the light that impinges on the sensor. This restriction is accomplished by a color filter array (CFA) that sits atop the sensor. Most CFAs use a Bayer pattern as shown in Fig. 3. The color of each square in the pattern indicates the part of the visible spectrum (R, G, or B) that the filter transmits at that location. Note that the R, G, and B filters of the CFA are distributed

in a consistent, periodic pattern. This periodicity is important because it is the key to this next forensic technique.

The CFA transmits only one part of the visible spectrum to each cell on the sensor. For a full color image, it is necessary to have all three measurements for each pixel. Since each sensor cell makes only one measurement, the other two values must be reconstructed. This process – CFA interpolation – reconstructs the missing RGB values by interpolating the surrounding values. Consider, for example, the cell in the second row and second column in the Bayer pattern shown in Fig. 3. This sensor cell measures the R-channel, but not the G-channel or B-channel. Values for the G-channel are measured by cells immediately above, below, and on either side. We can make a reasonable guess about the missing G-channel value from an average of its four neighbors. This basic process underlies all CFA interpolation algorithms.

Image Forensics, Fig. 3

A Bayer pattern used to record a subset of RGB pixels

As a result of CFA interpolation, two-thirds of all RGB values have been reconstructed by interpolating neighboring measurements. And, because the CFA pattern is periodic, the interpolation introduces periodic correlations between these values. These periodic correlations are highly distinctive, and so their presence provides a reliable sign that the image is authentic. We do not know, however, which pixels are CFA interpolated, nor do we know the precise form of the CFA correlations. The classic expectation/maximization (EM) algorithm can be used to simultaneously estimate both and localize parts of an image that violate the expected correlations [4, 6].

Photo Response Nonuniformity

In an ideal imaging device, the pixel values of the digital image would accurately reflect the amount of light recorded by each photo detector. Real devices, however, have imperfections that introduce noise in the image. One source of noise arises when stray electrons occur sporadically within sensor cells. These stray electrons introduce noise when they combine with the electrons generated by the photo detector as it responds to light. The resulting noise pattern is random, fluctuating from image to image. Another source of

noise arises from slight variations in the size and material properties of the sensor cells themselves. Physical inconsistencies across the sensor cells lead to differences in the efficiency with which the cells convert light into digital pixel values. Some cells consistently underreport the amount of light, while others consistently over-report the amount of light. These variations, termed photo-response nonuniformity (PRNU), lead to a stable noise pattern that is distinctive to the device.

To illustrate how PRNU noise might alter an image, imagine that we point our camera at a perfectly uniform gray wall. A noise-free sensor will record an image with exactly the same value at every pixel. Let's say that this pixel value is 128 (on a scale of 0 (black) to 255 (white)). PRNU noise modulates the value of each pixel by multiplying 128 by a value slightly less than or slightly greater than 1.0. Unlike sensor noise, which additively modulates the pixel regardless of its value, PRNU modulates the pixel proportional to its value. Also unlike sensor noise, PRNU is a fixed property of the sensor and does not vary from image to image.

With some modest assumptions, a maximum likelihood estimator can be used to estimate the PRNU. Although it is possible to get a crude estimate of a device's PRNU from a single image,

a reliable estimate requires 10–20 images (the exact number depends on the quality of the camera, as well as the quality and content of the images).

The PRNU associated with a particular device is not only stable, it is also distinctive. Even devices of the same make and model have different PRNUs. The stable and distinctive properties of the PRNU allow it to serve two forensic functions: It can be used to detect localized image tampering, and it can be used to link an image to a specific device [5].

File-Based Forensics

The first rule of any forensic analysis must surely be “preserve the evidence.” Because JPEG and other lossy image compression schemes discard and distort image information, they would seem to be a forensic analyst’s worst enemy. However, because the details of compression differ across devices, JPEG compression may provide an opportunity for the analyst. This section describes forensic techniques that exploit features of the image file that differ across devices. These features can be used to link an image to a device or to determine whether an image has been re-saved after its initial recording [7, 8].

Quantization

By way of background, the JPEG image format has emerged as the standard for devices that capture digital images. This image format uses a lossy compression scheme that allows for a trade-off between memory size and visual quality.

Specifically, given a three-channel color image, JPEG encoding consists of four basic steps: (1) transform the image from a three-channel color image (RGB) to a three-channel luminance/chrominance image (YCbCr); (2) convert the image into a spatial frequency representation by partitioning the individual channels into non-overlapping 8×8 pixel blocks. Each block is then converted to frequency space using a 2-D discrete cosine transform (DCT); (3) quantize the DCT values in each 8×8 block by an amount that depends on the frequency and channel (to quantize a value c by an amount q , divide c by q and round up or down to the nearest

integer); and (4) perform entropy-encoding on the quantized DCT coefficients. The decoding of a JPEG image follows the same steps but in reverse order.

Device and software engineers fine-tune this trade-off to suit their individual tastes and needs. The resulting variation in JPEG settings provides a distinctive signature for each type of device. These settings can be used to link an image to a specific camera type or to determine whether an image has been re-saved after its initial recording.

Decoding requires knowing the quantization values used to encode the image, and so the quantization values must be stored as part of a JPEG file. The quantization values are specified as a set of 192 integer values organized as three 8×8 tables. Each table contains the quantization values for 64 frequencies for one of the three image channels (YCbCr). Because the JPEG standard does not impose the use of specific quantization tables, engineers are free to select all 192 values resulting in quantization tables that vary greatly across devices and software.

An image that is edited and re-saved acquires the JPEG quantization tables of the editing software. If it can be determined that an image’s quantization tables are not the same as those of the original recording device, this may indicate that the image has been altered. To test whether the image and device quantization tables match, we need the camera make and model which is typically embedded in the image metadata. (The metadata for a digital image contains data about the camera make and model, the camera settings (e.g., exposure time and focal length), the date and time of image capture, the GPS location of image capture, and much more. The metadata is stored along with the image data in the image file, and it is readily extracted with various programs.) We also need to know the set of possible quantization tables for this device.

For most devices, the range of possible quantization tables can be determined by recording images at all possible pairings of quality, resolution, and, when it is adjustable, aspect ratio. Most devices have a relatively small number of these settings, yielding a small number of possible

quantization tables. The tables associated with a particular device can then be compared with the quantization tables of an image purportedly taken with that device [7].

This image-to-device comparison can be made more specific by including the dimensions of the image. Because the compression settings are often associated with a particular resolution, the quantization table and image resolution may be combined into a single device signature. This device signature can be honed further by considering the dimensions and quantization tables of the embedded thumbnail (which is stored as a separate JPEG image, typically with different quantization tables than the full-resolution image).

Markers

A JPEG image file contains data corresponding to the compressed image and thumbnail as well as their quantization tables. The way this data is organized within the file varies across devices and programs adding to the device signature details that can link an image to a specific camera type. A JPEG file consists of multiple labeled segments of data. Each data segment is labeled with a unique *marker*. Although the JPEG standard specifies that certain information must be stored in the JPEG file, it does not specify the location or order of these segments. Camera and software engineers are, therefore, free to organize file data in any way that they choose. As with the JPEG signature described above, the JPEG markers associated with a particular device can then be compared with the markers of an image purportedly taken with that device [8].

Pixel-Based Forensics

In the hands of a talented forger, the methods for manipulating images may be applied so skillfully that the faked image appears authentic, even to a trained eye. But these same methods often leave anomalous patterns that are too regular to be accidental. This section describes forensic techniques that can detect pixel-level anomalies that arise from different forms of tampering [9–11].

Double Compression

Because most digital images are initially recorded in the JPEG format, any image manipulation will lead to multiple compressions: A first compression on the camera and a second compression by the photo editing software. Multiple compressions – and in particular, multiple DCT quantizations – may leave behind a telltale artifact in the underlying DCT coefficients.

Consider a simple example of this double quantization (to quantize a value c by an amount q , divide c by q and round up or down to the nearest integer). Shown in Fig. 4 are the distributions for each of the following stages: (a) initial DCT values, (b) after quantization with $q_1 = 3$, (c) after re-scaling with $q_1 = 3$, and (d) after a second quantization with $q_2 = 2$. The shaded gray areas in panel (d) for bins 1 and 3 show how these values are transformed by the first quantization, the re-scaling, and the second quantization. Note that bins 2 and 5 are empty in the final distribution (d). This shouldn't be surprising because we initially condensed 12 bins into four and then later expanded the range to five bins.

For comparison, shown in Fig. 4e is the original distribution after a single quantization with $q_1 = 2$. This singly compressed distribution has the same number of bins as in panel (d), but the content of the bins is strikingly different. Unlike the doubly compressed distribution, the single compression produces no empty bins. The anomalous distribution after double compression is the telltale sign that the image was recompressed after the original recording.

When present, the anomalous pattern is repeated across the entire distribution of DCT values. In some cases, this periodic pattern is as simple as a populated bin followed by an unpopulated bin (e.g., $q_1 = 2$ and $q_2 = 1$). In other cases, this periodic pattern is a bit more complex. For example, with $q_1 = 5$ and $q_2 = 2$ the anomalous pattern is one populated bin, followed by two unpopulated bins, followed by one populated bin, followed by one unpopulated bin. This pattern of five then repeats. Regardless of the specific pattern, the detection of double compression is based on the presence of a

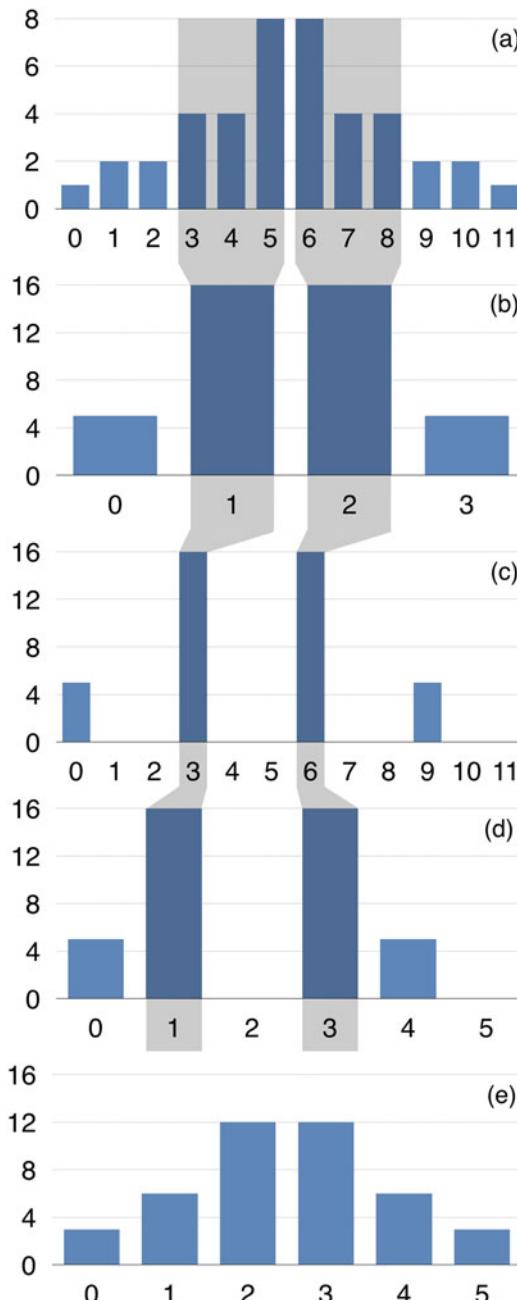

Image Forensics, Fig. 4 Double quantization with first quantization of $q_1 = 3$ and second quantization of $q_2 = 2$ (panels (a)-(d)). The shaded gray regions illustrate how values in the original histogram (a) are transformed through a single quantization (b), re-scaling (c), and a second quantization (d). The empty bins in the resulting distribution (d) are a telltale sign of double compression, as compared to the singly compressed distribution (with $q_1 = 2$) in panel (e)

periodic pattern in the distribution of DCT values. Because the double compression artifacts are so distinct, it is relatively straightforward to detect their presence [9, 11].

Cloning

In 2008, a photo of Iran's provocative missile test appeared on the front page of newspapers around the world. It was quickly revealed, however, that the photo of four airborne missiles had been doctored. To conceal the launch failure of one of the missiles, the image of a successful missile had been copied and pasted over the failed missile. This cloning was easily detected because of the suspicious similarity in the billowing dust clouds. Although the cloning in this image was detectable by eye, carefully executed clones can be visually imperceptible.

Detecting a clone involves two steps: the identification of potential matches and the verification of a match. The verification step is straightforward: If two regions are clones, their pixel values will be highly correlated. In contrast to the simplicity of verifying matches, the problem of identifying potential matches can easily lead to a combinatorial explosion. To see why this problem explodes, let's assume that we are searching a 1000×1000 pixel image for a cloned region of known size and shape. An image of this size contains 1,000,000 pixels and yields 500 billion region pairs that could be potential matches. (Ignoring overlapping regions and the edges of the image, there are 1,000,000 choose 2, equal to $(1,000,000 \times 999,998)/2 = 500,000,000,000$ possible pairings of pixels, each of which may be the center of a pair of cloned regions.) We do not typically know the cloned region's size and shape, nor do we know whether the cloned region has been resized or rotated before being added back into the image. Clearly, an exhaustive search of the potential matches in an image is computationally intractable.

With an easy verification step but a prohibitive search space, the task of detecting cloning reduces to finding an efficient and accurate way to search an image for two nearly identical regions. One particularly effective algorithm [10] consists of three basic steps: (1) the identification

of distinctive features in the image; (2) the extraction of a compact descriptor of each feature; and (3) the search for two clusters of features that have pairwise similar descriptors and that are related by a translation (and optionally a scaling and rotation).

The first step is to identify salient features in the image. These salient features should be sufficiently distinctive that they would have relatively few matches in the image. One such approach is the *Harris detector* which assigns a value to each pixel that is proportional to the amount of spatial variation in the pixels that surround it. Once the salient features in the image have been identified, the next step is to describe them in a compact way to allow for efficient matching. This description should retain the distinctiveness of the feature, but it should also be unaffected by common image transformations such as scaling, rotation, brightness and contrast adjustment, and compression. The *scale-invariant feature transform (SIFT)* or *histogram of oriented gradients (HOG)* descriptor offers a reasonable compromise between specificity and tolerance to transformations.

The third step in detecting potential matches is to search for two sets of similar features that are related by a translation (and optionally a scaling and rotation). Isolating these corresponding sets in a sea of features requires model-fitting in the presence of outliers. The *random sample consensus (RANSAC)* algorithm can be used to simultaneously extract the matching features and estimate the relationship between them.

The output of this clone detection algorithm will typically require a human analyst to review the purported matches to determine if they are semantically meaningful.

Recent Trends

There are many forensic techniques that can detect image tampering, and new techniques are constantly being developed. Each of these techniques, however, can be circumvented. A determined and skilled forger can, for example, build a custom JPEG coder that exactly mimics a camera's file packaging, carefully remove any DCT artifacts that arise from multiple

compressions, reinsert the expected color filter array interpolation correlations, analyze all shadows and reflections to ensure that they are physically consistent, and carefully work through all of the other traces used by dozens of different forensic techniques. The number, variety, and complexity of these techniques, however, make it difficult and time-consuming (but not impossible) for the average forger to create a fake that is completely indistinguishable from an authentic image.

Despite significant advances over the past two decades in the field of image forensics, much work remains to be done. While many forensic techniques are highly effective, many of them also require manual and careful oversight to apply them. This means that they require some expertise to apply and that they are not yet ready to be deployed at Internet-scale (to the tune of millions or billions of uploads a day).

Authentication will also be made more difficult by rapid advances in machine learning that have made it easier than ever to create sophisticated and compelling fakes [12–14]. These technologies have removed many of the time and skill barriers previously required to create high-quality fakes. Not only can these automatic tools be used to create compelling fakes, they can be turned against our forensic techniques in the form of generative adversarial networks (GANs) that modify fake content to bypass forensic detection [15]. There is little doubt that this arms race will continue into the foreseeable future.

Definition

The image plane is the planar surface on which the image is generated in an image formation process or a model thereof.

Background

In most cameras, the photosensitive elements are arranged on a planar support. In image formation models, the image plane is the (mathematical) plane where the image is formed and within which pixels or film are supposed to be located.

There exist cameras where the photosensitive area is not flat. For instance, in most early panoramic image acquisition systems that proceeded by scanning a scene with a rotating slit camera, the film was wrapped onto the inside of a cylindrical surface [1, 2]. In that case, one may still devise an equivalent theoretical image formation model that has a planar image support surface.

Synonyms

Gaussian pyramid; Laplacian pyramid

Definition

An image pyramid is a multi-scale representation of an image comprising a hierarchy of fine to coarse resolution versions. Generated by iterative filtering and sampling, a tapered pyramid structure is formed by the sequence of the input image at consecutively halved resolutions.

Background

The concept of an image pyramid was formulated by Tanimoto and Pavlidis [1] as a means to improve processing efficiency. Here, the issue of scale is raised through the need for selectivity of visual attention as in human visual systems. Scale is a crucial aspect in image representation as different objects may require different resolutions to faithfully represent the details in the scene. Since digital images comprise rasterized pixels in a fixed grid, explicit multi-scale representation

is required to mimic the efficiency of human vision.

The development of the Laplacian pyramid by Burt and Adelson [2] propelled the wide use of image pyramids. It combines a low-pass filtered copy of the image at reduced resolution together with band-pass filtered copies equivalent to the image sampled with Laplacian operators of many scales. This generates a multi-scale representation without redundancies and decorrelates pixels enabling efficient coding with minimal information loss. Moreover, it can be computed very efficiently by first constructing a Gaussian pyramid and approximating the Laplacian as the difference of two Gaussian filtered copies.

Both the Laplacian and Gaussian pyramids are overcomplete, as the number of pixels is larger than the original number of pixels (by a factor of 1/3). This motivated the development of more efficient methods such as the Wavelet transform [3].

Theory

This section describes the process to generate the Laplacian and Gaussian pyramids as originally given by Burt and Adelson [2,4].

The Gaussian Pyramid

The Gaussian pyramid must be first generated before generating the Laplacian pyramid. Let g_0 be the original image which contains C columns and R rows of pixels. This image becomes the bottom or zero level of the Gaussian pyramid. Pyramid level 1 contains image g_1 , which is a reduced or low-pass filtered version of g_0 . Each value within level 1 is computed as a weighted average of values in level 0 within some window. Each value within level 2, representing g_0 , is then obtained from values within level 1 by applying the same pattern of weights.

Assuming a 5×5 window size, the pixels of the subsequent level g_l is computed from the previous level g_{l-1} by the following weighting averaging process:

$$g_l(i, j) = \sum_{m=-2}^2 \sum_{n=-2}^2 w(m, n) g_{l-1}(2i + m, 2j + n), \quad (1)$$

where i, j is the two-dimensional pixel coordinate and $w(m, n)$ is the weight coefficients of the window, denoted as the generating kernel. Note that the spatial resolution of g_l is halved in each dimension compared to g_{l-1} .

The values of the generating kernel are chosen subject to the following constraints [4]:

- Separable: the two-dimensional kernel can be decomposed into two identical one-dimensional kernels to satisfy:

$$w(m, n) = \hat{w}(m)\hat{w}(n).$$

- Normalized:

$$\sum_{m=-2}^2 \hat{w}(m) = 1.$$

- Symmetric:

$$\hat{w}(i) = \hat{w}(-i) \quad \text{for } i = 0, 1, 2.$$

- Equal contribution: all pixels at a given level must contribute the same total weight ($=1/4$) to pixels at the next higher level.

If we denote $\hat{w}(0) = a$, $\hat{w}(-1) = \hat{w}(1) = b$, and $\hat{w}(-2) = \hat{w}(2) = c$, $a+2c = 2b$ must be satisfied since even numbered pixels contribute to 3 pixels in the next level (1 with weight a and 2 with weight c), while odd numbered pixels contribute to only 2 pixels (both with weight b). Thus:

$$\begin{aligned} \hat{w}(0) &= a, \\ \hat{w}(-1) &= \hat{w}(1) = 1/4, \\ \hat{w}(-2) &= \hat{w}(2) = 1/4 - a/2. \end{aligned}$$

The value of a becomes the sole parameter to control the shape of the kernel. When $a = 0.4$, it is particularly Gaussian-like, and when $a = 0.3$,

it is flatter and broader than a Gaussian. When $a = 0.5$, the shape is triangular, and with $a = 0.6$, the central positive mode is sharply peaked and is flanked by small negative lobes.

An important characteristic of the generating kernel stems from its recursive application. An equivalent kernel that generates the same result with recursively applying the generating kernel can be defined as follows:

$$g_l(i, j) = \sum_{m=-2}^2 \sum_{n=-2}^2 h_l(m, n) g_0(i2^l + m, j2^l + n). \quad (2)$$

It turns out the shape of $h_l(m, n)$ rapidly to a characteristic form with successively higher levels of the pyramid, so that only its scale changes. Thus a multi-scale image pyramid can be generated by recursively applying the simple generating kernel in Eq.(1). When $a = 0.4$, generated images in the pyramid approximate Gaussian filtered copies.

The Laplacian Pyramid

By storing the differences between consecutive pairs in the Gaussian pyramid, redundancies are removed, and image pixels are decorrelated. Formally, the Laplacian pyramid is a sequence of difference images L_0, L_1, \dots, L_N . Each is the difference between two levels of the Gaussian pyramid. Thus, for $0 \leq l < N$:

$$L_l = g_l - U_2(g_{l-1}), \quad (3)$$

where $U_2()$ denotes upsampling with interpolation by a factor of 2 to match the pixel resolution between the levels. We define the highest level $L_N = g_N$ to store the low-pass copy and since there is no image g_{N+l} . Figure 1 presents a visual description of the above process.

The original image can be reconstructed from the Laplacian pyramid exactly, by iteratively upsampling by a factor of 2 and adding it to the lower level, beginning from the highest level.

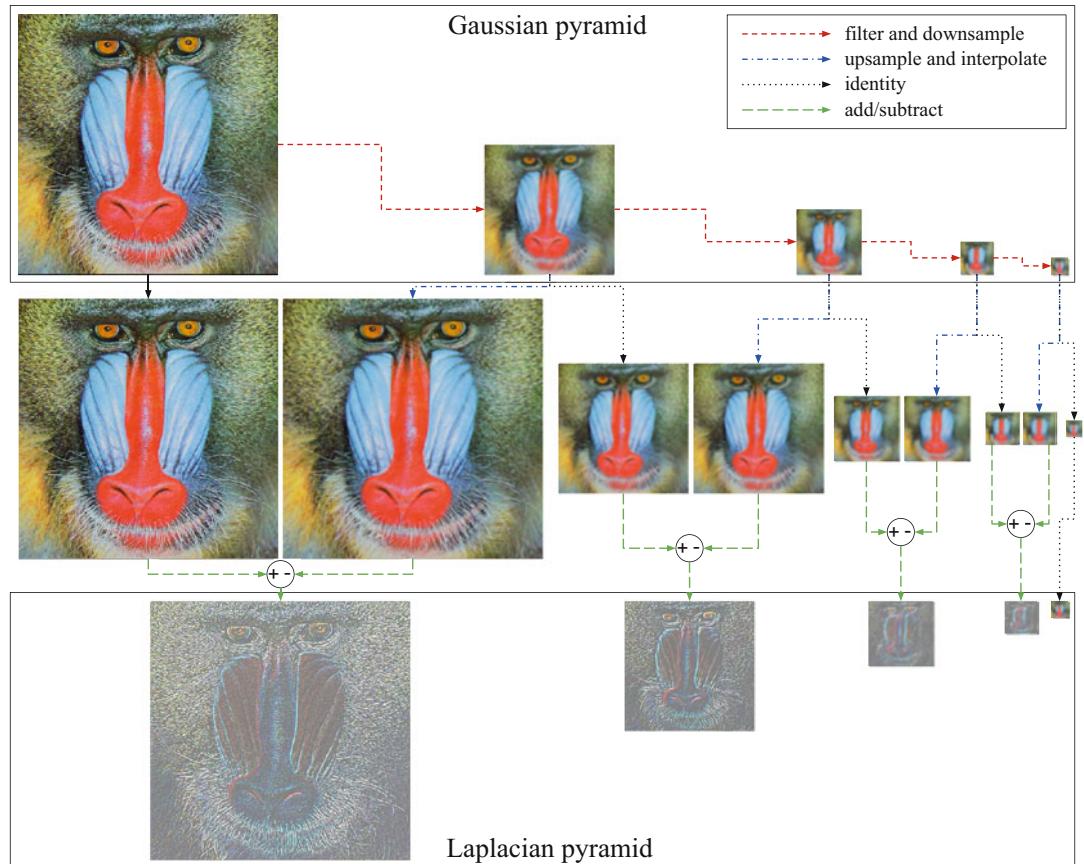

Image Pyramid, Fig. 1 Visual description of the processes for generating the Gaussian pyramid and the Laplacian pyramid

Application

Image pyramids have been applied to a very wide variety of image processing and computer vision problems. Its applications include image compression [2], image blending [5], image denoising [6], texture perception [7], feature point detection and description [8], and object detection [9]. Although scale-space theory [10, 11] provided a more rigorous theoretical basis with a continuous representation of scale, image pyramids are continued to be used due to their efficient multi-scale representation. Its basic framework can be found in deep learning methods where hierarchical filtering and sampling are embedded in convolutional neural networks through pooling or strided convolutions [12, 13].

Definition

Image registration aligns corresponding features of images via spatial transformations.

Background

Computer vision or image processing systems often need to align multiple images of the same or similar scenes. In medical imaging, for example, radiologists routinely compare images of a patient acquired at different times to monitor changes. The intensity difference between two images highlights such changes, but only if the corresponding features are in the same location. However, patients' positions in imaging devices vary between visits, so raw images never have perfect alignment. Image registration transforms or warps one image so that the important objects and the regions of interest are in the same position as in the other image. The difference image then reveals intrinsic physical changes. Figure 1 illustrates the idea. The problem becomes more challenging when the images come from different devices (inter-modality registration) or from different subjects (intersubject registration).

The same problem arises in nonmedical imaging applications. Surveillance systems, for example, often need to look for differences between images at different times, for example, to subtract the background and highlight activity in a scene viewed by a security camera. Fixed cameras can wobble in the wind and produce misaligned images that require registration before the difference image provides a meaningful result. Stitching images together to create panoramas [1] also requires image registration to align the overlapping parts of the images being stitched together, as illustrated in Fig. 2. Similarly super-resolution techniques [2] align multiple images of the same scene and infer sub-pixel details.

The theory of image registration is outlined in the following section, and an additional section has been included to introduce the recent development of image registration methods using deep learning, which share many theoretical and practical aspects of the “classical” registration approaches. The literature contains many review papers, for example, [3–8].

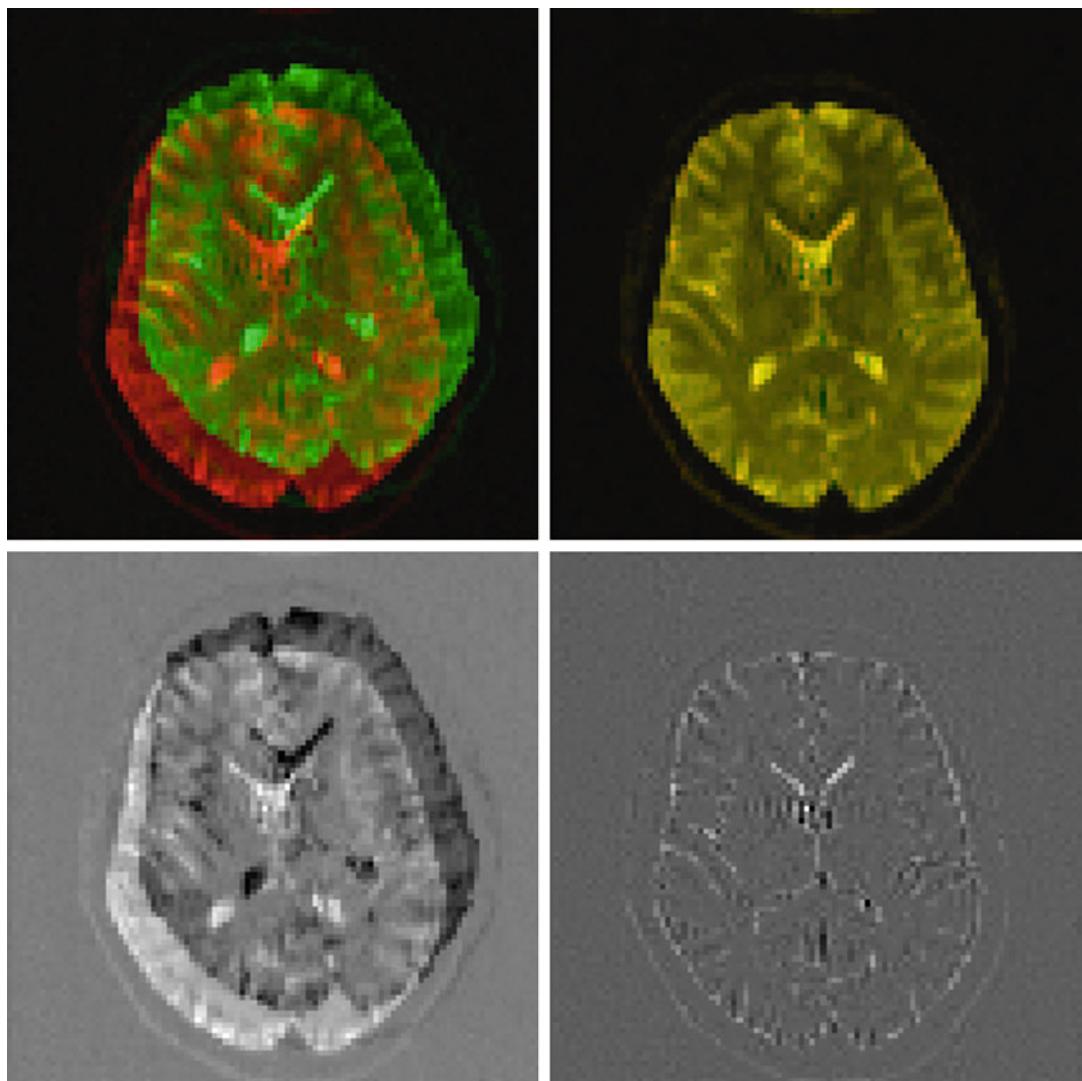

Image Registration, Fig. 1 Intra-subject brain image registration. Top left: overlaid images of the same brain from different acquisitions, one in red and one in green; bottom left: difference image of the two unaligned images;

top right: overlaid images after registration via a rigid transformation; bottom right: difference image after alignment

Theory

The process of automatic image registration involves optimizing a cost function, which expresses the similarity of the two images, with respect to the parameters of a transformation of one of the images. Mathematically, the optimization problem is

$$\{T^*, g^*\} = \operatorname{argmin}_{\{T,g\}} f(I_1, T(g(I_2))), \quad (1)$$

where I_1 is the target image, which is fixed; I_2 is the source image, which the transformations T and g act upon; T is a spatial transformation or warp; and g affects only the image intensity at each pixel position; the optimization seeks

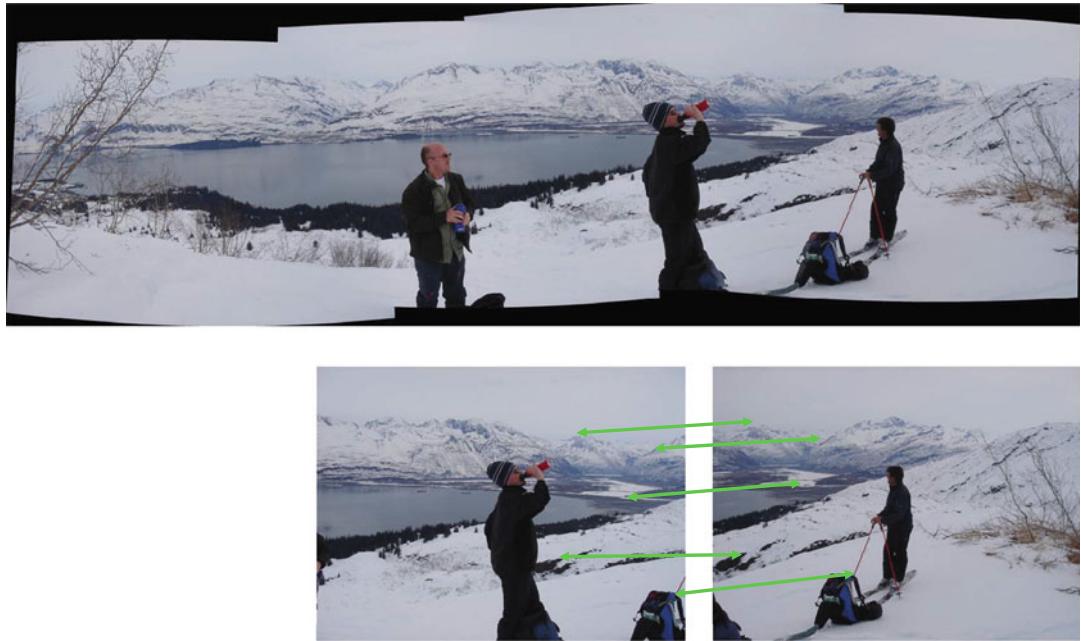

Image Registration, Fig. 2 Image registration for stitching. The panoramic image at the top comes from stitching together various images including the two at the bottom.

Image registration provides the spatial transformation that associates corresponding salient points in the two images, such as those marked by the green arrows

the transformations T^* and g^* that minimize the cost function f . The process decomposes into four key components, discussed in the following subsections.

Features

Various image features drive the registration process. Broadly, the feature set is either sparse or dense. Sparse feature sets consist of geometric features identified in the image through some preprocessing step. These features might be salient points identified by a user or by an automatic detector. Features may also be more complex geometric objects, such as salient lines, curves, surfaces, or regions. Dense features are typically pixel-by-pixel image intensities. Each feature may be a single scalar intensity or may have multiple components, as in multispectral images.

Cost Function

The cost function includes a measurement of similarity between two images. The definition of similarity depends on the set of features. For

sparse feature sets, the cost function typically uses a measure of distance between matched features in the two images. For example, Euclidean distance measures each corresponding pair of point features, although this requires a preceding step to establish correspondence between two point sets, a common problem in various other computer vision tasks, such as stereo matching.

Registration based on dense features, i.e., pixel intensities, typically uses statistical measures of similarity between pixel intensities in corresponding locations. The most direct measure of similarity uses the sum of squares (SSD) of intensity differences.

Direct intensity comparisons, as in SSD, assume the pixel intensity at corresponding locations is the same subject to some noise perturbation. However, that assumption often does not hold. For example, differences in intensity scale between images arise frequently. Where such intensity differences are likely, similarity measures based on the correlation of pixel intensities between the two images are

more appropriate, such as the normalized cross-correlation (NCC) and its variants.

The mapping between intensities of corresponding pixels is sometimes more complex than a simple scale change. It may be nonlinear and non-monotonic. For example, in inter-modality medical image registration, two images of the same object may have the same regional structure, but different regional contrast: image 1 has higher intensity than image 2 in some regions, vice versa in others, and intensity correlation at alignment remains low. Entropy-based similarity measures [9–12] provide a useful alternative. A common choice is the normalized mutual information.

The image similarity is often combined with a regularization term to form the cost function, especially when local transformation models are required (described in the next section), to encourage smoothness of the optimized transformation. While these smoothness measures can be highly application-dependent, general-purpose formulations are usually based on first- or second-order derivatives of local displacement, such as the L_2 norm of displacement gradients [13] or bending energy [14].

Transformation Model

A variety of models are available for the spatial transformation, T . Simple transformations, such as rigid, affine, or polynomial transformations, are global in the sense that even well-separated pixels undergo highly correlated displacements. More complex models, such as spline [14], radial basis function [15], elastic [16], or fluid [17] transformations, can have more local support, so that the displacement of one pixel under the transformation correlates only with that of proximal pixels. Other complex transformation models attempt to capture application-specific deformations, such as respiratory, cardiac, or interventional organ motion, using, for example, biomechanical models and statistical shape models.

In some applications, simple global transformations are sufficient. For example, in image-guided orthopedic surgery, rigid transformations are often sufficient to align two images from the

same subject. Since bones are rigid with little deformation between image acquisitions, the registration needs to correct only for the difference in position and orientation of the subject in the imaging device. However, higher-order global transformations, such as full affine or polynomial transformations, can improve alignment significantly even when the physical transformation is rigid, because they can capture artefactual distortions introduced by the image device. Image stitching often uses a homography, which is a global transformation that accounts for changes in perspective.

Local transformations can capture more subtle changes between images. They are essential, for example, for detecting and quantifying local atrophy (shrinkage) of brain tissue that occurs over time in various neurological conditions [18]. In general in medical imaging, local transformations are usually necessary for good alignment in inter-subject image registration, where local variations in size and shape of anatomical and pathological structures arise.

In practice, the intensity transformation, g in equation 1, is often the identity. However, g becomes important in images that contain more complex information at each pixel than single or multiple scalar values. For example, vector or tensor images are common in remote sensing and medical imaging. In such images, each pixel has an associated orientation. Nontrivial g is essential to ensure that local orientations remain consistent with the image structure through the spatial transformation; see, for example, [19, 20].

Optimization

The wide range of optimization algorithms available today, from simple line search or gradient descent to stochastic and genetic optimization procedures, provides many candidates for driving the minimization of the cost function that solves the registration problem. The choice of optimization procedure depends on the feature set and the transformation model. Registration via sparse feature matching often relies on application-specific algorithms such as RANSAC [21] and expectation-maximization [22], implicitly or explicitly establishing feature correspondence in

the process, whereas most image registration algorithms with dense features use some form of gradient descent. The cost function is almost always non-convex with potentially sub-optimal local minima. Furthermore, the optimization problem tends to become harder the more complex the transformation models with much larger number of parameters. Numerical optimization for these local transformation models often requires nontrivial computational resource and therefore more frequently resorts to parallel computing software and hardware such as GPU implementations. Hierarchical approaches, which start with a simple global registration to get a good starting point and gradually add parameters and re-optimize, are common to obtain a good local registration. Multi-resolution strategies, which start with low-resolution images and gradually increase image resolution and/or complexity of the transformation model, also help.

Machine Learning

Machine learning methods have long been important in developing different components of image registration algorithms. Deep neural networks (DNNs) with much improved representation learning capability [23] pose the entire registration process as a machine learning problem. The end-to-end DNN models can be trained using large data sets consisted of already aligned image pairs and then directly infer the displacement fields or the parameters of the transformation models without iterative optimization for unseen image pairs [24]. The efficient “one-pass” inference step automatically provides a substantial advantage in speed, with volumetric image registration which can now be performed in near real-time.

In practice, a key challenge for the supervised methods is to obtain ground-truth transformation for training the DNNs. Methods for estimating the ground-truth transformation between a pair of images include simulations, manual alignment (a very challenging task especially for local transformation), and iterative registration methods.

Without known ground-truth transformation to establish dense pixel-by-pixel correspondence, weak labels [25] can be used to train the DNNs. Labels delineating corresponding anatomical or pathological points, surfaces, and regions, similar to those used in sparse feature registration, provide sparse and partially known correspondence for weak supervision during training.

The transformation-predicting DNNs can also be trained in an unsupervised manner, minimizing a loss function based on the previously described cost functions over all training image pairs [26]. Unsupervised learning can also be combined with weak supervision to improve the registration performance [27]. Similar supervised and unsupervised learning paradigms that predict the transformation between input pairs of images have also been applied in other computer vision tasks, such as predicting optical flow [28] and estimating homography parameters [29]. Several surveys are dedicated to this topic [7,8].

Applications

The medical imaging community is a large consumer and developer of image registration techniques. Intra-subject image registration enables fusion of information in images from different devices. Intra-subject registration also enables tracking of changes over time during development or disease. In drug trials, for example, imaging offers the potential to observe the effects of a prospective treatment and establish its efficacy noninvasively; image registration is essential for monitoring such effects.

Image registration has increasingly been used in image-guided intervention and surgery, where diagnostic quality images acquired before the procedure are utilized during the operation, by aligning the key anatomical structures and pathological regions of interest between the pre-procedural images with real-time guidance images, the latter of which are often limited by intra-procedural requirements such as time and accessibility to patient. These are inherent inter-modality image registration tasks often involving

estimating the spatial transformation between MR, CT, ultrasound, camera video, and other imaging or non-imaging sensors with spatial encoding.

Another major application is spatial normalization for group studies, which study the variation in the size, shape, and internal organization of a particular organ or object. A common application is human brain mapping where morphological variability is well studied in a range of conditions. Intersubject image registration ensures a collection of similar images are in the same spatial frame of reference so that studies of variation are meaningful. This spatial normalization allows, for example, medical imaging researchers to characterize differences in organ size, shape, and structure between different populations, such as normal healthy adults and patients with a certain condition.

Image registration for image stitching enables day-to-day image processing for digital camera users, as standard packages like Photoshop include such operations. Google Maps is a large-scale application of the same technology.

Many implementations of image registration are freely available. Tried and tested global registration software includes the FLIRT package [30] and the popular b-spline registration algorithm [14] with some variations in FNIRT [31], NiftyReg [32], and ITK [33], some of which also offer GPU acceleration. The DARTEL package [34] is designed specifically for spatial normalization of large brain image ensembles. The recent ANTS package [35] combines several state-of-the-art ideas and performs well in a head-to-head evaluation with other standard packages [36]. Furthermore, most recent DNN-based registration methods have accompanying open-source code.

Open Problems

Similar to training the DNNs, the lack of ground-truth transformation in many computer vision and medical imaging applications directly led to a well-documented difficulty in validating registration algorithms in real-world

applications [3]. Quality labels from large-scale medical image data sets are scarce for validating registration algorithms and for training supervised or weakly supervised DNN-based methods. Many image registration algorithms including unsupervised DNN-based methods rely on a robust cost function for fully automated applications. Developing effective similarity measures as a cost function remains a challenge for many inter-modality image registration tasks. Examples include registration between preoperative MR images and intraoperative ultrasound images for prostate cancer biopsy, brain tumor resection, and laparoscopic liver resection. Most available guidance systems in these applications still require additional spatial information from manually identified landmarks and position-tracking instruments.

Properties assumed in the transformation models may not hold in real-world applications. For examples, topological differences or changes are not accommodated in most general-purpose registration algorithms. In fact, significant effort has gone into developing diffeomorphic transformation models that cannot fold or tear. However, topological differences arise frequently. In intersubject medical image registration, for example, it is not uncommon for an anatomical feature in one person to be entirely missing in another. The same problem can arise between intra-subject images, before and after surgery to remove a tumor, for example. Another example is inverse consistency. Basic asymmetric algorithms do not ensure that the transformation from registering image A to image B is the perfect inverse of that from registering image B to image A, which can become particularly problematic in tasks such as group-wise registration [34].

Definition

Image sensors are devices that produce an electronic signal proportional to the amount of light impinging on the device, typically arranged in two-dimensional pixel arrays. They can read out the image using on-chip amplification and analog-to-digital conversion and are typically controlled using electronic shutters.

Background

Materials and devices to sense light have a long history from antiquity to the present day. While camera obscura or pinhole cameras were being developed for centuries to focus light onto the image plane, only with the invention of the daguerreotype were images captured directly on plates in the late 1800s (Note: there were some camera precursors like heliography, but daguerreotypes were the first popular cameras). These plates would consist of polished metal such as silver exposed to photosensitive chemicals such as Bitumen of Judea, iodine, or halogen fumes, and after exposure with the scene, the resulting latent image was developed using mercury vapors. The resulting images had high spatial resolution but required dangerous chemicals and bulky equipment to be carried around with the camera. Later research was able to transfer image capture from plates to films containing photographic emulsions which are light-sensitive. Analog photography, utilizing film, emerged as the popular camera technology for most of the twentieth century. We refer the reader to Chapter 16 of [1] for more details about the history of photography.

The rise of digital electronics led to the use of silicon-based sensors for capturing images. CCDs (charge-coupled devices) were invented in 1969 at Bell Labs and featured an array of gate capacitors which are doped in silicon to be photoactive when a positive voltage is applied [2]. Incoming light accumulates electric charge proportional to the light irradiance, which is then transferred using a bucket-brigade readout scheme to the edges of the array where it is either transmitted in analog or digitized. CCDs become widely available in cameras, particularly for scientific applications where their low noise properties were beneficial.

However, the majority of image sensors used presently are made from CMOS technology used for fabricated integrated circuits. Work in the Jet Propulsion Laboratory in the early 1990s led to the development of the CMOS image sensor, which consisted of an array of photodiodes that contained a small amplifier per pixel, and column

electronics including further amplification and ADCs [3]. CMOS image sensors quickly grew in market share due to their ability to integrate electronics on the same silicon die as the photodiode array, and was mass-manufacturable in the CMOS process. Today, most cameras from DSLRs to cellphones utilize CMOS image sensors as their main image sensor of choice.

Theory

The theory behind image sensors is rooted in semiconductor physics, namely, optoelectronics, as well as mixed-signal circuit design for the readout, amplification, and analog-to-digital conversion. In this section, we briefly discuss these fundamentals and identify commonly used metrics for image sensor performance. We refer the reader to [4] for a more comprehensive introduction to image sensors.

After light arrives at a photodiode, it typically goes through a microlens and color filter before reaching the photodiode, as shown in Fig. 1a. Microlenses are small lenses on the order of microns (μm) that are fixed on top of the silicon photodiode to focus light. After passing through the microlens, light is sometimes filtered by a color filter, typically for either red, green, or blue visible wavelengths which are spatially arranged over the sensor in a Bayer pattern. This allows color spatial subsampling of the image with each

pixel sensing only one of those three primary wavelengths, and this subsampling is corrected in a process known as demosaicing in image processing. Finally the light reaches the photoactive silicon region, which is typically a p-n junction of doped silicon.

The photoactive region itself exploits the photoelectric effect (which Albert Einstein discovered in 1905 and for which he received the Nobel Prize in physics in 1921) where light displaces electrons in the semiconductor lattice and the corresponding charge carriers are swept across a diode junction to generate a photocurrent. Photodiodes can operate in photovoltaic mode with no bias across their diode, or more typically in photoconductive mode where the diode is reverse biased to increase the responsivity to light. The photocurrent is accumulated on a capacitor to aggregate charge proportional to the number of photons per second per meter squared (equivalent to irradiance). To expose the photodiode, typically one needs to reset the photodiode to its initial reverse bias by applying an external voltage across its terminals before floating the diode and allowing the photocurrent to accumulate charge.

After the charge has been accumulated, it is typically read out of the pixel using an in-pixel amplifier (typically known as a source follower in CMOS) or using a bucket-brigade readout in CCDs. A 2D spatial array of pixels are arranged in row-column format, and commonly one row is read out at a time in column-parallel fashion.

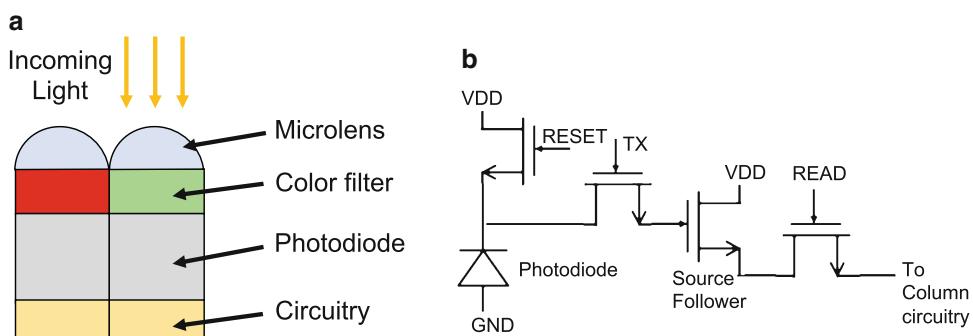

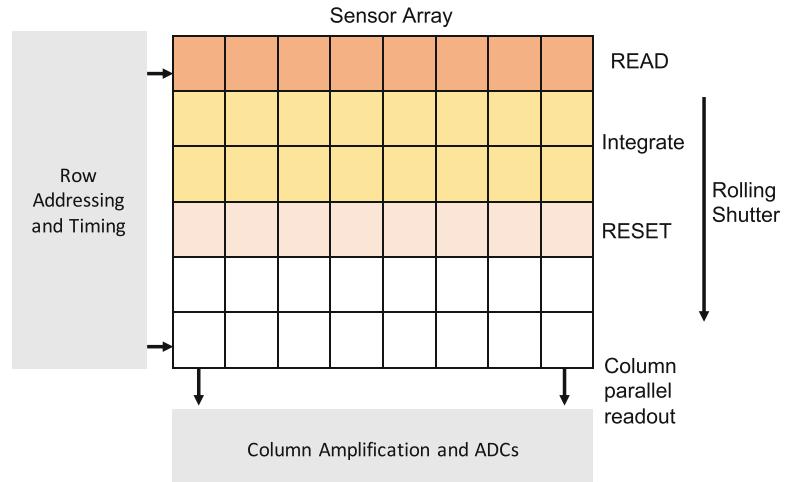

Image Sensors, Fig. 1 (a) The structure of a back-side illuminated photodiode consisting of microlens, color filter, photodiode, and circuitry underneath to read out the signals and (b) a 4T pixel architecture consisting of a reset

transistor for the photodiode, a transfer gate to transfer charge to the pixel amplifier (source follower), and a read transistor that selects the pixel voltage to travel down the column for amplification and digitization

Image Sensors, Fig. 2 A typical architecture for an image sensor array. Rows of pixels are individually reset, integrated or exposed, and then read out via column-parallel readout using a rolling shutter. The resulting column signals for every row are amplified and digitized before being sent off-chip for further processing and computation

Common pixel architectures include the 3T or 4T transistor topology shown in Fig. 1b. To expose and read out the entire array, either a rolling or global electronic shutter is used. In rolling shutter, each row is reset, then exposed, and read out in the timing of the sensor, which means that the entire image is exposed at slightly staggered times (corresponding to different rows), as shown in Fig. 2. Global shutter exposes the entire image sensor at the same time but requires in-pixel memories to store the charge while readout occurs or specialized circuits to do full array readout simultaneously.

After reading out each column signal in parallel (corresponding to one row), the voltage is usually amplified with a column amplifier and then passes through an analog-to-digital converter (ADC). This results in 8–16 bit images depending on the image quantization used, and the image readout is known as the RAW image. After this, the image is usually sent to an image signal/sensor processor (ISP) to perform image processing such as demosaicing, denoising, white balancing, color correction, tone mapping, and compression.

Image Sensor Metrics

There are several key metrics that are important for image sensor performance. Quantum efficiency, $QE(\lambda) = N_e(\lambda)/N_p(\lambda)$ where $N_p(\lambda)$ is the number of incident photons for a specific wavelength and $N_e(\lambda)$ is the number of

electrons produced, determines the sensitivity of the image sensor with higher efficiency meaning less wasted photons.

Various noise sources for the sensor include photon shot noise due to the physics of light collection and read noise of the sensor. Following a model formulated in [5], photon shot noise average power is given by $\sigma_{shot}^2 = q(i_{ph} + i_{dc}) \cdot t_{int}$ where i_{ph} is the photocurrent, i_{dc} is dark current (a type of noise), t_{int} is the integration time, and q is the charge of an electron. Read noise power is given by $\sigma_r^2 = \sigma_{Reset}^2 + \sigma_{Readout}^2 + \sigma_{FPN}^2$ where reset is the noise of resetting the photodiode, readout is the noise of all the electronics, and FPN is fixed pattern noise due to non-uniformities in the sensor. From these quantities, the signal-to-noise ratio is given by the following equation [5]:

$$SNR(i_{ph}) = \frac{(i_{ph}t_{int})^2}{q(i_{ph} + i_{dc})t_{int} + \sigma_r^2}. \quad (1)$$

The dynamic range of the pixel is the range of light intensities that can be represented by a single pixel (or equivalently the amount of charge that can be held by the photodiode). Dynamic range is defined as the ratio of the largest non-saturating input signal to the smallest detectable image signal. This is given by the following formula [5]:

$$DR = \frac{i_{max}}{i_{min}} = \frac{q_{max} - i_{dc}t_{int}}{\sqrt{q_i t_{int} + \sigma_r^2}}. \quad (2)$$

where q_{max} is the maximum charge the photodiode can hold. Note that i_{max} increases as the integration time decreases and i_{min} decreases as integration time increases. Thus, high dynamic range imaging needs short integration times for bright illumination, and long integration times for dark illumination.

Spatial resolution of the image sensor is partially governed by the pixel pitch of the sensor, with most modern CMOS image sensors being less than $1\text{ }\mu\text{m}$ in pitch (spatial resolution of the image is a complex formula of both pixel pitch but also the entire optical system's modulation transfer function (MTF)). Finally, the frame rate of the sensor (fps) is typically set by the exposure time and the readout timing and synchronization of the array. All these metrics are optimized for performance in modern image sensors.

Application

Images and video have become ubiquitous in the twenty-first century, generating content that is uploaded daily to the Internet, shared on social media, and used in a host of different applications. Image sensors are currently reaching tens of megapixels in resolution, frame rates that far exceed 60 frames per second, and are embedded on many different platforms. For photographers, high-end image sensors are found in digital single-lens reflex (DSLR) cameras, yet most typical pictures that are uploaded online are taken using image sensors on mobile devices and smartphones.

In fact, one main application of image sensors is the entire field of computer vision, the focus of this reference guide. Machine vision cameras have been developed to optimize image sensors for application-specific demands. Machine vision cameras typically offer both global and rolling shutter, fast interfaces for data transfer including Ethernet and camera-specific protocols, and have the ability to output RAW images or configure the ISP. These cameras are commonly used for computer vision methods that require accurate photometric measurements from the scene.

In addition to traditional CMOS and CCD image sensors, image sensors have been customized for various other imaging regimes. Image sensors for non-visible wavelengths including infrared and terahertz domains have been developed. These typically use semiconductor materials other than silicon (as silicon is only sensitive to visible and near infrared), such as III-V materials. Such image sensors have applications in remote sensing, surveillance, and biomedical imaging where these non-visible wavelengths yield additional spectral information from the scene.

Open Problems

There are several new frontiers for image sensors and their applications. Computational imaging and photography is a new field of research which co-designs optics, sensor hardware, and algorithms to capture new visual information. New sensors for computational photography include pixels for high dynamic range imaging [6], light field imaging [7, 8], polarization imaging [9], and compressive sensing [10]. Sensors have been developed to support coded exposure and readout [11] for motion deblurring, as well as support arbitrary region-of-interest readout [12] for selective imaging. Other computational image sensors include on-board image gradient calculation [13].

New pixel designs can expand the possibilities of visual data that can be captured on board the sensor. Neuromorphic silicon retinas are able to sense edge gradients and motion information directly through novel silicon detectors that emulate neurons [14]. Event-based sensors (also known as dynamic vision sensors) utilize pixels which output binary or trinary pixels when the pixel changes value temporally and can operate at extremely low powers and extremely fast frame rates [15]. These have been used for a host of applications in robotics, optical flow, and simultaneous localization and mapping.

Time-of-flight sensors have seen widespread application for depth sensing for computer vision. These typically feature either photogates [16] or single-photon avalanche diodes (SPADs) which

operate the photodiode in avalanche mode to be sensitive to a few photons at a time [17]. SPADs have been used widely in LIDAR systems and for emerging applications in non-line-of-sight and transient imaging. Finally, as CMOS technology shrinks to smaller sizes, the ability to sense individual photons has become possible. Quanta image sensors using jot pixels are able to achieve single-photon sensing without the use of avalanche gain, which allows for megapixel resolutions (1.1 μm pixel pitch) and 1000+ fps frame rates [18]. These new image sensors will open up new avenues for research in computer vision as these devices become more available and widespread.

Definition

Image stitching is the process of combining multiple overlapping images to generate a new image with a larger field of view than the originals.

Background

Image stitching can enhance the capabilities of an ordinary camera, enabling the capture of larger field-of-view, higher-resolution images. A popular example is the construction of panorama images by seamlessly combining several images of a scene taken from the same point (This process is known as panoramic stitching, which refers to the special case of image stitching for rotational motion). By capturing images with variable exposure settings, it can also be used to generate images with a higher dynamic range than the originals.

Stitching techniques were originally used in photogrammetry to produce maps from aerial and satellite images. Early techniques involved manual specification of matching images and control points (correspondences) between them [1]. Later methods used automated image alignment [2, 3] and interactive viewers to visualize the results [4]. Modern stitching pipelines offer fully automated operation [3], seam selection [5], and photometric, as well as geometric alignment [6].

A typical pipeline for image stitching consists of the following stages (see Fig. 1):

1. Estimating two-frame motion and discovering overlaps between the images
2. Global alignment (e.g., using bundle adjustment [7])
3. Photometric alignment and seam selection/deghosting
4. Rendering the final panorama with blending and/or tone mapping

Theory and Applications

Image stitching is possible when a one-to-one mapping exists between the source image coordinates. Two commonly occurring examples are: (1) a camera rotating about its optical center and (2) cameras viewing a planar scene. If the cameras are assumed to be rectilinear, the image coordinates are related by a homography

$$\tilde{\mathbf{u}}_2 = \mathbf{H}_{12}\tilde{\mathbf{u}}_1, \quad (1)$$

where $\tilde{\mathbf{u}}_1, \tilde{\mathbf{u}}_2$ are the homogeneous coordinates in image 1 and 2 and \mathbf{H}_{12} is a 3×3 matrix that encodes the relative camera positions. For example, in the rotational case, \mathbf{H}_{12} is given by

$$\mathbf{H}_{12} = \mathbf{K}_2 \mathbf{R}_2 \mathbf{R}_1^T \mathbf{K}_1^{-1}, \quad (2)$$

where $\mathbf{R}_1, \mathbf{R}_2$ are the rotation matrices of cameras 1 and 2 and $\mathbf{K}_1, \mathbf{K}_2$ contain the intrinsic parameters.

A typical image stitching approach begins by robustly estimating \mathbf{H}_{12} from correspondences of local image features [8]. A standard method is to use the RANSAC algorithm [9] to sample the space of transformation hypotheses, for all images with a sufficiently large number of feature matches. One can then reason about the adjacency relationships and recognize panoramas by making a match/no-match decision for each pair and finding connected components in the resulting graph of image matches [3].

After pairwise alignment, gaps and inconsistencies can still exist. Bundle adjustment [7] can be used to minimize projection errors between feature matches in all images and generate globally consistent results. Best results are achieved by parameterizing in terms of the intrinsic and extrinsic parameters of the cameras (e.g., rotation, focal length, radial distortion) [2]. Direct methods [10] (using all of the pixel data instead of only feature points) may optionally be used for accurate final registration.

Once the images are geometrically aligned, the remaining task is to render a seamless output view. The appropriate render surface may depend on the images being aligned: rectilinear renderings (preserving straight lines) might be best for stitching planar surfaces such as whiteboards, spherical or cylindrical render surfaces are popular for wide-angle panoramas. Multiperspective renderings can be used to preserve important geometric properties in the output [11].

Ideally, one can capture or estimate irradiance values per pixel, and given perfect alignment, these would be equal in all images overlapping a given ray. In practice, however, several sources of error contribute toward differences in

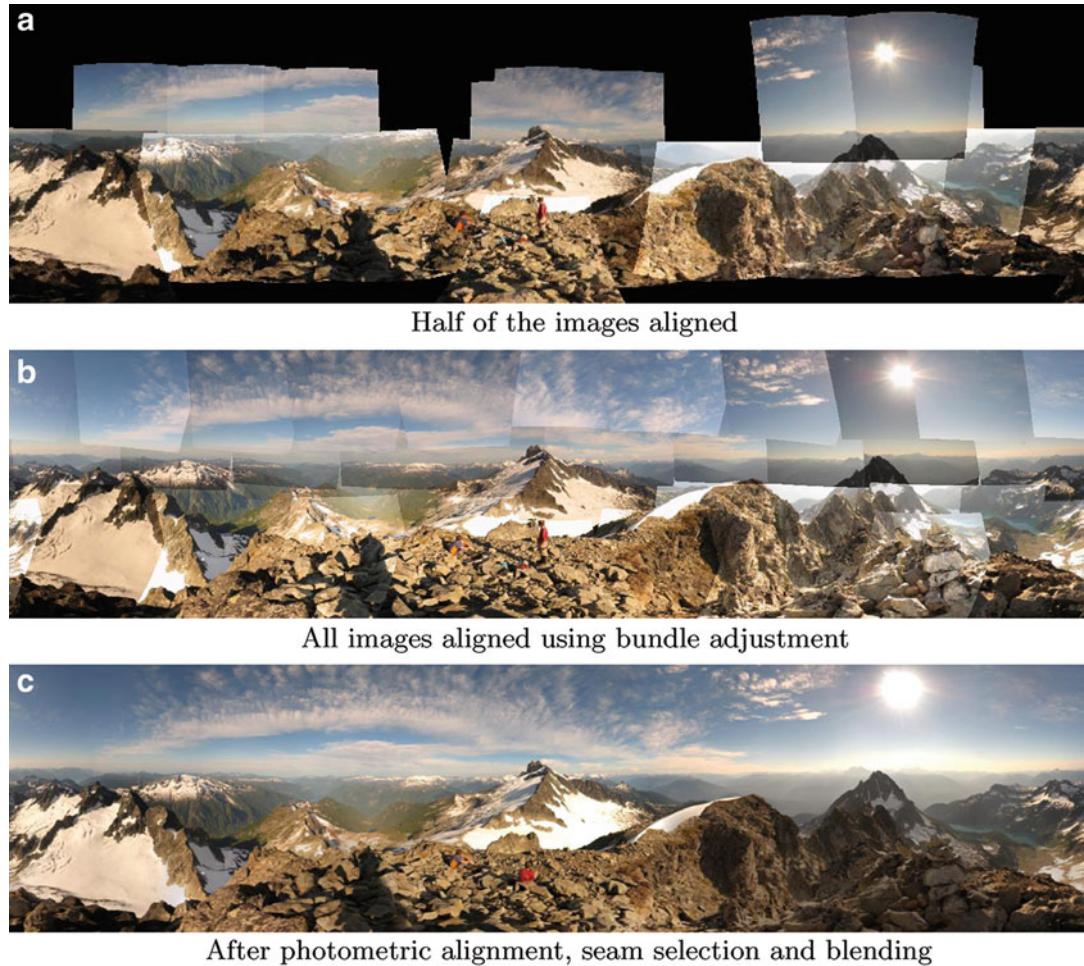

Image Stitching, Fig. 1 Panoramic stitching. Images are first geometrically aligned (using a rotational motion model in this case). Photometric alignment is used to compensate for brightness variations between the images,

and the final panorama is rendered using seam selection and pyramid blending. (a) Half of the images aligned. (b) All images aligned using bundle adjustment. (c) After photometric alignment, seam selection and blending

the recorded radiances. Some common examples are parallax due to motion of the camera center, errors or unmodeled parameters in the camera pose estimate, and moving objects in the scene. Several algorithms have been developed to eliminate the visual seams that result. The best approaches find seam lines which minimize differences between image intensities or radiances [12], and smoothly interpolate between images using pyramid blending [13] or gradient domain fusion [5]. The final results can be tone mapped for display.

An example of an automated capture system capable of stitching gigapixel panoramas with

feature-based alignment, seam selection, and dynamic tone mapping is given in [14].

Image Super-Resolution

Sanghyun Son and Kyoung Mu Lee
 Department of Electrical and Computer
 Engineering, Seoul National University,

Synonyms

Image upsampling; Image upscaling; Super-resolution

Definition

Image super-resolution (SR) problem is to reconstruct a high-resolution image from a given one or more low-resolution sample(s). While non-blind super-resolution methods assume that the exact formulation of the low-resolution image is known, blind algorithms are designed to handle arbitrary images from the real-world scenario.

Background

Digital images appear in various resolutions and may require resizing for specific purposes. For example, a thumbnail image in the PC browser is generated from a high-resolution counterpart. On the other hand, a low-resolution frame in a surveillance video should be enlarged to identify the suspect more accurately. Based on the sampling theory, the former can be effectively done by consecutive low-pass filtering and subsampling. However, the latter is an ill-posed problem since we have to reconstruct the missing high-frequency band only using the given low-resolution sample. While various spatial interpolation algorithms, e.g., bilinear or bicubic, can contribute to upscale an arbitrary example, results look blurry and less realistic compared to the natural high-resolution images.

Therefore, image super-resolution algorithms have played a critical role in the computer vision area to overcome the limitation. They have several practical applications such as image resizing, enhancement, restoration, surveillance, satellite imaging, and even graphics. The key idea of the super-resolution is that high-resolution images can be modeled with appropriate priors, which can be either learned from large-scale external data or carefully designed by considering various properties of natural images. Nevertheless, due to the many challenges in the real world, super-resolving an arbitrary image is still an open problem and requires careful consideration when selecting the algorithm.

Theory

Basic Theory The idea of image super-resolution is originated from the sampling theory about reconstructing a high-resolution signal from misaligned low-resolution samples [9]. However, the algorithm may not satisfy the needs of upscaling an arbitrary example, e.g., one from the Internet, as it requires multiple images. Therefore, recent approaches mostly focus on single-image super-resolution, where the high-resolution image is reconstructed from a single input.

To solve the ill-posed problem of restoring a high-resolution (HR) image, conventional methods first formulate the low-resolution (LR) image as follows:

$$\mathbf{I}_{\text{LR}} = (\mathbf{I}_{\text{HR}} * k)_{\downarrow s} + n, \quad (1)$$

where $\mathbf{I}_{\text{LR}} \in \mathbb{R}^{h \times w \times c}$ is a low-resolution image, $\mathbf{I}_{\text{HR}} \in \mathbb{R}^{sh \times sw \times c}$ is a high-resolution image, $*$ is a spatial convolution, $k \in \mathbb{R}^{k_h \times k_w}$ is a 2D downsampling kernel, s is a scale factor, and $n \in \mathbb{R}^{h \times w \times c}$ is a pixel-wise additive noise term, respectively. We also note that $h \times w$ and $k_h \times k_w$ refers to spatial resolutions and c is the number of color channels, e.g., 1 for luminance and 3 for RGB images.

Therefore, existing optimization-based algorithms solve the following equation to get a super-resolved image \mathbf{I}_{SR} from \mathbf{I}_{LR} :

$$\mathbf{I}_{\text{SR}} = \underset{\mathbf{I}}{\operatorname{argmin}} \|(\mathbf{I} * k)_{\downarrow s} - \mathbf{I}_{\text{LR}}\|_2^2 + \Phi(\mathbf{I}). \quad (2)$$

Due to the filtering and subsampling operations, \mathbf{I}_{SR} is not unique even when the exact k is known. Therefore, the selection of a proper prior term $\Phi(\cdot)$, e.g., total-variation regularization [2], plays a critical role in the reconstruction.

Example-Based Super-Resolution Instead of estimating the high-resolution image directly from a given input, several methods leverage training pairs of $(\mathbf{I}_{\text{LR}}^i, \mathbf{I}_{\text{HR}}^i)$ in image super-resolution. Here, \mathbf{I}_{LR}^i is a low-resolution

counterpart of \mathbf{I}_{HR}^i as shown in Eq.(1). In dictionary-based [18] or sparse coding [21] approaches, each local patch in \mathbf{I}_{SR} is represented by dictionary elements as follows:

$$\mathbf{P}_{\text{SR}}^p = \sum_i w_{ip} \mathbf{I}_{\text{HR}}^i, \quad (3)$$

where \mathbf{P}_{SR}^p is a p -th local patch in \mathbf{I}_{SR} and w_{ip} is a weight which can be estimated using a dictionary of low-resolution patches. For such methods, constructing better dictionaries is of great interest to reconstruct more accurate results [22].

On the other hand, learning-based algorithms aim to train a parametric super-resolution model $f(\cdot; \theta)$ directly over the training samples by minimizing the following objective function:

$$\begin{aligned} \mathcal{L}(\theta) = & \mathbb{E}_i \left[\|f\left(\mathbf{I}_{\text{LR}}^i; \theta\right) - \mathbf{I}_{\text{HR}}^i\|_2^2 \right] \\ & + R(\theta), \end{aligned} \quad (4)$$

where $f(\mathbf{I}_{\text{LR}}^i; \theta) = \mathbf{I}_{\text{SR}}^i$ is a super-resolved image and $R(\cdot)$ is a regularization term. While various parameterization techniques such as deep convolutional neural networks (CNNs) and random forests [16] can be adopted for the mapping f , deep learning and CNN-based approaches have drawn huge attention after significant success of the SRCNN [7] model.

Deep Image Super-Resolution In the deep learning era, designing powerful CNN architectures plays a critical role in achieving high reconstruction performance. Therefore, earlier methods [7, 11, 14] have proposed various building styles of super-resolution CNNs. Such algorithms outperform the conventional methods by a significant margin, demonstrating the capacity of deep CNNs in image super-resolution problem. Especially, a residual connection in the VDSR [11], recursive structure in the DRCN [12], and large-scale network in the EDSR [14] model have proved their efficiency.

One of the notable successes of deep image super-resolution is a perceptual model for reconstructing photo-realistic results. Considering that multiple \mathbf{I}_{HR} can be mapped to the same \mathbf{I}_{LR} as shown in Eq. (1), optimizing Eq. (4) may yield a blurry and less realistic output since an optimal \mathbf{I}_{SR} is an average of all possible solutions. Therefore, Ledig et al. [13] have introduced adversarial training framework to effectively model the natural image prior by the following:

$$\begin{aligned} \mathcal{L}_p(\theta) = & \mathbb{E}_i \left[\|\phi\left(\mathbf{I}_{\text{SR}}^i\right) - \phi\left(\mathbf{I}_{\text{HR}}^i\right)\|_2^2 \right. \\ & \left. - \alpha \log p\left(\mathbf{I}_{\text{SR}}^i\right) \right], \end{aligned} \quad (5)$$

where $\phi(\cdot)$ is a deep convolutional feature extractor for perceptual loss, $p(\mathbf{I}_{\text{SR}}^i)$ is a probability of \mathbf{I}_{SR}^i occurring in the natural high-resolution image manifold, and α is a hyperparameter. Since it is infeasible to calculate $p(\mathbf{I}_{\text{SR}}^i)$ directly, a discriminator CNN is jointly trained with the super-resolution network to predict the probability. The resulting SRGAN [13] model has demonstrated its ability to reconstruct realistic and detailed textures over diverse test examples.

Datasets and Metrics Conventional image super-resolution methods usually synthesize low-resolution examples following Eq. (1) with bicubic or Gaussian kernels. Therefore, collecting diverse high-resolution images is essential for building a generalizable training dataset. For example, Yang et al. [21] have collected 91 images from the Internet to train their super-resolution algorithm. Recent methods further adopt larger datasets like DIV2K [1] and Flickr2K [14] toward better generalization. For evaluation, diverse benchmark datasets [4, 8, 22] are adopted. While PSNR and SSIM [19] between super-resolved and ground-truth images serve as representative measures, the needs of evaluating visual quality [13] of images and appropriate perceptual metrics [5] are arising these days.

Applications

The concept of image super-resolution is very broad, and there exist various methods which narrow down the scope and concentrate on specialized situations. For example, video super-resolution [17] aims to obtain multiple high-resolution frames from low-resolution sequences. Such algorithms can benefit from temporal information and deliver more accurate reconstructions than single-image methods. In the reference-based super-resolution [20], it is possible to utilize reference high-resolution images that are similar to the given low-resolution input. Given proper references, rich textures and impressive details can be reconstructed, which may not be available in naïve single-image super-resolution. It is also possible to design super-resolution models on a specific domain rather than diverse natural images. Face hallucination [23] is a representative term for such algorithms which mainly targets facial images.

Open Problems

Most of the existing super-resolution methods are developed on bicubic-downsampled images, where k corresponds to a bicubic kernel in Eq. (1). However, the formulation of real-world images may not follow such an assumption, which prevents the conventional super-resolution algorithms from generalizing on diverse inputs from the wild. Therefore, recent approaches aim to overcome this challenge by collecting real-world training pairs [6], finding more suitable downsampling kernels [3], or generating realistic low-resolution images directly [15]. Nevertheless, designing a robust super-resolution algorithm against arbitrary input images is still remaining as an open problem to be solved.

Experimental Results

Figure 1 compares $\times 4$ super-resolution results of various methods. Figure 1a and b visualizes ground-truth HR image and its cropped region.

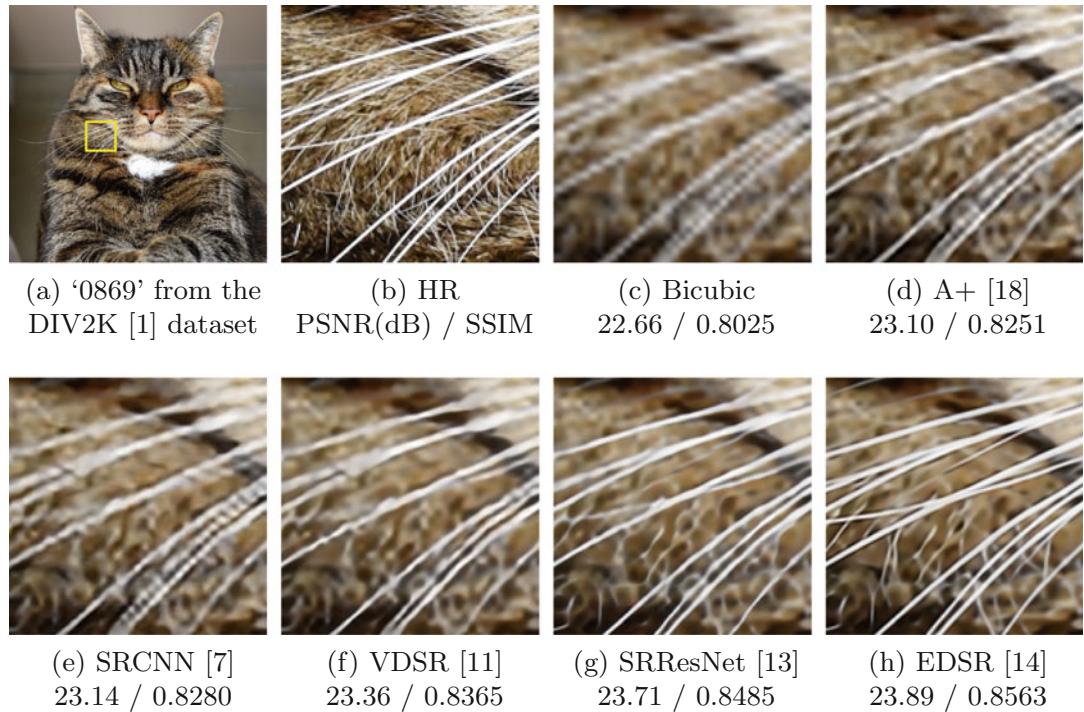

Image Super-Resolution, Fig. 1 Examples of $\times 4$ super-resolution results [14]. (a) and (b) are the original HR image and its cropped region; (c) and (d) are the results of traditional bicubic and exemplar-based methods,

An input LR image of the super-resolution methods is a $\times 4$ downsampled version of the HR example. Figure 1c shows a reconstructed image from the traditional bicubic interpolation, while Fig. 1d is a result from the dictionary-based A+ [18] algorithm. Figure 1e–h illustrates the outputs from CNN-based models that show much better performance than the conventional approaches. PSNR and SSIM between the ground-truth HR and reconstructed images are also provided for reference.

► Plenoptic Function

Definition

Image-based lighting [1, 2] is a rendering technique to compute the reflection from a 3D object lit in a distant environment, represented as an image, typically in the form of a cubemap (Fig. 1).

Background

Due to the computational expense of global illumination (e.g., radiosity and Monte Carlo ray tracing), most real-time graphics systems are depth-buffering based and only support local illumination. This hurts the realism of the rendered images. Environment mapping [1, 3] is proposed to simulate the reflection

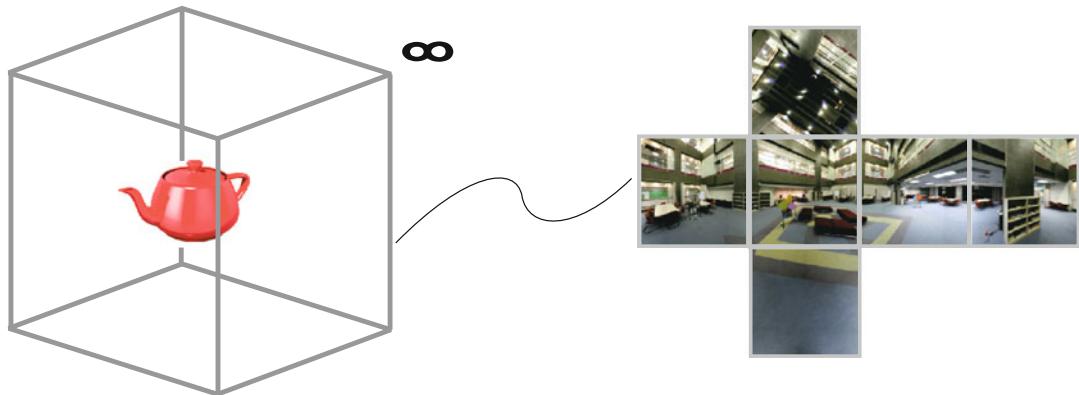

Image-Based Lighting, Fig. 1 Image-based lighting assumes the object being rendered is enclosed by an image-based environment positioned infinitely far away,

of the surrounding environment on an object surface (Fig. 1). The enclosing environment is assumed to be infinitely far away (distant environment) because all surface points on the object are assumed to be lit by the same environment. Due to the high computational expense, early implementations of environment mapping account only for the light contribution along the mirror reflection direction. Hence, most surfaces rendered by the environment mapping are over-shiny.

Image-based lighting can be regarded as a more comprehensive realization of the environment mapping, by accounting not only the light contribution along the mirror reflection but also the whole enclosing sphere. The surface reflectance property (bidirectional reflectance distribution function, BRDF) is also considered so as to render not only shiny or glossy surfaces but also most kinds of surfaces. Moreover, the environment maps are usually captured as high dynamic range (HDR) images to further increase the photorealism. Note that the image-based lighting remains work even low-dynamic range (LDR) environment maps are used instead.

Theory

Extending from accounting only the mirror reflection direction to the whole enclosing sphere drastically increases the computational expense.

or equivalently, the object is infinitesimally small. The environment map is typically represented as a cubemap

Hence, the challenge is how to efficiently compute the following integration for each surface point:

$$I(x, s) = \int_{\Omega} L_{\text{in}}(\omega) \rho(x, \omega, u) v(x, \omega) (\omega \cdot n) d\omega \quad (1)$$

where x is the current surface point of interest; Ω is the surrounding environment (the distant environment map); ω is the incoming light direction; u is the viewing direction from x towards the eye; I is the reflected light; $L_{\text{in}}(\omega)$ is the incoming light contribution along direction ω , in other words, a point in the environment map; v is the visibility function; ρ is the BRDF; and n is the surface normal at x . Note that L_{in} , ρ , and v are spherical functions.

One way to evaluate the above integration is to approximate the environment map by a much smaller number (say m) of point light sources. The position and color of the point lights are obtained by importance sampling of the environment map [4]. In other words, the above integration is approximated by a summation of light contribution of m point lights. The rendered image can simply be generated by adding m images, each rendered by illuminating the scene with a point light source.

By adopting the image-based relighting techniques [5], the above integration can be evaluated more efficiently. The idea is to first encode

the spherical function with basis functions. This effectively converts a huge spherical function (table) into a coefficient vector s_i as follows. Since the basis functions B_i are known, they need not be stored:

$$S(\omega) \approx \sum_i^k s_i B_i(\omega) \quad (2)$$

where S is a spherical function and k is the total number of basis functions, which is much smaller than the number of entries in the original spherical table.

By embedding $\rho(x, \omega, u)v(x, \omega)(\omega \cdot n)$ into a spherical function C , both C and L_{in} can be encoded with the same basis and stored as two coefficient vectors, c_i and l_i , respectively. If the selected basis functions are orthonormal, the above integration (Eq. 1) can be simply evaluated as a dot product between two coefficient vectors [1],

$$I \approx \sum_i^k c_i l_i \quad (3)$$

Basis Functions

The key to efficient image-based lighting is to select an appropriate basis for representing the spherical functions. Various bases have been proposed for image-based relighting [5]. They are directly applicable to image-based lighting.

A pioneer work is proposed by Nimeroff et al. [6]. They efficiently relit the scene under various natural illumination (overcast or clear skylight). The illumination function is decomposed into a linear combination of *steerable functions*.

Principal component analysis is naturally a potential choice for basis function [7]. Singular value decomposition can be used to extract a set of eigenimages from the input reference images. The desired image can then be synthesized by a linear combination of these basis images given a set of coefficients [8, 9] if all surfaces are Lambertian.

Earlier works do not consider the spherical nature of the illumination computation. Wong et al. [5, 10] chose the *spherical harmonic basis*, which is commonly used for compressing BRDF.

Pleasant rendering results are obtained with 16–25 basis functions. However, spherical harmonic is also well known in over-smoothing the high-frequency signal (e.g., shadow) in the original spherical function, leading to low-frequency results.

To achieve all-frequency rendering, Haar *wavelet basis* is proposed [11]. It may introduce visual artifact when the distant environment contains a dominant but small-size spot. The cause of such artifact is due to the digitization of the spherical function and the limited reconstruction involving only important wavelet coefficients.

Spherical radial basis function (SRBF) [12–14] is another approach to capture all-frequency signal. The local support nature of SRBF allows its implementation to be very efficient and simple. The multiscale spherical radial basis function [15] avoids the visual artifact of the Haar wavelet basis while remains able to achieve all-frequency rendering.

Application

Image-based lighting can be applied to produce realistic rendering for both off-line movie production or real-time computer games. The parallel nature of image-based lighting (all surface points have to evaluate Eq. 1 independently) facilitates its real-time realization on modern graphics processing unit (GPU).

Definition

Image-based modeling refers to the process of using 2D images to create 3D models. These 3D models are often represented by triangle meshes with texture maps. These models can be used for visualization or may be used for planning in robotics applications. The image-based modeling process can be roughly divided into three major steps: (1) sparse 3D reconstruction (also known as structure-from-motion), (2) dense 3D reconstruction (i.e., multi-view stereo), and (3) surface reconstruction and texture mapping.

Background

Many applications require 3D models of real objects or scenes. These applications include virtual reality (VR) or augmented reality (AR), mapping, manufacturing, robotics, etc. Thus, digitizing real objects into high-quality 3D models has been an important research topic since the early days of computer vision.

Earlier works such as [1] employ a range scanner to model the 3D shape and estimate reflectance from the images. This entry focuses on methods using only regular RGB images without resorting to range scanners or RGB-D cameras. One important advantage of these image-based methods is that the same pipeline can be adopted to model objects and scenes at different scales, from desktop toys to city scale maps.

Early image-based modeling methods [2, 3] still require human inputs in the loop to facilitate segmentation or model generation. More recent works [4, 5] have automated the whole process, starting from structure-from-motion, multi-view stereo, till surface reconstruction. There are commercial software packages [6, 7] and open source solutions [4] for the complete

image-based modeling pipeline. Figure 1 illustrates a typical pipeline for a city scene.

Theory

A typical image-based modeling pipeline usually consists of three standard steps: (1) sparse reconstruction, (2) dense reconstruction, and (3) surface reconstruction and texture mapping.

The sparse reconstruction step solves the structure-from-motion problem, which recovers camera poses and a sparse set of 3D points of the scene from the input images. This problem has been intensively investigated in the field of computer vision and is probably one of the most important achievements of the field. Many of the fundamental mathematical results are summarized in the textbook [8]. A typical structure-from-motion system includes the following components: (a) Feature detection and matching computes local image features such as SIFT [9] or SURF [10] features and finds corresponding features across different images. (b) Relative motion estimation between image pairs or triplets solves the relative rotation and translation between two or three cameras by the five-point [11] or six-point [12] algorithms. (c) Camera registration solves all camera poses (including orientations and positions) and sparse scene points in a single global coordinate system from the pairwise relative motions. There are incremental approaches [13, 14] that solve cameras one by one and also global approaches [15, 16] that solve all cameras together. (d) Bundle adjustment [17] is a non-linear optimization to refine camera poses and scene point coordinates by minimizing the reprojection error to guarantee a maximum likelihood estimation of the result.

The dense reconstruction step aims to densify the point clouds by recovering the 3D position for each pixel in the input images. Toward this goal, some methods [18, 19] estimate semi-dense point clouds through correspondence propagation. Other methods solve the multi-view stereo problem to recover a dense model. Many early multi-view stereo algorithms are summarized and

benchmarked in [20]. A more recent survey can be found at [21] with an updated benchmark provided in [22]. Broadly speaking, conventional methods can be divided into two categories including volumetric methods like space carving [23] and depth map-based methods [24, 25] which are more flexible at large-scale scenes. There is a strong open source implementation for multi-view stereo known as COLMAP [26]. It is still challenging to reconstruct textureless or reflective surfaces such as water, glasses, reflective metal, or mirrors. More recently, deep convolutional neural networks have been employed to solve the multi-view stereo problem in [27, 28], which can potentially incorporate high-level semantics to ease the reconstruction at textureless places.

The surface reconstruction can be solved easily with the Poisson surface reconstruction algorithm [29] if the dense reconstruction step successfully generates dense point clouds with little gaps or holes. Surface reconstruction is more challenging when the point cloud is incomplete, e.g., due to textureless or reflective surfaces, or when the underlying surface is discontinuous such as hair fibers (linear structure), flower petal or plant leaves (open surface patches), or tree branches (tree and fractal structure). To deal with incomplete point clouds, a minimal surface might be solved by the level set method [30] from the input points, which minimizes a functional of the following form,

$$\int \int w ds.$$

Here, ds is the infinitesimal surface element, and w is the consistency of the surface according to the input 3D points and 2D images. This consistency can be simply the Euclidean distance [31], or point to plane distance [32], or further combined with reprojection errors and silhouette constraints [33]. To deal with discontinuous surfaces, there are many methods that exploit shape priors of the object to facilitate modeling. Wei et al. [34] modeled hair by “growing” 3D smooth curves guided by 3D points and images. Bhat et al. [35] used videos to obtain the parameters of a cloth simulation system. Tan et al. [36]

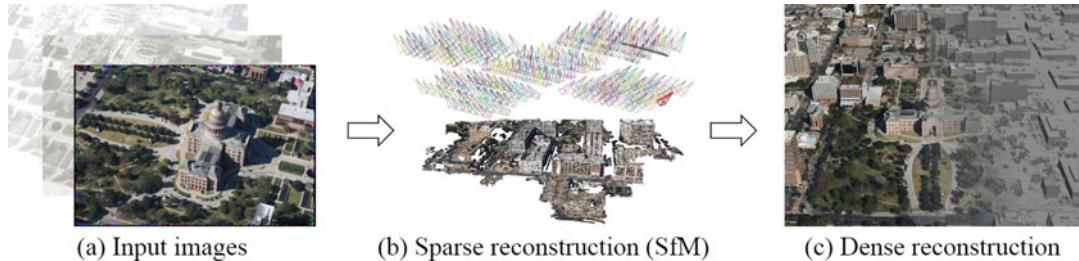

Image-Based Modeling, Fig. 1 A typical pipeline of image-based modeling. In the *left* are some input images. In the *middle* is the result by structure-from-motion, which generates sparse point clouds of the scene and calibrates

all camera poses. In the *right* is the dense mesh model with texture maps generated from the input images. (These pictures are from [5])

recovered some basic branch elements from the 3D points and used them to generate a fractal branch structure. Though generating good results, these methods are limited to model the type of surface that matches their underlying prior shape assumption. A general modeling method is still missing to handle all these different data in a unified framework.

Application

Image-based modeling can be applied in robotics or autonomous driving to generate a 3D map of their environment for path/action planning. It can also be used in industry vision for product quality inspection. The 3D models can also be applied for visualization purposes in games, movies, and VR/AR.

- [Light Field](#)
- [Lumigraph](#)
- [Plenoptic Function](#)

Definition

Image-based rendering (IBR) refers to a collection of techniques and representations that allows 3D scenes and objects to be visualized and manipulated in a realistic way without full 3D model reconstruction.

Background

One of the primary goals in computer graphics is photorealistic rendering. Motivated by the difficulties in achieving full photorealism with conventional 3D and model-based graphics, image-based rendering which works directly with real images has proposed as an alternative approach to reduce the rendering and capturing complexity. Depending on how the images are being taken and the auxiliary information, such as

depths, etc., required, a number of image-based representations supporting different viewing freedom and functionalities are available. These range from the familiar two-dimension (2D) panoramas to more sophisticated representations such as the four-dimension (4D) light fields [9], lumigraphs [8], and variants, which are special cases of the radiance received at every viewing position, visual angle, wavelength, and time, called the plenoptic function.

The rendering of novel views can therefore be viewed as the reconstruction of the plenoptic function from its samples. Image-based representations are usually densely sampled high-dimensional data with large data sizes, but their samples are highly correlated. Because of the multidimensional nature of image-based representations and scene geometry, much research has been devoted to the efficient capturing, sampling, rendering, and compression of IBR.

Theory

Representation

In IBR, new views of scenes are reconstructed from a collection of densely sampled images or videos. Examples include the well-known panoramas [5], light fields [9], lumigraph [8], layered depth images [13], concentric mosaics (CM) [14], etc. Figure 1 summarizes the concept of CM and light field (see the sections on light field, lumigraph, and plenoptic function for more illustration). The reconstruction problem (i.e., rendering) is treated as a multidimensional sampling problem, where new views are generated from densely sampled images and depth maps instead of building accurate 3D model of the scenes.

Depending on the functionality required, there is a spectrum of IBR as shown in Fig. 2. They differ from each other in the amount of geometry information of the scenes/objects being used. At one end of the spectrum, like traditional texture mapping, very accurate geometric models of the scenes and objects say generated by animation techniques is used, but only a few images are required to generate the textures.

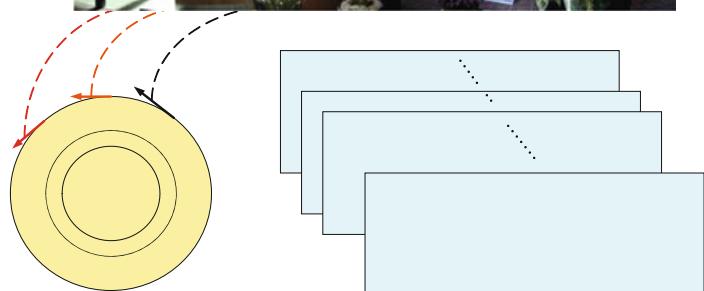

Given the 3D models and the lighting conditions, novel views can be rendered using conventional graphic techniques. Moreover, interactive rendering with movable objects and light sources can be supported using advanced graphic hardware.

At the other extreme, light field or lumigraph rendering relies on dense sampling (by capturing more image/videos) with no or very little geometry information for rendering without recovering the exact 3D models. An important advantage of the latter is its superior image quality, compared with 3D model building for complicated real world scenes. Another important advantage is that it requires much less computational resources for rendering regardless of the scene complexity because most of the quantities involved are precomputed or recorded. This has attracted considerable attention in the computer graphic community in developing fast and efficient rendering algorithms for real-time relighting and soft-shadow generation [2, 12, 19, 22].

Broadly speaking, image-based representations can be classified according to the geometry information used into three main categories: (1) representations with no geometry, (2) representations with implicit geometry, and (3) representations with explicit geometry. 2-D panoramas, McMillan and Bishop's plenoptic modeling [11], and 3D concentric mosaics and light fields/lumigraph belong to the first category, and they can be viewed as the direct interpolation of the plenoptic function. Layer-based, object-based representations [4], pop-up light [16] using depth maps fall into the second. Finally, conventional 3D computer graphic models and other more sophisticated representations [7, 21, 22] belong to the last category. Although these representations also sample the plenoptic function, further processing of the plenoptic function has been performed to infer the scene geometry or surface property such as bidirectional reflectance distribution function (BRDF) of objects. Such image-based modeling approach has emerged as a more promising approach to enrich the photorealism and user interactivity of IBR. Moreover, since 3D models of the scenes are unavailable, conventional

Concentric mosaic

By constraining camera motion to planar concentric circles, concentric mosaic can be created by compositing slit images taken at different locations of each circle.

**Light field**

Using this 2D array of images, light field is possible to render different views of the object or scene at different viewing angles.

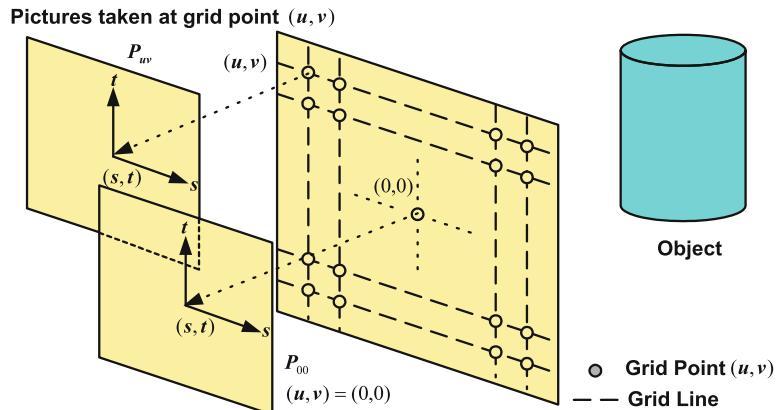

Image-Based Rendering, Fig. 1 Concentric mosaic and light field [3]

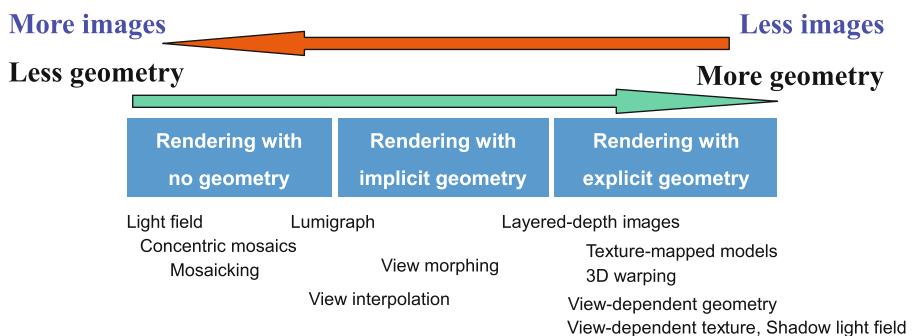

Image-Based Rendering, Fig. 2 Spectrum of IBR representations

image-based representations are limited to the change of viewpoints and sometimes limited amount of relighting. Recently, it was found that real-time relighting and soft-shadow computation are feasible using the IBR concepts and the associated 3D models using precomputed

radiance transfer (PRT) [19] and precomputed shadow fields [22].

Earlier image-based representations are usually static, and their extension usually requires multiple camera arrays. Much research has been devoted to the capturing, compression, transmis-

sion, and processing of these dynamic representations. For a review as of 2007, see [17].

Rendering

Rendering refers to the process of rendering of new views from the images and possibly other auxiliary information captured in the representations. For early image-based representations which do not employ any geometry information, rendering can be done simply by image blending as in panoramas [5] and ray-space interpolation in light field [9]. In ray-space interpolation, each ray that corresponds to a target screen pixel is mapped to nearby sampled rays. Figure 4a shows the example renderings of a simplified light field using ray-space interpolation [17]. For more sophisticated representations which use more geometry information such as layered depth images [13], surface light field [21], and pop-up light field [16], graphics hardware has been exploited to accelerate the rendering process. The geometry information can either be implicit that relies on positional correspondences or explicit in the form of depth along known lines-of-sight or 3D coordinates. Representations of the former usually involve weakly calibrated cameras and rely on image correspondences to render new views, say by triangulating two reference images into patches according to the correspondences as in joint view triangulation (JVT) [10]. These include view interpolation, view morphing, JVT, and transfer methods with fundamental matrices and trifocal tensors. Representations employing explicit geometry include sprites, relief textures, layered depth images (LDIs), view-dependent texture, surface light field, pop-up light field, shadow light field, etc.

In general, the rendering methods can be broadly classified into three groups [17]: (1) point-based, (2) layer-based, and (3) monolithic.

Point-Based Rendering works on 3D point clouds or point correspondences, and typically each point is rendered independently. Points are mapped to the target screen through forward mapping and variants. For the 3D point X in Fig. 3, the mapping can be written as

$$X = C_r + \rho_r P_r x_r = C_t + \rho_t P_t x_t \quad (1)$$

where x_t and x_r are homogeneous coordinates of the projection of X on target screen and reference images, respectively. C and P are camera center and projection matrix, respectively, and ρ is a scale factor. Since C_t , P_t , and the focus length f_t are known for the target view, ρ_t can be computed using the depth of X . Given x_r and ρ_r , one can compute the exact position of x_t on the target screen and transfer the color accordingly. Gaps or holes may exist due to magnification and disocclusion, and splatting techniques have been proposed to alleviate this problem. The painter's algorithm is frequently used to avoid the problem of the mapping of multiple pixels from the reference view to the same pixel in the target view.

Layered Techniques usually discretize the scene into a collection of planar layers with each layer consisting of a 3D plane with texture and optionally a transparency map. The layers can be thought of as a continuous set of polygonal models, which is amenable to conventional texture mapping and view-dependent texture mapping. Usually, each layer is rendered using either point-based or polygon meshes as in monolithic rendering techniques before being composed in the back-to-front order using the painter's algorithm to produce the final view. Layer-based rendering is also easier to implement using graphic processing unit (GPU). Since the rendering of IBR requires very low complexity, it is even possible to perform the calculation using CPU by working on individual layer or object [4].

Monolithic Rendering usually represents the geometry as continuous polygon meshes with textures, which can be readily rendered using graphics hardware. The 3D model normally consists of vertices, normals of vertices, faces, and texture mapping coordinates. The data can be stored in a variety of data formats. The most popular formats are .obj, .3ds, .max, .stl, .ply, .wrl, .dxf, etc.

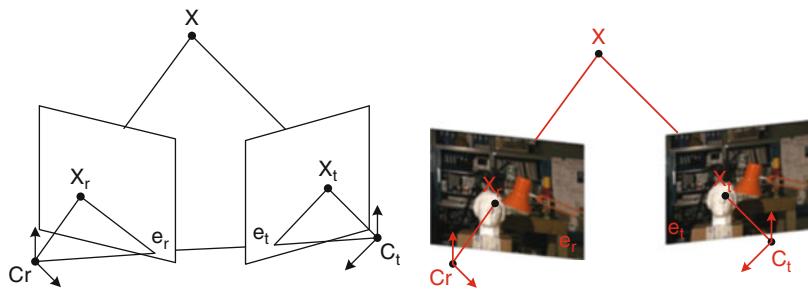

Image-Based Rendering, Fig. 3 Forward mapping

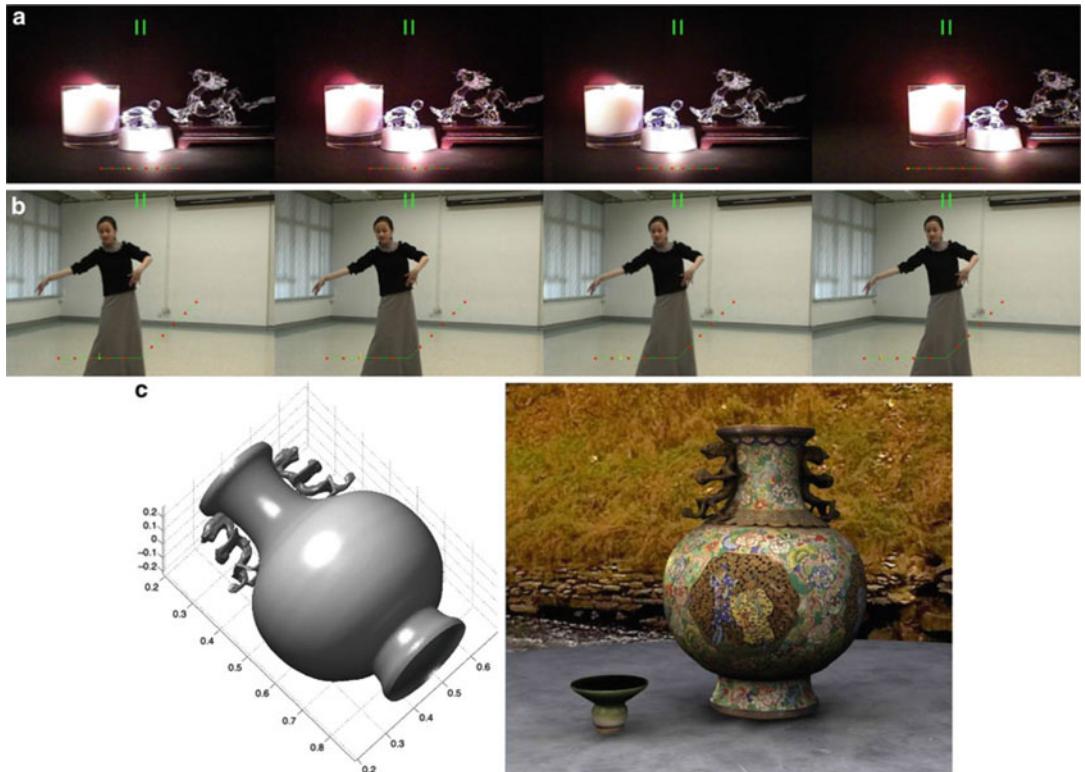

Image-Based Rendering, Fig. 4 Example renderings using (a) ray-space interpolation [17], (b) forward mapping in layered representation (with two layers – dancer and background) [4], (c) monolithic rendering using 3D

polygonal mesh (*left*) estimated by multiview stereo and real-time rendering with shadow light field technique on GPU [23]

Relighting, shadow generation, and interactivity have played an increasingly important role in 3D interactive rendering. The most popular algorithms are shadow mapping, shadow volume, ray tracing, precomputed radiance transfer, precomputed shadow field, etc. Some of them have better rendering quality, while others are more efficient for real-time

rendering. Thanks to the development of GPU, basic lighting, and shading algorithms like shadow mapping and shadow volume have been realized on the fly. Modern GPUs can even offer programmable rendering pipelines for customized rendering effects and “shader” is a set of software instructions running on these GPUs to control the pipelines. Using shader

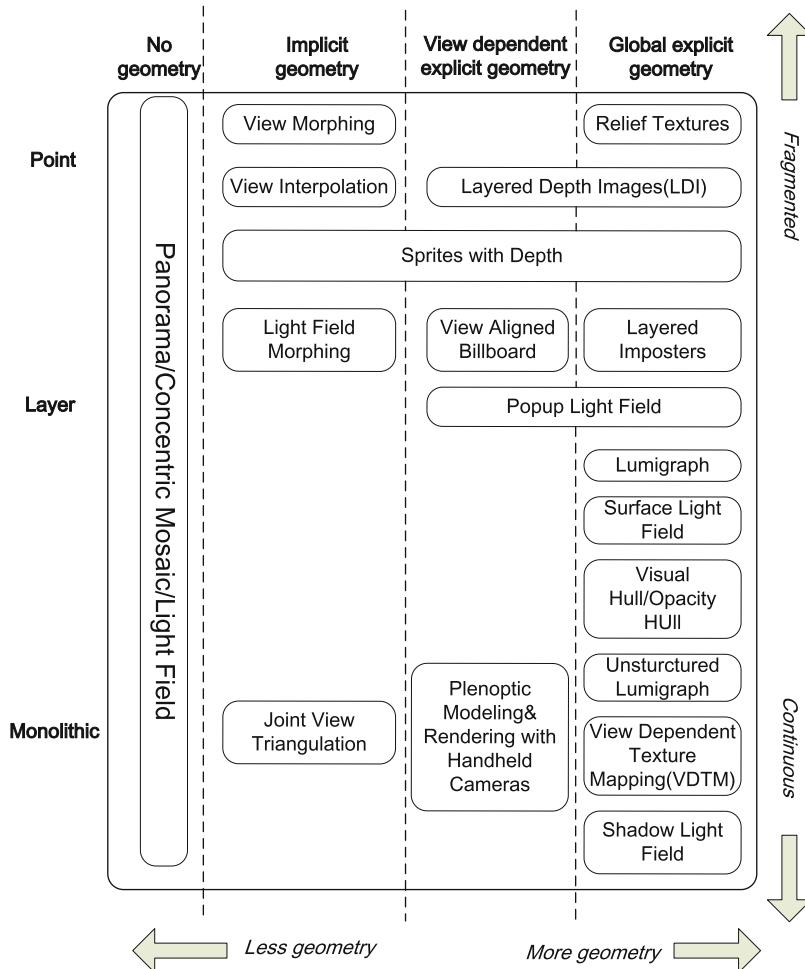

Image-Based Rendering, Fig. 5 Geometry-rendering matrix

programming, high-quality shadow rendering algorithms like precomputed shadow field can be done in real time. Figure 4 shows example renderings of the three techniques, and Fig. 5 summarizes the types of representations and rendering in IBR called the geometry-rendering matrix.

Compression

In general, there are two approaches to reduce the data size of image-based representations. The first one is to reduce their dimensionality, often by limiting viewpoints or sacrificing some realism. Panoramas and concentric mosaics are such examples. The second approach is to exploit the high correlation (i.e., redundancy) within

the representation using waveform coding or model-based techniques. The scene geometry may be used explicitly or implicitly. The second approach can be further classified into four broad categories: pixel-based methods, disparity compensation/prediction (DCP) methods, model-based/model-aided methods, and object-based approach.

In pixel-based methods, the correlation between adjacent image pixels is exploited using conventional techniques such as vector quantization and transform coding. In the DCP methods, scene geometry is utilized implicitly by exploiting the disparity of image pixels, resulting in better compression performance. (Disparity refers to the relative displacement

of pixels in images taken at adjacent physical locations.) Model-based/model-aided approaches recover the geometry of the objects or scene in coding the observed images. The models and other information such as prediction residuals or view-dependent texture maps are then encoded. In the object-based approach, the representations are segmented into IBR objects, each with its image sequences, depth maps, and other relevant information such as shape information. The main advantage is that it helps to reduce the rendering artifacts and hence the required sampling rate. For additional references, see the section on light fields.

Unlike conventional video coding, higher dimensional image-based representations such as 3D concentric mosaics (CMs) require random access at the line level, whereas the 4D light field and lumigraph require random access at the pixel level. It is usually time-consuming to retrieve and decode a single line or pixel from the compressed which is of variable length due to entropy coding. This is referred to as the “random access problem” of IBR and is usually tackled by grouping the compressed data of several basic units for rendering (such as lines in CMs or image blocks in light fields) together and employ pointers to locate them efficiently. Moreover, interdependence of decoding resulting from DCP should be reduced to avoid decoding excessively unnecessary intermediate data. This is also required for selective transmission or decoding of the compressed representations due to their large bandwidth and storage requirement. A simple comparison of difficult image-based representations and compression methods in terms of their complexities, compression ratios, and ease of random access is shown in Fig. 6. For more information, see [15, 17] and references in the light field section.

Application

The potential for photorealistic visualization and simplicity in rendering of IBR has tremendous appeal. They have already found applications

in architectural modeling [6], cultural heritage preservation [23], virtual tour, and digital museum [18], multiview TV [3, 4], etc. Other potential applications include digital edutainment, E-commerce and photorealistic modeling, and real-time rendering in computer graphics and mobile devices. Another emerging application is view synthesis in 3D and multiview videos and display.

Open Problems

Though there has been substantial progress in capturing, representing, rendering, and modeling of scenes, the ability to handle general complex scenes remains challenging for IBR. A substantial amount of work is still required to ensure robustness in handling reflection translucency, highlights, depth estimation, capturing complexity, object manipulation, etc. Since IBR uses images for rendering, interacting with IBR representations remains challenging. Recent approaches have focused on using advanced computer vision techniques, such as stereo/multiview vision and photometric stereo, and depth sensing devices to extract more geometry information from the scene so as to enhance the functionalities of IBR representations. While there has been considerable progress in relighting and interactive rendering of individual real static objects, such operations are still difficult for real and complicated scenes. For dynamic scenes, the huge amount of data and vast amount of viewpoints to be provided present one of the major challenges to IBR. Advanced algorithms for processing and manipulation of the high-dimensional representation to achieve such function as object extraction, model completion, scene inpainting, etc., are all major challenges to be addressed. Finally, the efficient transmission, compression, and display of dynamic IBR and models are also urgent issues awaiting for satisfactory solution in order for IBR to establish itself as an essential media for communication and presentation.

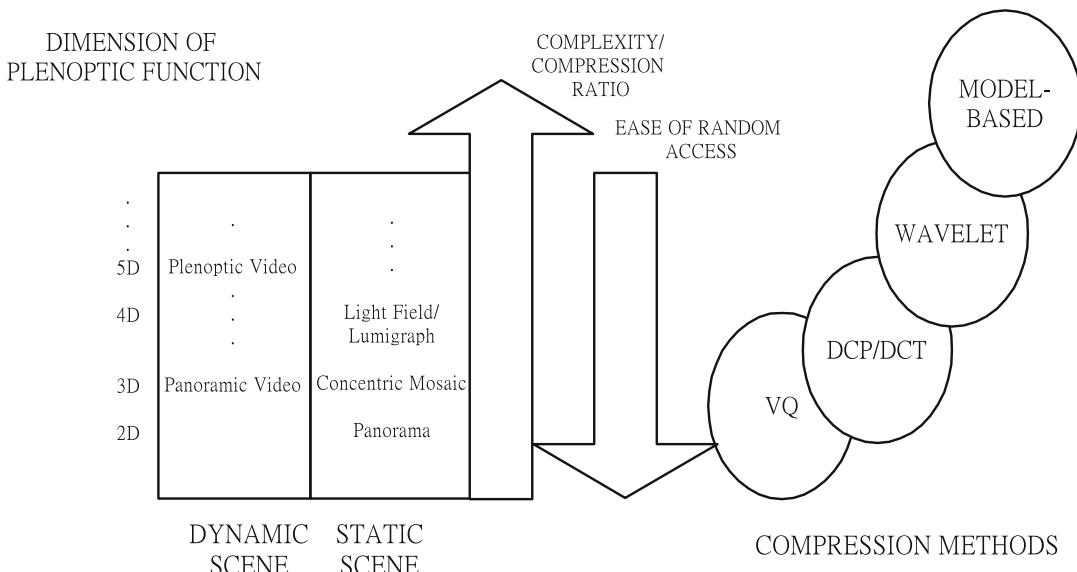

Image-Based Rendering, Fig. 6 Comparison of different image-based representation and compression methods in terms of their complexity. The ease of random access increases as the dimension of plenoptic function

decreases, while the complexity and potential for compression both increase with the dimension. *DCP* disparity compensation/prediction, *VQ* vector quantization

Incident Light Measurement

Definition

Incident light measurement is the recording of incoming illumination at a given scene point or in a given scene.

Background

The distribution and intensity of light incident upon a surface point or in a scene affects the amount of reflected radiance to the camera and more generally the appearance of objects. Knowledge of the incident light can aid in shape recovery through photometric analysis techniques such as shape-from-shading and photometric stereo or may be used in reducing appearance variation caused by lighting. Various methods have been used for measurement of incident light. Different from algorithms for illumination estimation, incident light measurement does not infer lighting from indirect scene cues such as shading, but rather obtains direct observations of the light sources.

Methods for incident light measurement typically introduce a probe or a sensor into the scene to view the incoming radiance. In general, the probes are mirrored spheres that allow for precise readings of light from a broad range of incident directions. Besides lighting distribution, the color of incident illumination may be measured using a color calibration target such as a white reference standard. Unlike illumination estimation methods, light measurement with such devices often allows for accurate recovery of both direct

illumination from light sources and more subtle indirect illumination from reflected light within the scene.

Some techniques are intended to measure incident light at a certain scene point. Excluding the effects of light occluders, these methods equivalently measure far lighting that originates from distant light sources and is considered to be uniform throughout the scene. Other methods are more general in that their measurements also determine the location and brightness of near light sources, whose illumination varies within the scene. Such methods utilize triangulation, usually from two or more probes or sensors placed in the scene, to locate the positions of local light sources.

Methods

Several methods for incident light measurement are described in the following.

Spherical Probes

To measure distant illumination or the light incident at a given scene point, a common approach is to place a mirrored spherical probe at the scene point. From the reflections on the sphere, the corresponding directions of the incident light are computed from the known surface orientation of each sphere point and the mirror reflection property, which states that the incident angle of light is equal to the reflected light angle. Incident lighting environments of various scenes were measured in this manner by Debevec [1]. High dynamic range imaging was used to obtain accurate measurements of relative light source brightness.

To recover spatially variant incident lighting due to local light sources, Powell et al. [2] used three mirrored spheres at known relative positions to triangulate light source locations. For triangulation, correspondences need to be computed among the mirrored reflections of the spheres. Illumination color is also measured from the color of diffuse reflections on the spheres. Zhou and Kambhamettu [3] also employed triangulation, but instead computed correspon-

dences in a stereo image pair of a single sphere. Shifts in specular reflections as seen from the two stereo viewpoints indicate the distance of light sources. Here, the spheres also exhibit diffuse reflection, which provides information on light intensities. Using this setup, they later proposed a method [4] based on ray tracing and convex hull computation to measure a more general light source model [5].

Hemispherical Imaging

An alternative to lighting probes is to directly place sensors within the scene. Drettakis et al. [6] employed image mosaicing of several snapshots captured within the scene to form a panoramic image of the incident lighting. Sato et al. [7] instead used a pair of omnidirectional cameras, each outfitted with a fish-eye lens. Correspondences in the omnidirectional images are computed with an omnidirectional stereo algorithm to obtain a 3D model of the incident lighting, and high dynamic range imaging is used to measure the intensity of radiance.

Color Calibration Target

The incident light color may be measured by inserting a white reference standard into the scene. Deviations from white of the reflected light indicate the color of illumination. This approach to measuring incident lighting color is described by Barnard et al. [8] for their construction of an image dataset for computational color constancy. Directional variations in illumination color may be measured by imaging the white reference standard at different orientations.

Application

Incident light measurement is often employed for augmented reality [1, 7], to ensure that inserted virtual objects exhibit an appearance consistent with the scene's illumination environment. Measurements of real-world lighting have also been utilized in computer graphics applications to give rendered objects a more natural appearance. Applications of light color measurement include evaluation of color constancy algorithms [8]

and spectral reflectance recovery using multiple illumination colors [9].

Definition

Infrared thermal imaging is a technique to generate quantitative radiometric digital images of object scenes recorded in the thermal infrared wavelength range between 0.8 and 15 μm . Besides qualitative visualization, it allows to measure surface temperatures of objects [1–3].

Background

Infrared (IR) radiation was discovered in 1800 by Sir William Herschel while studying radiation from the sun. One hundred years later, Max Planck was the first to correctly describe the underlying laws of thermal radiation quantitatively. Several decades thereafter the first infrared-detecting cameras with cooled semiconductor detectors were developed. While initially developed for military purposes, small portable systems soon became available also for commercial applications, and nowadays they are used extensively by physicists, technicians, engineers, and even science teachers. The enormous progress of microsystem technologies toward the end of the twentieth century resulted in uncooled microbolometer cameras, and the

respective mass production of infrared focal plane array detector arrays led to comparatively low-price cameras. Meanwhile, miniaturized cameras resembling smartphone accessories exist [4], and IR cameras are nowadays already available as high-end consumer products for everyone.

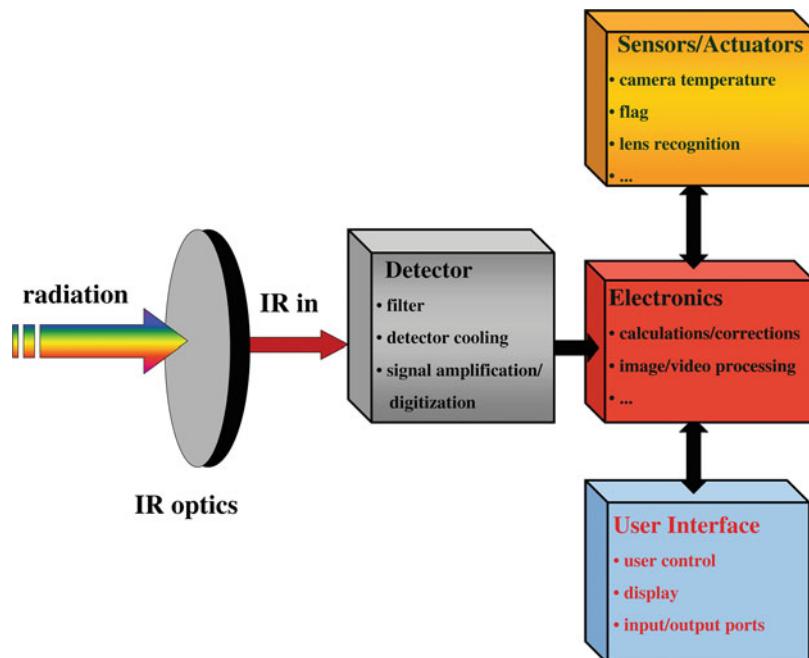

Setup, Components, and Quantitative Imaging

IR cameras operate very similar to any visible light (VIS) camera (Fig. 1) [3]. The electromagnetic radiation from objects passes a lens system and maybe additional optical components before forming an image of the object on a detector, nowadays exclusively a focal plane array (FPA). Subsequently, the information from the individual pixels is gathered by some readout integrated circuit. The camera may – though need not – be operated remotely using a computer interface.

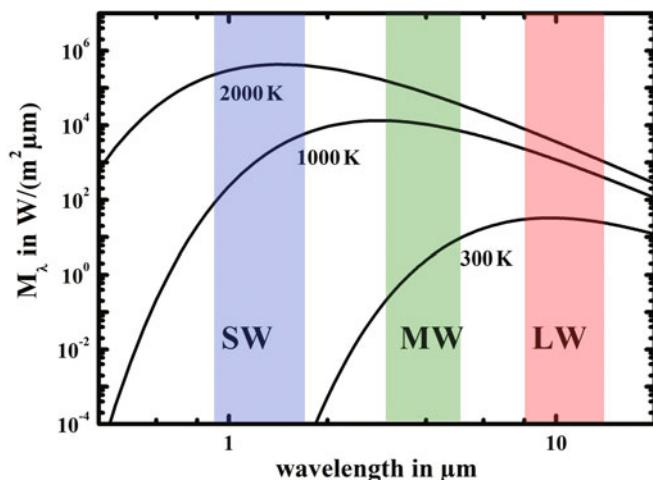

Besides this common basic setup, infrared cameras differ from visual cameras in several aspects. First, the radiation is in the infrared part of the spectrum, typically from $0.8\text{ }\mu\text{m}$ to around

$25\text{ }\mu\text{m}$ wavelength (VIS: $0.4\text{ }\mu\text{m}$ to $0.8\text{ }\mu\text{m}$). Second, this radiation is mostly thermally emitted radiation [3,5,6], whereas visual images typically reflect scenes of scattered light. Third, the optical materials of the lenses, filters, etc. must transmit this radiation and are therefore usually not made from glass but semiconductors. Fourth, the detectors are not silicon based as in VIS cameras but – depending on the used wavelength region – chosen from a wide possible range of materials and techniques including cooled photoelectron as well as uncooled thermal detectors [1–3,5–7]. Infrared detectors are more complex than VIS detectors, and, so far, IR FPA's have much lower pixel numbers than VIS cameras, typically below 1 Mpixel. Fifth, the pixel signals are usually not spectrally filtered and therefore resemble monochrome images. Using image processing, these are then displayed either as gray scale or false color images. Sixth, for quantitative measurements there are several temperature sensors within the camera which together with additional user input (emissivity, ambient temperature, object distance, relative humidity) and some calibration procedure allow to evaluate the signals [3]. Seventh, most IR

Infrared Thermal Imaging, Fig. 1 Block diagram with main IR camera components

Infrared Thermal Imaging, Fig. 2 Black body spectra for three different temperatures. The colored regions indicate the typical wavebands used in IR imaging. Please note the logarithmic scales

cameras come with additional analysis software to evaluate signals quantitatively (e.g., line plots, time series, etc.). The use of the software requires basic knowledge of the underlying physics. As a rule, more or less everybody is able to produce nicely looking false color images, but only the experts know how to correctly interpret them.

Infrared radiation from objects only depends on the temperature of the objects and a material property called emissivity. Objects which emit the maximum possible radiation are black bodies. Their spectrum is defined by Planck's law [1–3, 5, 6], and it only depends on the object temperature. The larger the temperature, the more the spectrum shifts toward shorter wavelengths (see Fig. 2). Most observations are made within the earth atmosphere; therefore certain spectral regions with low atmospheric transmission are not utilized for IR imaging. Mostly three ranges are commercially used, the long-wave (LW: 8–14 μm), mid-wave (MW: 3–5 μm), and short-wave (SW: 0.9–1.7 μm) region [3]. Real objects emit less radiation than black bodies, defined by their emissivity. Any quantitative analysis requires knowledge of the correct emissivity of the objects. Analysis is usually complicated by the fact that every image represents a combination of temperature as well as emissivity contrast.

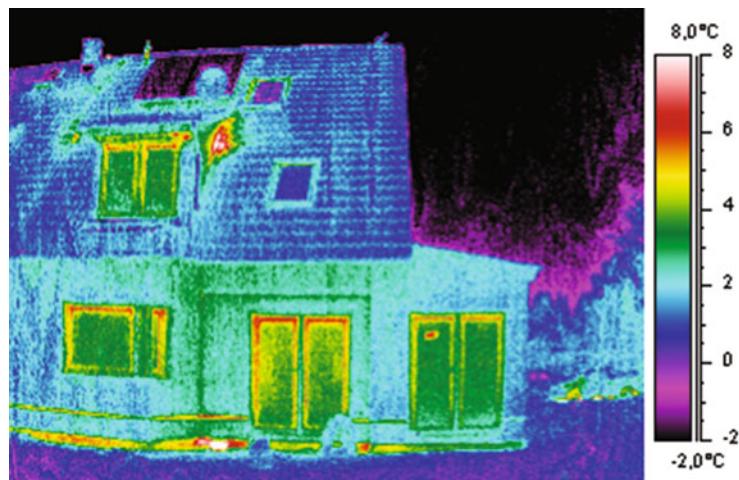

For camera calibration, artificial black bodies of known temperatures are analyzed. Measured objects signals are compared to them with the goal to deduce surface temperatures (assuming

opaque objects). The real problem then is to understand the observed object temperature distributions, i.e., relate them, e.g., to heat transfer processes associated with the objects.

Variety of Systems

Modern IR camera systems differ in many respects, first of all detector type and waveband. Often, an additional VIS camera is included, and both VIS and IR images are recorded simultaneously. The most important characteristic specifications of the cameras [3] are first their ability to spatially resolve objects. This depends on the pixel numbers of the FPAs, the used lens, and the distance between camera and object. Second, the time resolution of the camera is important whenever non-still scenes shall be recorded. Most cameras nowadays allow for 25 fps or 30 fps; however, those with thermal detectors often show cometary tails of moving objects due to the long time constant of the detectors. In contrast, photoelectron detector cameras also allow high-speed IR recordings; they are, however, much more expensive. Third, for quantitative measurements, cameras are specified by their absolute accuracy of measuring temperatures (e.g., 1 to 3 K) and their ability to detect small T differences (typically 20 to 50 mK).

Infrared Thermal Imaging, Fig. 3 IR thermal images of a house for specific temperature span (10 K) and color palette. Emissivity was 0.96, distance 10 m to the nearest wall, outside air temperature 0 °C, inside room temperatures 20 °C. There is an obvious insulation leak close to the dormer window

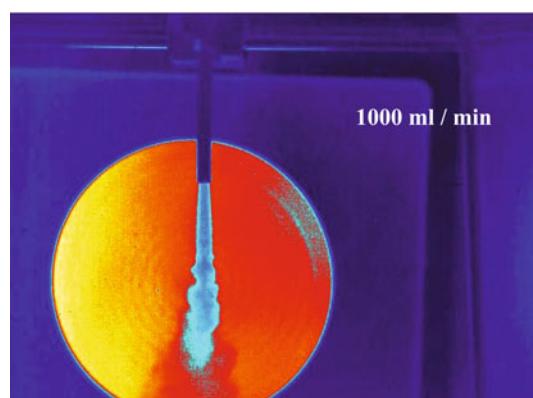

The most common cameras today including the ones available as smartphone accessories are microbolometer LW cameras. Several industrial or scientific applications do, however, require very special conditions which led to the development of specialized IR camera systems, e.g., for nondestructive testing [8, 9] or detection of gases [3].

Applications

Applications of infrared thermal imaging are numerous and growing each year [3]. They range from condition monitoring and predictive maintenance in many industrial fields to building inspections for energy savings (Fig. 3) and gas detection (Fig. 4). In addition, there is growing use in the medical field [10], in sports, the automotive and aerospace industry, surveillance, and even volcanology and visualization of thermal features in nature [11].

Open Problems

The field of IR cameras is constantly developing. Current trends are further miniaturization, which will lead to more qualitatively used and less expensive consumer product cameras. The detector FPA's will be getting larger pixel numbers to enhance spatial resolution. Using two cameras may allow for thermal stereo vision. In addition, multi-waveband cameras are being

Infrared Thermal Imaging, Fig. 4 Raw data of (in this case turbulent) CO₂ flow (1000 ml/min), recorded with a MW camera, uncooled narrow band filter, and background black body at 50 °C. Commercial cameras allow detection of a huge number of volatile organic compounds (VOCs) and many other gaseous inorganic compounds. Gas detection is often qualitative, only

developed which will help to better deal with emissivity uncertainties, in particular of low emissivity materials such as metals.

Disocclusion; Error concealment; Filling in

This contribution is dedicated to the memory of Vicent Caselles, outstanding researcher, exceptional friend.

Definition

Given an image and a region Ω inside it, the inpainting problem consists in modifying the image values of the pixels in Ω so that this region does not stand out with respect to its surroundings. The purpose of inpainting might be to restore damaged portions of an image (e.g., an old photograph where folds and scratches have left image gaps) or to remove unwanted elements present in the image (e.g., a microphone appearing in a film frame). See Fig. 1. The region Ω is always given by the user, so the localization of Ω is not part of the inpainting problem. Almost all inpainting algorithms treat Ω as a hard constraint, whereas some methods allow some relaxing of the boundaries of Ω .

This definition, given for a single-image problem, extends naturally to the multi-image case; therefore, this entry covers both image and video inpainting. What is not however considered in this text is *surface* inpainting (e.g., how to fill holes in 3D scans), although this problem has been addressed in the literature.

Background

The term *inpainting* comes from art restoration, where it is also called *retouching*. Medieval artwork started to be restored as early as the Renaissance, the motives being often as much to bring medieval pictures “up to date” as to fill in any gaps. The need to retouch the image in an unobtrusive way extended naturally from paintings to photography and film. The purposes remained the same: to revert deterioration (e.g., scratches and dust spots in film) or to add or remove elements (e.g., the infamous “airbrushing” of political enemies in Stalin era USSR). In the digital domain, the inpainting problem first appeared under the name “error concealment” in telecommunications, where the need was to fill in image blocks that had been lost during data transmission. One of the first works to address automatic inpainting in a general setting dubbed it “image disocclusion” since it treated the image gap as an

Inpainting, Fig. 1 The inpainting problem. *Left*: original image. *Middle*: inpainting mask Ω , in black. *Right*: an inpainting result. (Figure taken from [20])

occluding object that had to be removed, and the image underneath would be the restoration result. Popular terms used to denote inpainting algorithms are also “image completion” and “image fill-in.”

Application

The extensive literature on digital image inpainting may be roughly grouped into three categories: patch-based, sparse, and PDEs/variational methods.

From Texture Synthesis to Patch-Based Inpainting

Efros and Leung [14] proposed a method that, although initially intended for texture synthesis, has proven most effective for the inpainting problem. The image gap is filled in recursively, inwards from the gap boundary: each “empty” pixel P at the boundary is filled with the value of the pixel Q (lying outside the image gap, that is, Q is a pixel with valid information) such that the neighborhood $\Psi(Q)$ of Q (a square patch centered in Q) is most similar to the (available) neighborhood $\Psi(P)$ of P . Formally, this can be expressed as an optimization problem:

$$\text{Output}(P) = \text{Value}(Q), P \in \Omega, Q \notin \Omega, \quad (1)$$

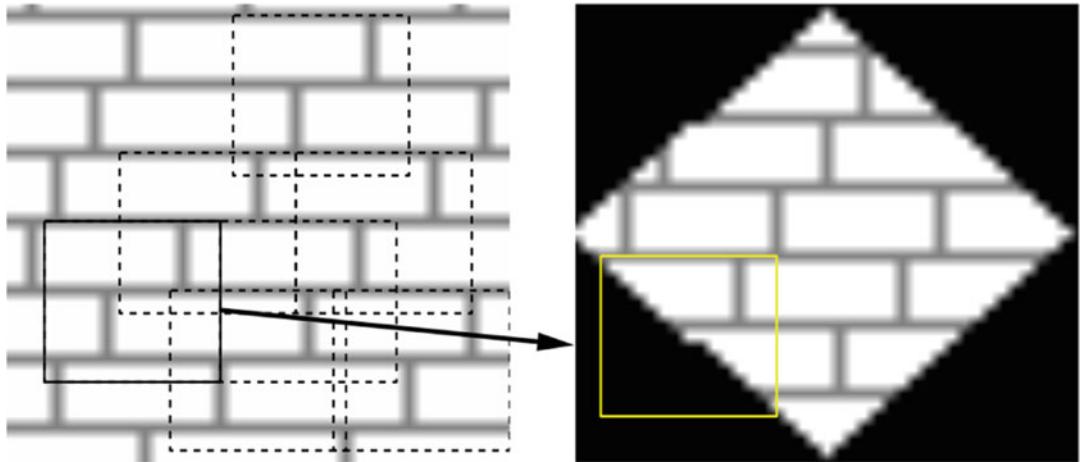

$$Q = \arg \min d(\Psi(P), \Psi(Q)),$$

where $d(\Psi(P), \Psi(Q))$ is the sum of squared differences (SSD) among the patches $\Psi(P)$ and $\Psi(Q)$ (considering only available pixels):

$$d(\Psi_1, \Psi_2) = \sum_i \sum_j \left| \Psi_1(i, j) - \Psi_2(i, j) \right|^2, \quad (2)$$

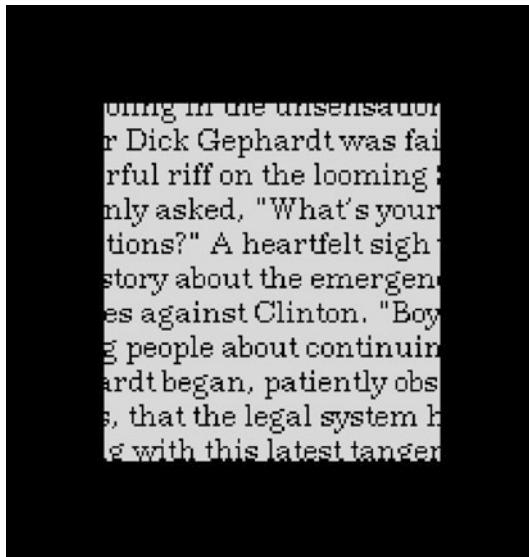

and the indices i, j span the extent of the patches (e.g., if Ψ is an 11×11 patch, then $0 \leq i, j \leq 10$). Once P is filled in, the algorithm marches on to the next pixel at the boundary of the gap, never going back to P (whose value is, therefore, not altered again). See Fig. 2 for an overview of the algorithm and Fig. 3 for an example of the outputs it can achieve. The results are really impressive for a wide range of images. The main shortcomings of this algorithm are its computational cost, the selection of the neighborhood size (which in the original paper is a global user-selected parameter but which should change locally, depending on image content), the filling order (which may create unconnected boundaries for some objects), and the fact that it cannot deal well with image perspective (it was intended to synthesize frontal textures; hence, neighborhoods are compared always with the same size and orientation). Also, results are poor if the image gap is very large and disperse (e.g., an image where 80% of the pixels have been lost due to random *salt and pepper noise*).

Criminisi et al. [12] improved on this work in two aspects. Firstly, they changed the filling order from the original “onion-peel” fashion to a priority scheme where empty pixels at the edge of an image object have higher priority than empty pixels on flat regions. Thus, they are able to correctly inpaint straight object boundaries which could have otherwise ended up disconnected with the original formulation. See Fig. 4. Secondly,

Inpainting, Fig. 2 Efros and Leung's algorithm overview. (Figure taken from [14]). Given a sample texture image (*left*), a new image is being synthesized one pixel at a time (*right*). To synthesize a pixel, the algorithm

first finds all neighborhoods in the sample image (boxes on the *left*) that are similar to the pixels neighborhood (box on the *right*) and then randomly chooses one neighborhood and takes its *center* to be the newly synthesized pixel

During the unsensational trial of Dick Gephardt was failed to ruffle the loomingly asked, "What's your fations?" A heartfelt sigh story about the emergence of new forces against Clinton. "Boystong people about continuing" Gephardt began, patiently observing that the legal system had come with this latest tangent. The result is a restored version of the text where the black mask has been removed, revealing the original text.

Inpainting, Fig. 3 *Left:* original image, inpainting mask Ω in black. *Right:* inpainting result obtained with Efros and Leung's algorithm. (Images taken from their paper [14])

they copy entire patches instead of single pixels, so this method is considerably faster. Several shortcomings remain, though, like the inability to deal with perspective and the need to manually select the neighborhood size (here, there are two sizes to set, one for the patch to compare with and another for the patch to copy from). Also, objects with curved boundaries may not be inpainted correctly.

Ashikhmin [2] contributed as well to improve on the original method of Efros and Leung [14]. With the idea of reducing the computational cost of the procedure, he proposed to look for the best candidate Q to copy its value to the empty pixel P not searching the whole image but only searching among the candidates of the neighbors of P which have already been inpainted. See Fig. 5. The speedup achieved with this simple

Inpainting, Fig. 4 *Left:* original image. *Right:* inpainting result obtained with the algorithm of Criminisi et al. [12]. (Images taken from their paper)

technique is considerable, and also there is a very positive effect regarding the visual quality of the output. Other methods reduce the search space and computational cost involved in the candidate patch search by organizing image patches in tree structures, reducing the dimensionality of the patches with techniques like principal component analysis (PCA), or using randomized approaches.

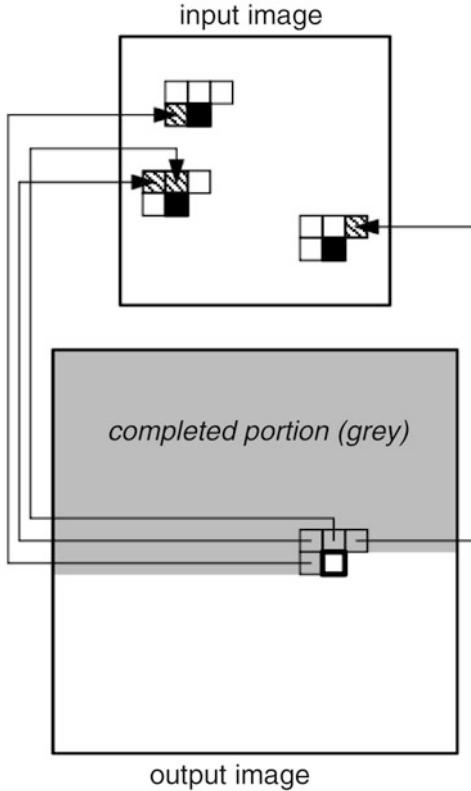

While most image inpainting methods attempt to be fully automatic (aside from the manual setting of some parameters), there are user-assisted methods that provide remarkable results with just a little input from the user. In the work by Sun et al. [27], the user must specify curves in the unknown region, curves corresponding to relevant object boundaries. Patch synthesis is performed along these curves inside the image gap, by copying from patches that lie on the segments of these curves which are outside the gap, in the “known” region. Once these curves are completed, in a process which the authors call *structure propagation*, the remaining empty pixels are inpainted using a technique like the

one by Ashikhmin [2] with priorities as in Criminisi et al. [12]. Barnes et al. [5] accelerate this method and make it interactive, by employing randomized searches and combining into one step the structure propagation and texture synthesis processes of Sun et al. [27].

The Role of Sparsity

After the introduction of patch-based methods for texture synthesis by Efros and Leung [14], and image inpainting by Criminisi et al. [12], it became clear that the patches of an image provide a good dictionary to express other parts of the image. This idea has been successfully applied to other areas of image processing, for example, denoising and segmentation.

More general sparse image representations using dictionaries have proven their efficiency in the context of inpainting. For instance, using overcomplete dictionaries adapted to the representation of image geometry and texture, Elad et al. [15] proposed an image decomposition model with sparse coefficients for the geometry

Inpainting. Fig. 5 Ashikhmin’s texture synthesis method. (Figure taken from [2]). Each pixel in the current L-shaped neighborhood generates a shifted candidate pixel (*black*) according to its original position (*hatched*) in the input texture. The best pixel is chosen among these candidates only. Several different pixels in the current neighborhood can generate the same candidate

and texture components of the image and showed that the model can be easily adapted for image inpainting. A further description of this model follows.

Let u be an image represented as a vector in \mathbb{R}^N . Let the matrices D_g and D_t of sizes $N \times k_g$ and $N \times k_t$ represent two dictionaries adapted to geometry and texture, respectively. If $\alpha_g \in \mathbb{R}^{k_g}$ and $\alpha_t \in \mathbb{R}^{k_t}$ represent the geometry and texture coefficients, then $u = D_g \alpha_g + D_t \alpha_t$ represents the image decomposition using the dictionaries collected in D_g and D_t . A sparse image representation is obtained by minimizing

$$\min_{(\alpha_g, \alpha_t) : u = D_g \alpha_g + D_t \alpha_t} \|\alpha_g\|_p + \|\alpha_t\|_p, \quad (3)$$

where $p = 0, 1$. Although the case $p = 0$ represents the sparseness measure (i.e., the number of nonzero coordinates), it leads to a nonconvex optimization problem whose minimization is more complex. The case $p = 1$ yields a convex and tractable optimization problem leading also to sparseness. Introducing the constraint by penalization (thus, in practice, relaxing it) and regularizing the geometric part of the decomposition with a total variation semi-norm penalization, Elad et al. [15] propose the variational model:

$$\begin{aligned} \min_{(\alpha_g, \alpha_t)} & \|\alpha_g\|_1 + \|\alpha_t\|_1 + \lambda \|u - D_g \alpha_g - D_t \alpha_t\|_2^2 \\ & + \gamma TV(D_g \alpha_g), \end{aligned} \quad (4)$$

where TV denotes the total variation, $\lambda, \gamma > 0$. This model can be easily adapted to a model for image inpainting. Observe that $u - D_g \alpha_g - D_t \alpha_t$ can be interpreted as the noise component of the image and λ is a penalization parameter that depends inversely on the noise power. Then the inpainting mask can be interpreted as a region where the noise is very large (infinite). Thus, if $M = 0$ and $= 1$ identify the inpainting mask and the known part of the image, respectively, then the extension of (4) to inpainting can be written as

$$\begin{aligned} \min_{(\alpha_g, \alpha_t)} & \|\alpha_g\|_1 + \|\alpha_t\|_1 \\ & + \lambda \|M(u - D_g \alpha_g - D_t \alpha_t)\|_2^2 \\ & + \gamma TV(D_g \alpha_g). \end{aligned} \quad (5)$$

Writing the energy in (5) using $u_g := D_g u$, $u_t := D_t u$ as unknown variables, it can be observed that $\alpha_g = D_g^+ u_g + r_g$, $\alpha_t = D_t^+ u_t + r_t$, where D_g^+, D_t^+ denote the corresponding pseudoinverse matrices and r_g, r_t are in the null spaces of D_g and D_t , respectively. Assuming for simplicity, as in Elad et al. [15], that $r_g = 0$, $r_t = 0$, the model (5) can be written as

$$\min_{(\alpha_g, \alpha_t)} \|D_g^+ u_g\|_1 + \|D_t^+ u_t\|_1$$

$$+ \lambda \|M(u - u_g - u_t)\|_2^2 + \gamma TV(u_g). \quad (6)$$

This simplified model is justified in Elad et al. [15] by several reasons: it is an upper bound for (5), it is easier to solve, it provides good results, it has a Bayesian interpretation, and it is equivalent to (5) if D_g and D_t are non-singular or when using the ℓ^2 norm in place of the ℓ^1 norm. The model has nice features since it permits to use adapted dictionaries for geometry and texture and treats the inpainting as missing samples, and the sparsity model is included with ℓ^1 norms that are easy to solve.

This framework has been adapted to the use of dictionaries of patches and has been extended in several directions like image denoising, filling in missing pixels (Aharon et al. [1]), color image denoising, demosaicing, and inpainting of small holes (Mairal et al. [21] and further extended to deal with multiscale dictionaries and to cover the case of video sequences in Mairal et al. [22]. To give a brief review of this model, some notation is required. Image patches are squares of size $n = \sqrt{n} \times \sqrt{n}$. Let D be a dictionary of patches represented by a matrix of size $n \times k$, where the elements of the dictionary are the columns of D . If $\alpha \in \mathbb{R}^k$ is a vector of coefficients, then $D\alpha$ represents the patch obtained by linear combination of the columns of D . Given an image $v(i, j)$, $i, j \in \{1, \dots, N\}$, the purpose is to find a dictionary \hat{D} , an image \hat{u} , and coefficients $\hat{\alpha} = \{\hat{\alpha}_{i,j} \in \mathbb{R}^k : i, j \in \{1, \dots, N\}\}$ which minimize the energy

$$\begin{aligned} & \min_{(\alpha, D, u)} \lambda \|v - u\|_2 + \sum_{i,j=1}^N \mu_{i,j} \|\alpha_{i,j}\|_0 \\ & + \sum_{i,j=1}^N \|D\alpha_{i,j} - R_{i,j}u\|_2, \end{aligned} \quad (7)$$

where $R_{i,j}u$ denotes the patch of u centered at (i, j) (dismissing boundary effects), and $\mu_{i,j}$ are positive weights. The solution of the nonconvex problem (7) is obtained using an alternate minimization: a sparse coding step where one computes $\alpha_{i,j}$ knowing the dictionary D for all i, j , a

dictionary update using a sequence of one rank approximation problem to update each column of D (Aharon et al. [1]), and a final reconstruction step given by the solution of

$$\min_u \lambda \|v - u\|_2 + \sum_{i,j=1}^N \|\hat{D}\alpha_{i,j} - R_{i,j}u\|_2. \quad (8)$$

Again, the inpainting problem can be considered as a case of nonhomogeneous noise. Defining for each pixel (i, j) a coefficient $\beta_{i,j}$ inversely proportional to the noise variance, a value of $\beta_{i,j} = 0$ may be taken for each pixel in the inpainting mask. Then the inpainting problem can be formulated as

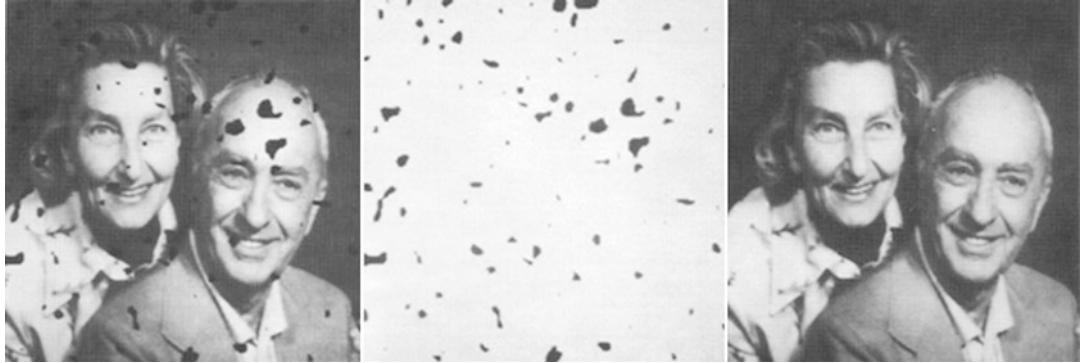

$$\begin{aligned} & \min_{(\alpha, D, u)} \lambda \|\beta \otimes (v - u)\|_2 + \sum_{i,j=1}^N \mu_{i,j} \|\alpha_{i,j}\|_0 \\ & + \sum_{i,j=1}^N \|(R_{i,j}\beta) \otimes (D\alpha_{i,j} - R_{i,j}u)\|_2, \end{aligned} \quad (9)$$

where $\beta = (\beta_{i,j})_{i,j=1}^N$ and \otimes denotes the element-wise multiplication between two vectors.

With suitable adaptations, this model has been applied to inpainting (of relatively small holes), to interpolation from sparse irregular samples and super-resolution, to image denoising, to demosaicing of color images, and to video denoising and inpainting, obtaining excellent results; see Mairal et al. [22].

PDEs and Variational Approaches

All the methods mentioned so far are based on the same principle: a missing/corrupted part of an image can be well synthetized by suitably sampling and copying uncorrupted patches (taken either from the image itself or built from a dictionary). A very different point of view underlies many contributions involving either a variational principle, through a minimization process, or a (non necessarily variational) partial differential equation (PDE).

Inpainting, Fig. 6 An inpainting experiment taken from Ogden et al. [24]. The method uses a Gaussian pyramid and a series of linear interpolations, downsampling, and upsampling

An early interpolation method that applies for inpainting is due to Ogden et al. [24]. Starting from an initial image, a Gaussian filtering is built by iterated convolution and subsampling. Then, a given inpainting domain can be filled in by successive linear interpolations, downsampling, and upsampling at different levels of the Gaussian pyramid. The efficiency of such approach is illustrated in Fig. 6.

Masnou and Morel proposed in [23] to interpolate a gray-valued image by extending its isophotes (the lines of constant intensity) in the inpainting domain. This approach is very much in the spirit of early works by Kanizsa, Ullman, Horn, Mumford, and Nitzberg to model the ability of the visual system to complete edges in an occlusion or visual illusion context. This is illustrated in Fig. 7. The general completion process involves complicated phenomena that cannot be easily and univocally modeled. However, experimental results show that, in simple occlusion situations, it is reasonable to argue that the brain extrapolates broken edges using elastica-type curves, that is, curves that join two given points with prescribed tangents at these points, a total length lower than a given L , and minimize the Euler elastica energy $\int |k(s)|^2 ds$, with s the curve arc length and k the curvature.

The model by Masnou and Morel [23] generalizes this principle to the isophotes of a gray-valued image. More precisely, denoting $\tilde{\Omega}$ a domain slightly larger than Ω , it is proposed in [23] to extrapolate the isophotes of an image

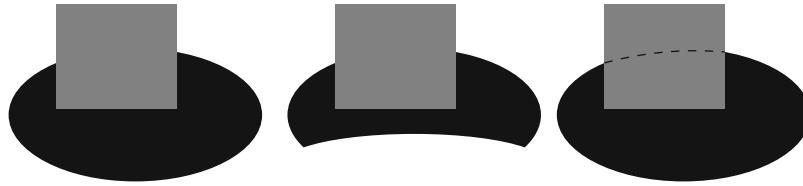

u , known outside Ω and valued in $[m, M]$, by a collection of curves $\{\gamma_t\}_{t \in [m, M]}$ with no mutual crossings, that coincide with the isophotes of u on $\tilde{\Omega} \setminus \Omega$ and that minimize the energy

$$\int_m^M \int_{\gamma_t} (\alpha + \beta |k_{\gamma_t}|^p) ds dt. \quad (10)$$

Here α, β are two context-dependent parameters. This energy penalizes a generalized Euler's elastica energy, with curvature to the power $p > 1$ instead of 2, of all extrapolation curves γ_t , $t \in [m, M]$.

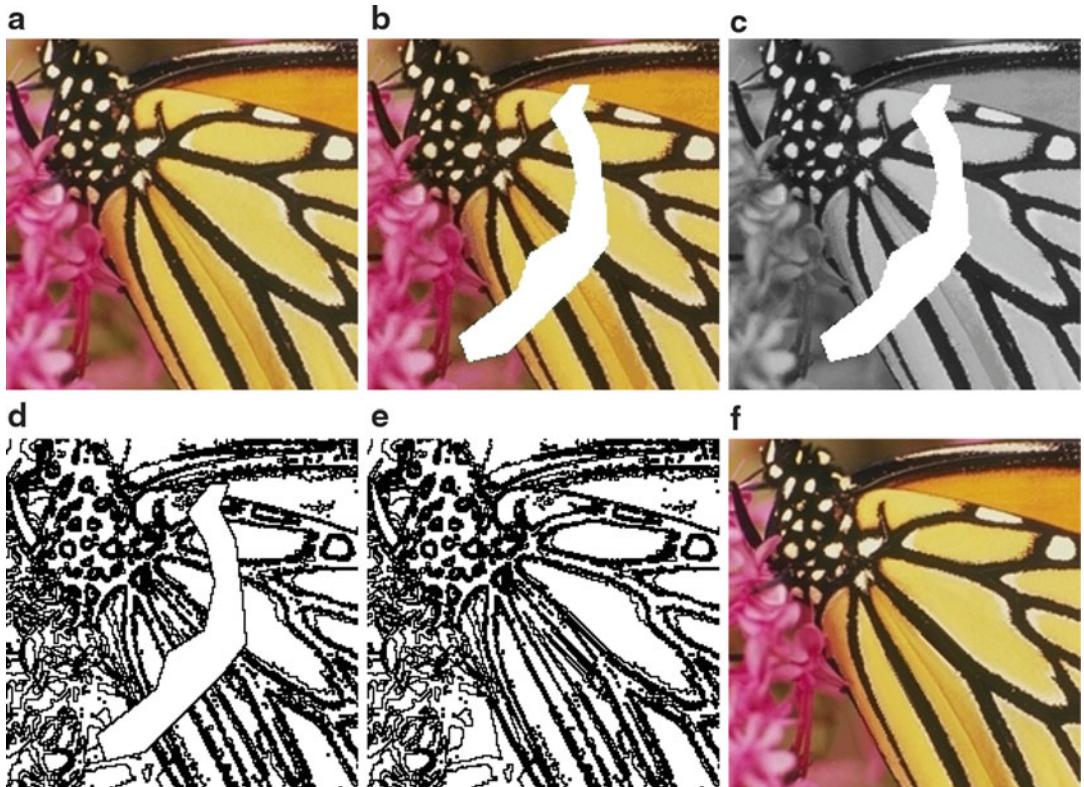

An inpainting algorithm, based on the minimization of (10) in the case $p = 1$, is proposed by Masnou and Morel in [23]. A globally minimal solution is computed using a dynamic programming approach that reduces the algorithmical complexity. The algorithm handles only simply connected domains, that is, those with no holes. In order to deal with color images, RGB images are turned into a luma/chrominance representation, for example, YCrCb, or Lab, and each channel is processed independently. The reconstruction process is illustrated in Fig. 8.

The word *inpainting*, in the image processing context, has been coined first by Bertalmío, Sapiro, Caselles, and Ballester in [6], where a PDE model is proposed in the very spirit of real paintings restoration. More precisely, u being a gray-valued image to be inpainted in Ω , a time-stepping method for the transport-like equation

Inpainting, Fig. 7 Amodal completion: the visual system automatically completes the broken edge in the *left* figure. The *middle* figure illustrates that, here, no global symmetry process is involved: in both figures, the same

edge is synthesized. In such simple situation, the interpolated curve can be modeled as Euler's elastica, that is, a curve with clamped points and tangents at its extremities and with minimal oscillations

Inpainting, Fig. 8 (a) is the original image and (b) the image with occlusions in *white*. The luminance channel is shown in figure (c). A few isophotes are drawn in figure (d), and their reconstruction by the algorithm of Masnou

and Morel [23] is given in figure (e). Applying the same method to the luminance, hue, and saturation channels yields the final result of figure (f)

$$\begin{aligned} u_t &= \nabla^\perp u \cdot \nabla \Delta u \text{ in } \Omega, \\ u &\text{ given in } \Omega^c \end{aligned} \quad (11)$$

is combined with anisotropic diffusion steps that are interleaved for stabilization, using the following diffusion model:

$$u_t = \varphi_\epsilon(x) |\nabla u| \nabla \cdot \frac{\nabla u}{|\nabla u|}, \quad (12)$$

where φ_ϵ is a smooth cutoff function that forces the equation to act only in Ω , and $\nabla \cdot (\nabla u / |\nabla u|)$ is the curvature along isophotes. This diffusion equation, which has been widely used for denoising an image while preserving its edges, compensates any shock possibly created by the transport-like equation. What is the meaning of Eq. (11)? Following Bertalmío et al. [6], Δu is a measure of image smoothness, and stationary points for

the equation are images for which Δu is constant along the isophotes induced by the vector field $\nabla^\perp \Delta u$. Equation (11) is not explicitly a transport equation for Δu , but, in the equivalent form,

$$u_t = -\nabla^\perp \Delta u \cdot \nabla u, \quad (13)$$

it is a transport equation for u being convected by the field $\nabla^\perp \Delta u$. Following Bornemann and März [9], this field is in the direction of the level lines of Δu , which are related to the Marr-Hildreth edges. Indeed, the zero crossings of (a convoluted version of) Δu are the classical characterization of edges in the celebrated model of Marr and Hildreth. In other words, as in the real paintings restoration, the approach of Bertalmío et al. [6] consists in conveying the image intensities along the direction of the edges, from the boundary of the inpainting domain Ω toward the interior. The efficiency of such approach is illustrated in Fig. 9. From a numerical viewpoint, the transport equation and the anisotropic diffusion can be implemented with classical finite difference schemes. For color images, the coupled system can be applied independently to each channel of any classical luma/chrominance representation. There is no restriction on the topology of the inpainting domain.

Another perspective on this model is provided by Bertalmío, Bertozzi, and Sapiro in [7], where connections with the classical Navier-Stokes equation of fluid dynamics are shown. Indeed, the steady-state equation of Bertalmío et al. [6],

$$\nabla^\perp u \cdot \nabla \Delta u = 0,$$

is exactly the equation satisfied by steady-state inviscid flows in the two-dimensional incompressible Navier-Stokes model. Although the anisotropic diffusion equation (12) is not the exact counterpart of the viscous diffusion term used in the Navier-Stokes model for incompressible and Newtonian flows, a lot of the numerical knowledge on fluid mechanics seems to be adaptable to design stable and efficient schemes for inpainting. Results in this direction are shown in Bertalmío et al. [7].

Chan and Shen propose in [10] a denoising/inpainting first-order model based on the joint minimization of a quadratic fidelity term outside Ω and a total variation criterion in Ω , that is, the joint energy

$$\int_A |\nabla u| dx + \frac{\lambda}{2} \int_\Omega |u - u_0|^2 dx,$$

with $A \supset \Omega$ the image domain and λ a Lagrange multiplier. The existence of solutions to this problem follows easily from the properties of functions of bounded variation. As for the implementation, Chan and Shen look for critical points of the energy using a Gauss-Jacobi iteration scheme for the linear system associated to an approximation of the Euler-Lagrange equation by finite differences. More recent approaches to the minimization of total variation with subpixel accuracy should nowadays be preferred. From the phenomenological point of view, the model of Chan and Shen [10] yields inpainting candidates with the smallest possible isophotes. It is therefore more suitable for thin or sparse domains. An illustration of the model's performances is given in Fig. 10.

Turning back to the criterion (10), a similar penalization on $\tilde{\Omega}$ of both the length and the curvature of all isophotes of an image u yields two equivalent forms, in the case where u is smooth enough (see Masnou and Morel [23]):

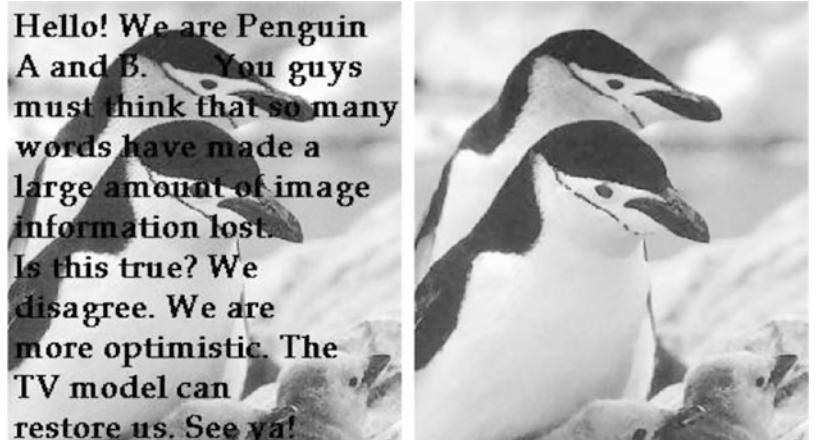

$$\begin{aligned} & \int_{-\infty}^{+\infty} \int_{\{u=t\} \cap \tilde{\Omega}} (\alpha + \beta |k|^p) ds dt \\ &= \int_{\tilde{\Omega}} |\nabla u| \left(\alpha + \beta \left| \nabla \cdot \frac{\nabla u}{|\nabla u|} \right|^p \right) dx. \end{aligned} \quad (14)$$

There have been various contributions to the numerical approximation of critical points for this criterion. A fourth-order time-stepping method is proposed by Chan et al. in [11] based on the approximation of the Euler-Lagrange equation, for the case $p = 2$, using upwind finite differences and a min-mod formula for estimating the curvature. Such high-order evolution method suffers from well-known stability and convergence issues that are difficult to handle.

Inpainting, Fig. 9 An experiment taken from Bertalmío et al. [6]. *Left*: original image. *Middle*: a user-defined mask. *Right*: the result with the algorithm of [6]

Inpainting, Fig. 10 An experiment taken from Chan and Shen [10]. *Left*: original image. *Right*: after denoising and removal of text

A model, slightly different from (14), is tackled by Ballester et al. in [4] using a relaxation approach. The key idea is to replace the second-order term $\nabla \cdot \frac{\nabla u}{|\nabla u|}$ with a first-order term, depending on an auxiliary variable. More precisely, Ballester et al. study in [4] the minimization of

$$\int_{\tilde{\Omega}} |\nabla \cdot \theta|^p (a + b|\nabla G * u|) dx \\ + \alpha \int_{\tilde{\Omega}} (|\nabla u| - \theta \cdot \nabla u) dx,$$

under the constraint that θ is a vector field with subunit modulus and prescribed normal component on the boundary of $\tilde{\Omega}$, and u takes values in the same range as in Ω^c . Clearly, θ plays the role of $\nabla u / |\nabla u|$, but the new criterion is much less singular. As for G , it is a regularizing kernel introduced for technical reasons in order to ensure the existence of a minimizing couple (u, θ) . The main difference between the new relaxed criterion and (14), besides singularity, is the term $\int_{\tilde{\Omega}} |\nabla \cdot \theta|^p$ which is more restrictive, despite the relaxation, than $\int_{\tilde{\Omega}} |\nabla u| |\nabla \cdot \frac{\nabla u}{|\nabla u|}|^p dx$. However, the new model has a nice property: a gradient descent with respect to

Inpainting, Fig. 11 Two inpainting results obtained with the model proposed by Ballester et al. [4]. Observe in particular how curved edges are restored

(u, θ) can be easily computed and yields two coupled second-order equations whose numerical approximation is standard. Results obtained with this model are shown in Fig. 11.

The Mumford-Shah-Euler model by Esedoglu and Shen [16] is also variational. It combines the celebrated Mumford-Shah segmentation model for images and the Euler's elastica model for curves. Being u_0 the original image defined on a domain A , and $\Omega \subset A$ the inpainting domain, Esedoglu and Shen propose to find a piecewise weakly smooth function u , that is a function with integrable squared gradient out of a discontinuity set $K \subset A$, that minimizes the criterion

$$\int_{A \setminus \Omega} \lambda \|u - u_0\|^2 dx + \int_{A \setminus K} \gamma |\nabla u|^2 dx + \int_K (\alpha + \beta k^2) d s,$$

where $\alpha, \beta, \gamma, \lambda$ are positive parameters. The resulting image is not only reconstructed in the inpainting domain Ω , but also segmented all over A since the original image is not imposed as a hard constraint.

Two numerical approaches to the minimization of this model are discussed in Esedoglu and

Shen [16]: first, a level set approach based on the representation of K as the zero-level set of a sequence of smooth functions that concentrate, and the explicit derivation, using finite differences, of the Euler-Lagrange equations associated with the criterion; second, a Γ -convergence approach based on a result originally conjectured by De Giorgi and recently proved by Röger and Schätzle in dimensions 2, 3. In both cases, the final system of discrete equations is of order four, facing again difficult issues of convergence and stability.

More recently, following the work of Grzibovskis and Heintz on the Willmore flow, Esedoglu et al. [17] have addressed the numerical flow associated with the Mumford-Shah-Euler model using a promising convolution/thresholding method that is much easier to handle than the previous approaches.

Tschumperlé proposes in [28] an efficient second-order anisotropic diffusion model for multivalued image regularization and inpainting. Given a \mathbb{R}^N -valued image u known outside Ω , and starting from an initial rough inpainting obtained by straightforward advection of boundary values, the pixels in the inpainting domain are iteratively updated according to a finite difference

approximation to the equations

$$\frac{\partial u_i}{\partial t} = \text{trace} \left(T \nabla^2 u_i \right), \quad i \in \{1, \dots, N\}.$$

Here, T is the tensor field defined as

$$T = \frac{1}{(1 + \lambda_{\min} + \lambda_{\max})^{\alpha_1}} v_{\min} \otimes v_{\min} \\ + \frac{1}{(1 + \lambda_{\min} + \lambda_{\max})^{\alpha_2}} v_{\max} \otimes v_{\max},$$

with $0 < \alpha_1 \ll \alpha_2$, and $\lambda_{\min}, \lambda_{\max}, v_{\min}, v_{\max}$ are the eigenvalues and eigenvectors, respectively, of $G_\sigma * \sum_{i=1}^N \nabla u_i \otimes \nabla u_i$, being G_σ a smoothing kernel and $\sum_{i=1}^N \nabla u_i \otimes \nabla u_i$ the classical structure tensor, which is known for representing well the local geometry of u . Figure 12 reproduces an experiment taken from Tschumperlé [28].

The approach of Auroux and Masmoudi in [3] uses the PDE techniques that have been developed for the inverse conductivity problem in the context of crack detection. The link with inpainting is the following: missing edges are modeled as cracks, and the image is assumed to be smooth out of these cracks. Given a crack, two inpainting candidates can be obtained as the solutions of the Laplace equation with Neumann condition along the crack and either a Dirichlet or a Neumann condition on the domain's boundary. The optimal cracks are those for which the two candidates are the most similar in quadratic norm, and they can be found through topological analysis, that is, they correspond to the set of points where putting a crack mostly decreases the quadratic difference. Both the localization of the cracks and the associated piecewise smooth inpainting solutions can be found using fast and simple finite difference schemes.

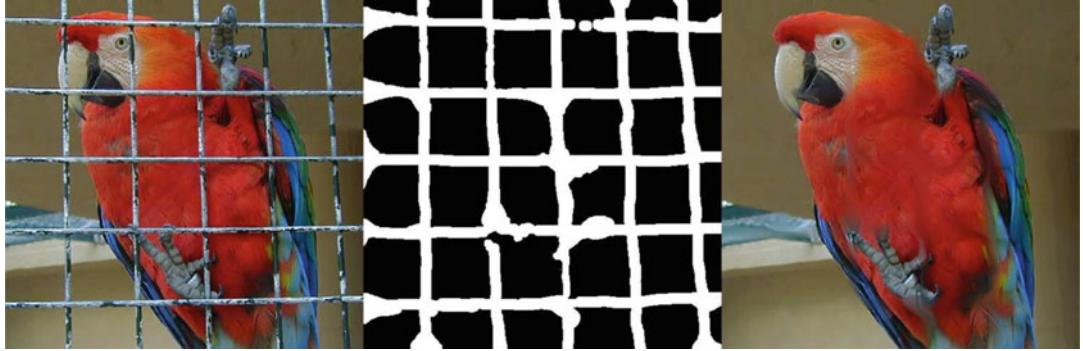

Finally, Bornemann and März propose in [9] a first-order model to advect the image information along the integral curves of a coherence vector field that extends in Ω the dominant directions of the image gradient. This coherence field is explicitly defined, at every point, as the normalized eigenvector to the minimal eigenvalue of a smoothed structure tensor whose computation carefully avoids boundary biases in the vicinity of

$\partial\Omega$. Denoting c the coherence field, Bornemann and März show that the equation $c \cdot \nabla u = 0$ with Dirichlet boundary constraint can be obtained as the vanishing viscosity limit of an efficient fast-marching scheme: the pixels in Ω are synthesized one at a time, according to their distance to the boundary. The new value at a pixel p is a linear combination of both known and previously generated values in a neighborhood of p . The key ingredient of the method is the explicit definition of the linear weights according to the coherence field c . Although the Bornemann-März model requires a careful tune of four parameters, it is much faster than the PDE approaches mentioned so far and performs very well, as illustrated in Fig. 13.

Combining and Extending PDEs and Patch Models

In general, most PDE/variational methods that have been presented so far perform well for inpainting either thin or sparsely distributed domains. However, there is a common drawback to all these methods: they are unable to restore texture properly, and this is particularly visible on large inpainting domains, for instance, in the inpainting result of Fig. 12 where the diffusion method is not able to recover the parrot's texture. On the other hand, patch-based methods are not able to handle sparse inpainting domains like in Fig. 14, where no valid squared patch can be found that does not reduce to a point. On the contrary, most PDE/variational methods remain applicable in such situation, like in Fig. 14 where the model proposed by Masnou and Morel [23] yields the inpainting result. Obviously, some geometric information can be recovered, but no texture.

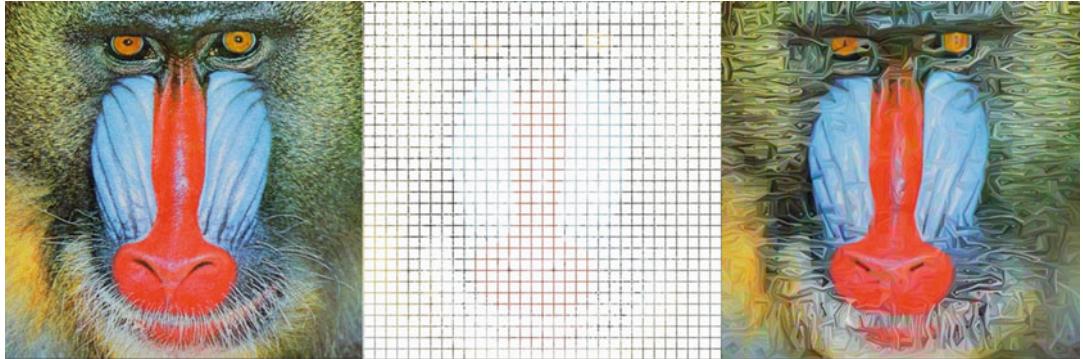

There have been several attempts to explicitly combine PDEs and patch-based methods in order to handle properly both texture and geometric structures. The contribution of Criminisi et al. [12] was mentioned already. The work of Bertalmío et al. [8] uses an additive decomposition of the image to be inpainted into a geometric component that contains all edges information, and a texture component. Then the texture image is restored using the Efros and Leung's

Inpainting, Fig. 12 An inpainting experiment (the *middle* image is the mask defined by the user). (Taken from Tschumperlé [28])

Inpainting, Fig. 13 An inpainting experiment taken from Bornemann and März [9], with a reported computation time of 0.4 s

Inpainting, Fig. 14 A picture of a mandrill, the same picture after removal of 15×15 squares (more than 87% of the pixels are removed), and the reconstruction with the

method introduced by Masnou and Morel [23] using only the one-pixel-wide information at the squares' boundaries

algorithm of [14], while the geometric image is inpainted following the method proposed in Bertalmío et al. [6] (several subsequent works have proposed other methods for the individual reconstruction of each component). The final image is obtained by addition of the restored texture and geometric components. In a few situations where the additive decomposition makes

sense, this approach does indeed improve the result and extends the applications domain of inpainting.

In Komodakis and Tziritas [20], the authors combine variational and patch-based strategies by defining an inpainting energy over a graph whose nodes are the centers of patches over the image. The inpainting energy has two terms,

one being a texture synthesis term and the other measuring the similarity of the overlapping area of two neighboring patches (centered on nodes which are neighbors in the graph). By minimizing this energy with belief propagation, a label is assigned to each node, which amounts to copying the patch corresponding to the label over the position of the node. The results are very good on a variety of different images (e.g., Fig. 1), and the method is fast. Some potential issues are the following: there is no assurance that the iterative process converges to a global minimum, and visual artifacts may appear since the method uses a fixed grid and entire patches are copied for each pixel of the mask.

The work by Drori et al. in [13] does not involve any explicit geometry/texture decomposition, but the search for similar neighborhoods is guided by a prior rough estimate of the inpainted values using a multiscale sampling and convolution strategy, in the very spirit of Ogden et al. [24]. In addition, in contrast with many patch-based methods, the dictionary of valid patches is enriched using rotations, rescalings, and reflections. An example extracted from Drori et al. [13] is shown in Fig. 15.

Beyond Single-Image Inpainting

All the methods mentioned above involve just a single image. For the multi-image case, there are two possible scenarios: video inpainting and inpainting a single image using information from several images.

Basic methods for video inpainting for data transmission (where the problem is known as “error concealment” and involves restoring missing image blocks) and for film restoration applications (dealing with image gaps produced by dust, scratches, or the abrasion of the material) assume that the missing data changes location in correlative frames and therefore use motion estimation to copy information along pixel trajectories. A particular difficulty in video inpainting for film restoration is that, for good visual quality of the outputs, the detection of the gap and its filling in are to be tackled jointly and in a way which is robust to noise, usually employing prob-

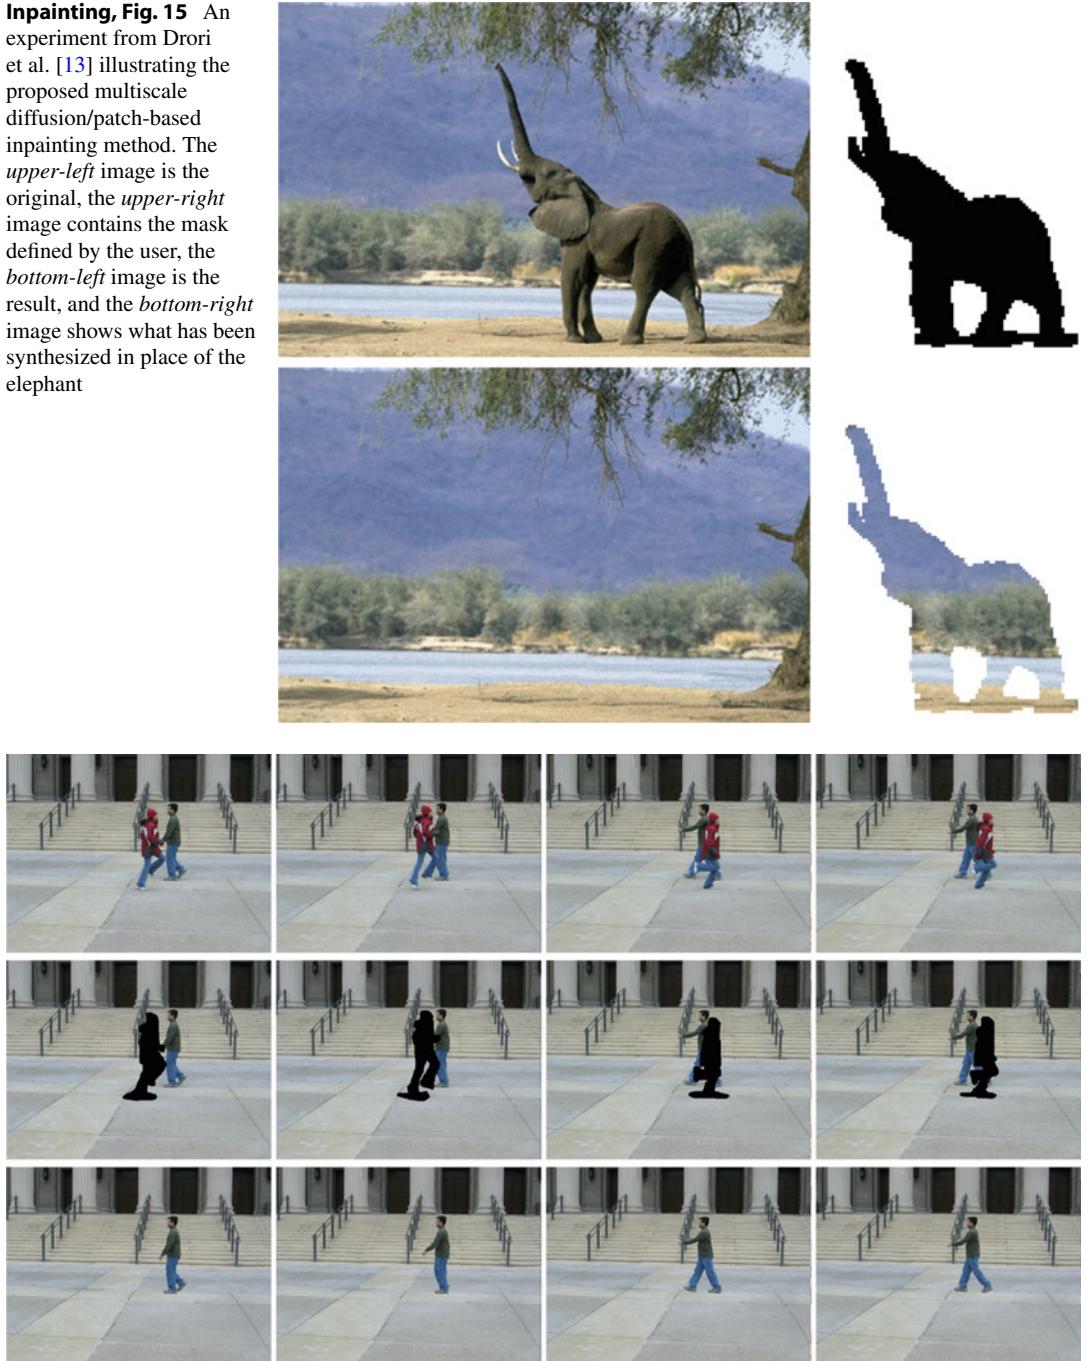

abilistic models in a Bayesian framework; see, for example, the book by Kokaram [19].

Wexler et al. [29] propose a video inpainting algorithm that extends to space-time the technique of Efros and Leung [14] and combines it with the idea of coherence among neighbors developed by Ashikhmin [2]. First, for each empty pixel P , they consider a space-time cube centered in P , compare it with all possible cubes in the video, find the most similar, and keep its center pixel Q , which will be the correspondent of P . For each cube the information considered and compared is not only color but also motion vectors. Then, instead of copying the value of Q to P , they copy to P the average of all the values of the shifted correspondents of the neighbors of P : for instance, if R is at the *right* of P , and S is the correspondent of R , then the pixel to the *left* of S will be involved in the average to fill in P . This is based on the idea by Ashikhmin [2], see Fig. 5. The shortcomings of this video inpainting method are that the results present significant blur (due to the averaging), it seems to be limited only to static-camera scenarios (probably due to the simple motion estimation procedure involved) and periodic motion without change of scale, and the computational cost is quite high (due to the comparison of 3D blocks).

Shiratori et al. [26] perform video inpainting by firstly inpainting the motion field with a patch-based technique like that of Efros and Leung [14] and then propagating the colors along the (inpainted) motion trajectories. The method assumes that motion information is sufficient to fill in holes in videos, which is not always the case (e.g., with a static hole over a static region). The results present some blurring, due to the bilinear interpolation in the color propagation step.

Patwardhan et al. [25] propose a video inpainting method consisting of three steps. In the first step they decompose the video sequence into binary motion layers (foreground and background), which are used to build three image *mosaics* (a mosaic is the equivalent of a panorama image created by stitching together several images): one mosaic for the foreground, another for the background, and a third for the motion information. The other two steps

Inpainting, Fig. 15 An experiment from Drori et al. [13] illustrating the proposed multiscale diffusion/patch-based inpainting method. The *upper-left* image is the original, the *upper-right* image contains the mask defined by the user, the *bottom-left* image is the result, and the *bottom-right* image shows what has been synthesized in place of the elephant

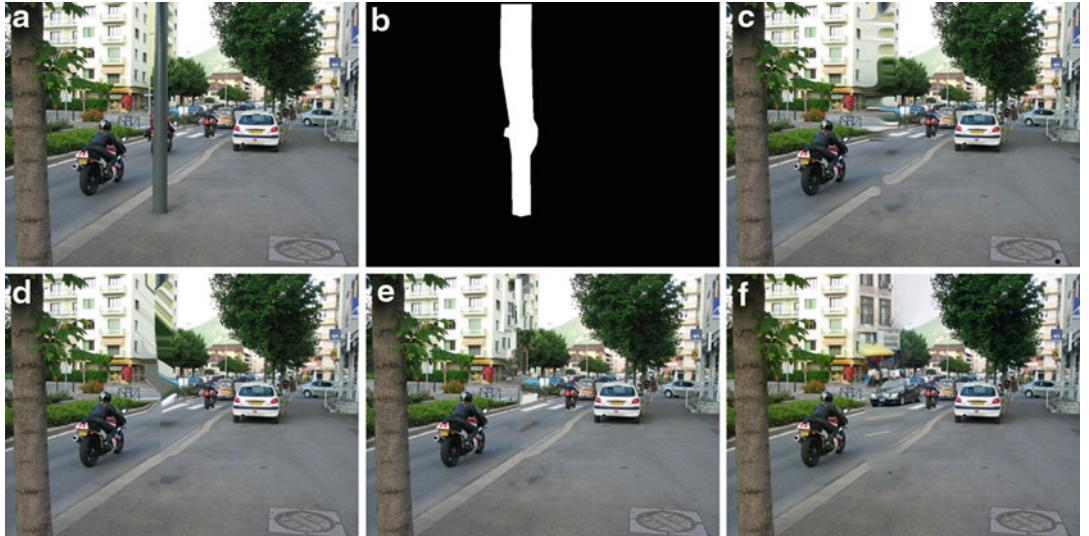

Inpainting, Fig. 16 *Top row:* some frames from a video. *Middle row:* inpainting mask Ω in black. *Bottom row:* video inpainting results obtained with the algorithm of Patwardhan et al. [25]

of the algorithm perform inpainting, first from the foreground and then from the background: these inpainting processes are aided and sped up

by using the mosaics computed in the first step. See Fig. 16 for some results. The algorithm is limited to sequences where the camera motion

Inpainting, Fig. 17 *Left:* original image. *Middle:* inpainting mask Ω , in white. *Right:* inpainting result obtained with the method by Hays and Efros [18]. (Images taken from their paper)

Inpainting, Fig. 18 An example where no inpainting method seems to work. (a) Original image, from the database provided by Hays and Efros [18]. (b) In white, the mask to be inpainted, which is not the initial mask proposed by Hayes and Efros but derives from the fuzzy mask actually used by their algorithm. (c) Result courtesy

of D. Tschumperlé using the algorithm from [28]. (d) Result courtesy of T. März and F. Bornemann using the algorithm from [9]. (e) Result using a variant of the algorithm from Criminisi et al. [12]. (f) Result from Hays and Efros [18]

is approximately parallel to the image plane and foreground objects move in a repetitive fashion and do not change size: these restrictions are imposed so that a patch-synthesis algorithm like that of Efros and Leung [14] can be used.

Hays and Efros [18] perform inpainting of a single image using information from a database with several millions of photographs. They use a scene descriptor to reduce the search space from two million to two hundred images, those images from the database which are *semantically* closer to the image the user wants to inpaint. Using template matching, they align the 200 best match-

ing scenes to the local image around the region to inpaint. Then they composite each matching scene into the target image using seam finding and image blending. Several outputs are generated so the user may select among them, and the results can be outstanding; see Fig. 17. The main shortcoming of this method is that it relies on managing and operating a huge image database. When the algorithm fails, it can be due to a lack of good scene matches (if the target image is atypical), or because of *semantic violations* (e.g., failure to recognize people, hence copying only part of them), or in the case of uniformly textured

backgrounds (where this algorithm might not find the precise same texture in another picture of the database).

Open Problems

Inpainting is a very challenging problem, and it is far from being solved; see Fig. 18. Patch-based methods work best in general, although for some applications (e.g., very spread, sparsely distributed gap Ω) geometry-based methods might be better suited. And when the image gap lies on a singular location, with surroundings that cannot be found anywhere else, then all patch-based methods give poor results, regardless if they consider or not geometry. For video inpainting the situation is worse; the existing algorithms are few and with very constraining limitations on camera and object motion. Because video inpainting is very relevant in cinema postproduction, in order to replace the current typical labor intensive systems, important developments are expected in the near future.

Definition

Interactive image segmentation is a (near) real-time mechanism for accurately marking/labeling an object of interest based on visual user interface (VUI) specifying seeds, rough delineation, partial labeling, bounding box, or other constraints. Semiautomatic interactive segmentation methods incorporate various generic image cues and/or

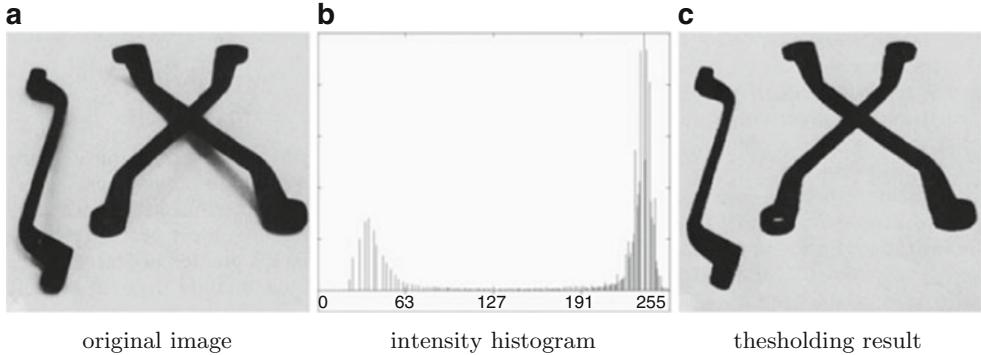

object-specific feature detectors in order to facilitate acceptable results with minimum user efforts.

Background

The most basic object extraction techniques like *thresholding* (Fig. 1) and *region growing* are based on simple but very fast heuristics. The spectrum of applications for such techniques is limited as they are prone to many problems, most notably *leaking* as in Fig. 2. Despite significant problems, thresholding and region growing are widely known due to their simplicity and speed. For example, they could be easily run on personal computers available 15–20 years ago. More recent generations of commodity PCs allow much more robust segmentation techniques, which rely on optimization of some segmentation cost function, or an energy. An energy functional should define an explicit measure of goodness for evaluating any specific segmentation result. The main goal of optimization is to find the best segmentation with respect to the specified criteria. In the context of interactive segmentation, the energy can embed some *soft* and *hard* constraints specified by the user.

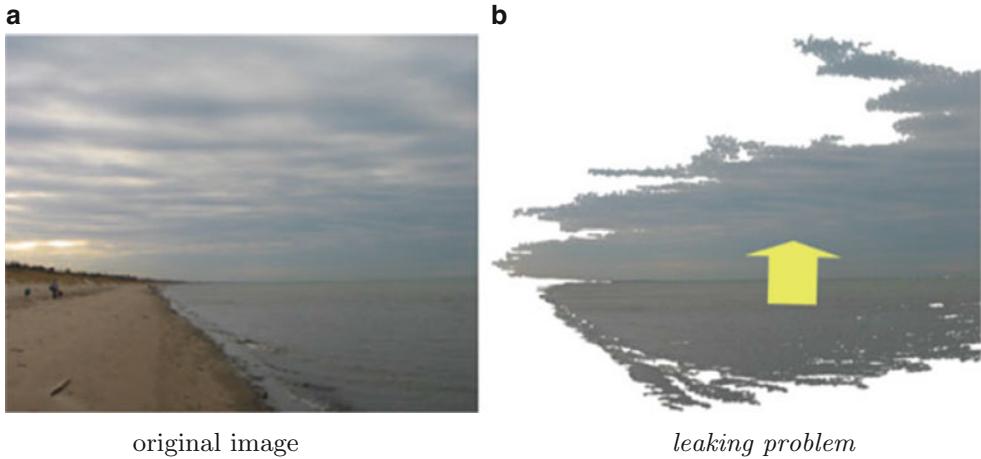

Discrete Segmentation Functionals

Many discrete optimization methods for interactive segmentation are based on classical combinatorial optimization techniques: *dynamic programming* (DP) or *s/t graph cuts*. In general, these approaches are guaranteed to find the exact global minimum solution in finite (low-order polynomial) number of steps. There are no numerical convergence issues (e.g., oscillations), and they work in near real time even on a single CPU. For efficiency, these methods are often implemented using the simplest 4-neighbor grids. In theory, this basic approach may generate some discrete metrication artifacts, but they are rarely observable on real images. Increasing the neighborhood size (e.g., to eight neighbors) adequately addresses the problem [8, 9].

Interactive Segmentation, Fig. 1 Image thresholding segments a subset of pixels with intensities in a certain range, for example, $\{p: I_p < T\}$ in (c). Some threshold T

works only if there is no overlap between the object and background intensities. The images above are from [1]

Interactive Segmentation, Fig. 2 Region growing is a greedy heuristic often associated with the leaking problem. Segment S is initialized by some seed in the object of interest (lake). Adjacent pixels q are iteratively added to S

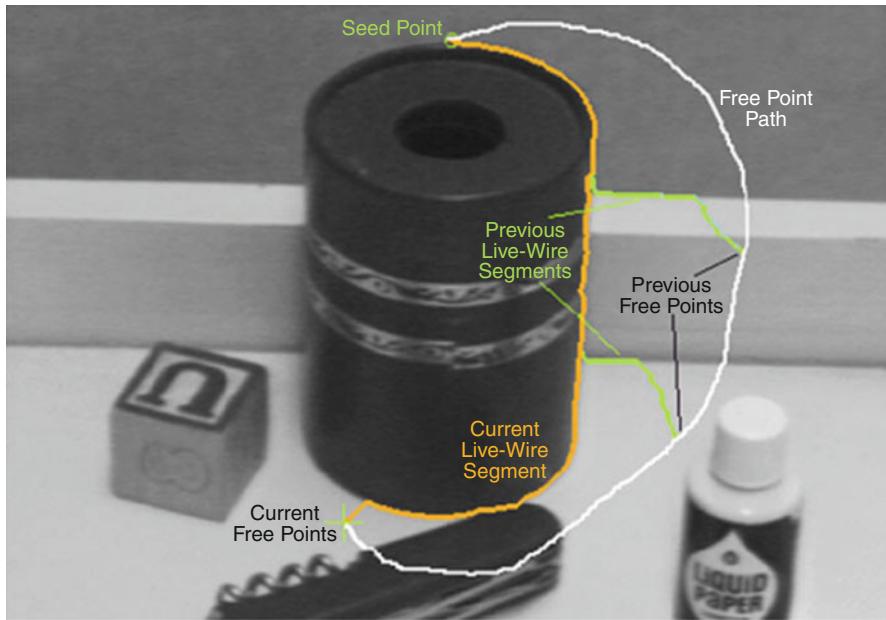

as long as some “growing” criteria are met, for example, $\|I_q - I_p\| < T$ for some neighbor $p \in S$. A single low-contrast spot on the object boundary (horizon) will make the lake leak into the sky (b)

Graph-path segmentation models are designed for 2D image segmentation. *Intelligent scissors* [2], also known as *live wire* in the medical imaging community [3], requires user to place seeds on the desired object boundary; see Fig. 3. The algorithm connects these seeds by computing the shortest path on a graph where edges (or nodes) are image weighted according to local contrast (intensity gradient). Such weighting makes paths “stick” to image boundaries. The shortest paths from each new seed to all other image pixels can be pre-computed in $O(n \log n)$ time. Then, an optimal path from any mouse position to the seed can be previewed in real time.

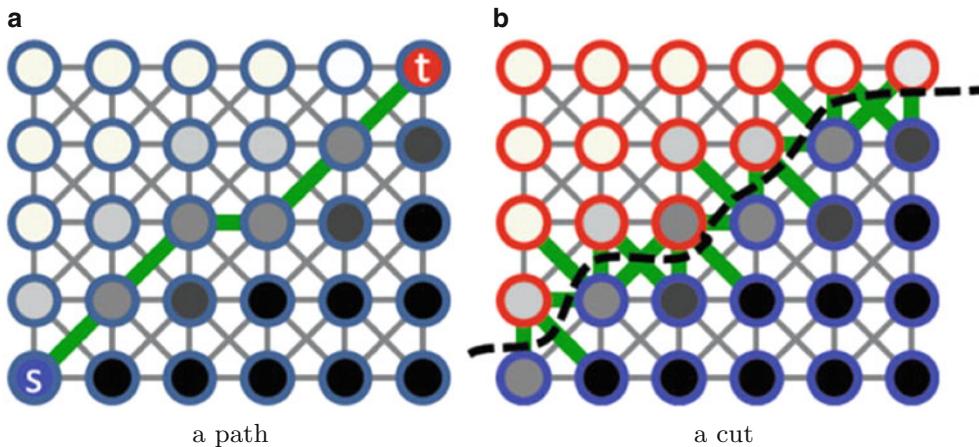

This method evaluates segmentation boundary as a path between two seeds (see Fig. 4a) using energy functionals like

$$E(\mathcal{P}_{s,t}) = \sum_{\{p,q\} \in \mathcal{P}_{s,t}} w_{pq} \quad (1)$$

where $\mathcal{P}_{s,t}$ is a set of adjacent edges from source seed s to terminal seed t and edge weights $w_{pq} \geq 0$ are segmentation boundary costs based on some local measure of intensity contrast across edge $\{p, q\}$. One example of weights w_{pq} is

Interactive Segmentation, Fig. 3 Intelligent scissors or live-wire methods connect seeds placed on object boundaries. Optimal segmentation boundary (orange curve) can be previewed for any mouse position in real time

Interactive Segmentation, Fig. 4 Segmentation on graphs. The path-based methods [2–4] represent segmentation boundary as a sequence of adjacent (green) edges (a). A path could connect two seeds or form a closed cycle. The graph-cut methods [5–7] assign to pixels different

labels, for example, red and blue in (b). Any such labeling implicitly defines a segmentation boundary, which is a *cut*, as a collection of (green) edges between differently labeled pixels

$$w_{pq} \propto \frac{1}{1 + |\nabla I \cdot n_{pq}|^2} \cdot \|p - q\|$$

where ∇I is image gradient, vector n_{pq} is a normal to edge $\{p, q\}$, and $\|p - q\|$ is the geometric length of edge $\{p, q\}$. Factor $\|p - q\|$

differentiates diagonal edges from horizontal and vertical edges on grids with higher connectivity, which can reduce the grid bias.

There is a number of other interactive segmentation methods based on efficient DP-based optimization algorithms. For example, the methods in

[10, 11] compute globally optimal cycles (closed contours), minimizing ratios of different measures of segment's boundary and region. For example, [11] can find a segment with the largest average contrast on its boundary. (Ratio of some cumulative contrast measure and the boundary length.) Optimization of ratio functionals evaluating boundary's curvature was addressed in [12].

Graph-cut segmentation models: Boykov and Jolly [5] and Boykov and Funka-Lea [6] proposed an object extraction functional for N-dimensional images that evaluates boundary and region properties of segments as

$$\begin{aligned} E(x|\theta) = & - \sum_{p:x_p=0} \ln \Pr(I_p|\theta_0) \\ & - \sum_{p:x_p=1} \ln \Pr(I_p|\theta_1) \\ & + \sum_{\{p,q\} \in \mathcal{N}} w_{pq} \cdot [x_p \neq x_q] \end{aligned} \quad (2)$$

where $[\cdot]$ are Iverson brackets, variables x_p are binary object/background labels at pixels p , parameters $\theta = \{\theta_0, \theta_1\}$ define object and background intensity distributions, and edge weights w_{pq} are a cost of discontinuity between a pair of neighboring pixels. For example,

$$w_{pq} \propto \exp\left(-\frac{|\nabla I \cdot e_{pq}|^2}{\sigma^2}\right) \cdot \frac{1}{\|p - q\|}$$

where e_{pq} is a unit vector collinear to edge $\{p, q\}$ and σ is a parameter controlling sensitivity to intensity contrast that is often set according to the level of noise in the image. Similarly to energy (1), the last term in (2) evaluates the image-weighted length of the segmentation boundary. In contrast to edge weights in (1), the weights above are based on intensity contrast along the edge $\{p, q\}$; see Fig. 4b. Normalization by edge length $\|p - q\|$ is required for grids with higher connectivity, reducing the grid bias [13].

The first two terms in (2) evaluate how well pixel intensities inside the object and background segments fit the corresponding distributions. In general, image intensity/color distributions could

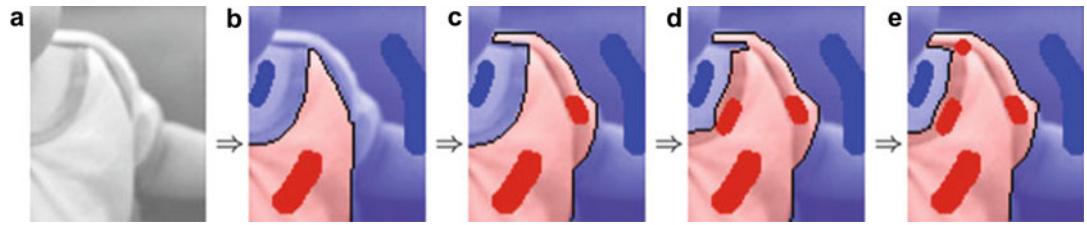

be extended by more sophisticated features and appearance models, for example, texture. The appearance models could be estimated from seeds or from prior data. The *grab-cut* method in [7] also uses an iterative EM-style scheme for additionally optimizing functional $E(x|\theta)$ in (2) with respect to parameters θ . In this case, sufficiently good initial appearance models can be often estimated from a user-placed box around the object. The graph-cut segmentation model also extends to video; for example, see the *snapshot* method [14].

Functional (2) can be globally minimized over binary variables x by low-order polynomial algorithms from combinatorial optimization [15] that are fast even on a single CPU. Also, there are efficient techniques [5, 6] for integrating interactive hard constraints (seeds) as in Fig. 5. Instead of segmentation energy (2), graph-cut framework can also use various ratio functionals [16].

Segmentation energy (2) works for N objects (labels). In general, its optimization is NP-hard for $N > 2$. An approximate solution with a factor of 2 optimality guarantee can be found via α -expansion optimization algorithm [17]. Interestingly, imposing some additional geometric constraints between object boundaries (e.g., inclusion, exclusion, minimum margin) may lead to exact polynomial optimization algorithms [18–20].

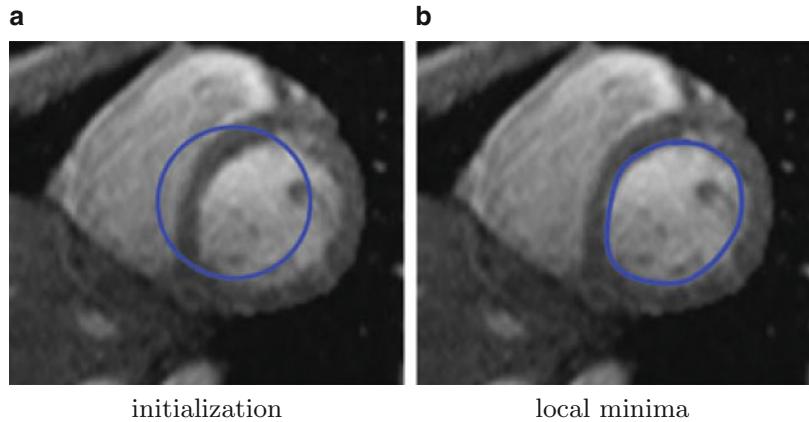

Continuous Segmentation Functionals

Many popular interactive segmentation methods use continuous representation of segments where boundaries are contours in \mathcal{R}^2 or surfaces in \mathcal{R}^3 . Such methods use either physics-based or geometric functionals to evaluate such continuous segments. Traditionally, variational calculus and different forms of *gradient descent* were used to converge to a local minima from a given initial contour; see Fig. 6. This motivates the general term, *active contours*, commonly used for such methods. Recent convex formulations for standard continuous regularization functionals [21, 22] and development of continuous max-flow

Interactive Segmentation, Fig. 5 Interactive editing of segments via hard constraints (seeds) based on graph cuts [5, 6]. A fragment of an original photo is shown in (a). Initial seeds and segmentation are shown in (b). The

results in (c–e) illustrate changes in optimal segmentation as new hard constraints are successively added. The computation time for consecutive corrections in (c–e) is marginal compared to time for initial results in (b)

Interactive Segmentation, Fig. 6 Snakes and other active contour methods are initialized by rough delineation of the desired object (a). Minimization of an energy

associated with the contour leads to a local minimum (b) with better alignment to image boundaries

techniques [23, 24] now also allow good quality approximations of the global minima.

Physics-based segmentation models: Snakes [25, 26], balloons [27], spline snakes [28], and other methods explicitly represent object boundaries as an elastic band or a balloon. The band is normally assigned an internal energy (elasticity and stiffness) and a potential energy with respect to some external field of predefined *image forces* attracting the band to image boundaries, that is, locations with large intensity gradients. A user can also place seeds defining additional attraction or repulsion potentials.

Geometry-based segmentation models: Note that two visually identical *snakes* appearing in the same image position may have different internal elastic energies. In many cases this may contradict a natural assumption that a segmenta-

tion result can be evaluated only by its visible appearance (In some video applications the goal is to track specific points on a moving segment, e.g. muscles of a beating heart. Physics-based (e.g. elastic) segmentation energy is well motivated in such cases). Based on this criticism of the physics-based approach, [29, 30] proposed *geodesic active contour* model evaluating contour C on a (bounded) domain Ω via geometric functionals like

$$\begin{aligned} E(C) = & \int_{int(C)} f_1(p) \, dp + \int_{\Omega/int(C)} f_0(p) \, dp \\ & + \int_{\partial C} g(s) \, ds \end{aligned} \quad (3)$$

which is similar to discrete model (2). The first two integrals in (3) are over the interior and exterior regions of C , and the third integral is the Riemannian length of C under metric g . Image-based *density* function g , for example,

$$g(p) = \frac{1}{1 + \|\nabla I(p)\|^2}, \forall p \in \Omega$$

shortens the length of contour C if it follows image boundaries where the density is small. The geometric length term in (3) is a continuous analogue of (1) and the spatial smoothness term in (2); see [13].

Scalar functions f_1 and f_0 on Ω are interior and exterior potentials based on some known appearance models for the object and background regions. For example, one can use $f_i(p) = -\ln \Pr(I_p | \theta_i)$ as in (2). Similarly, these potentials could also enforce user-placed hard constraints (seeds).

Geometric contours C can be represented as *level sets* of some scalar embedding function $u : \Omega \rightarrow \mathcal{R}^1$, for example, $C = \{p \in \Omega : u(p) = \text{const}\}$. This approach avoids some numerical issues, for example, the need for *reparameterization*, often associated with explicit representation of contour points needed for physics-based bands. The level-set framework does not pose any topological constraints on contours and yields easy-to-implement gradient descent equations for geometric energies like (3). More recently, geometric energies like (3) are addressed with various continuous convex formulations [24, 31, 32] that are shown to converge to a good approximation of the global minimum.

The continuous geometric models are very closely related to discrete segmentation energies in the graph-cut framework [8, 13]. One theoretical advantage of the continuous formulations is absence of the grid bias. Continuous numerical schemes guarantee certain convergence rate, but some stopping threshold often needs to be chosen. Current fast implementations of continuous optimization methods, for example, [32], require GPU acceleration.

Distance-Based Segmentation Methods

Many interactive segmentation techniques optimize objective functions that are only indirectly related to the visual appearance of the segments and their boundaries. In particular, a large number of methods compute optimal (image-weighted) distance functions computed from seeds. For example, *fast-marching method* [33] extracts the boundary reached at time T by a front expanding with an image-weighted speed. This can be seen as a generalization of *region growing*. These ideas were extended in [34] where the segments are Voronoi cells w.r.t. geodesic distance $d(p, s)$ from the object and background seeds $s \in S_O \cup S_B$

$$x_p^* = \arg \min_{l \in \{O, B\}} \min_{s \in S_l} d(p, s)$$

Their image-based metric is based on gradients of the appearance models likelihoods instead of intensity gradients. Distance transforms can also work as the unary potentials in the segmentation models (2) and (3); for example, see [35].

Instead of the standard *min-sum* geodesic distance $d(p, s)$, many segmentation methods use other measures to compute Voronoi cells from the seeds. For example, *fuzzy-connectedness* methods [36, 37] compute Voronoi cells with respect to some *max-min* affinity measure. *Random walker* [38] outputs Voronoi cells for probabilistic distance function $d(p, s)$, measuring the expected time of arrival for a random walk from p to s . *Watershed* method, for example, [39], connect points to seeds using *water-drop paths* instead of geodesics. *Power watershed* algorithm [40] unifies the ideas of *watershed* and *random walker*.

Some Open Problems

Energy functionals like (2) and (3) represent only the most standard ideas for evaluating segments. Accurate evaluation of the higher-order geometric properties of the boundary, for example, curvature [12, 41], remains a difficult optimiza-

tion issue. Shape priors for globally optimal segmentation [42, 43] as well as enforcement of topological constraints [44, 45] are largely open problems.

Definition

Interreflections are reflections of light from one surface to another surface.

Background

Surfaces are illuminated not just by light sources but also by each other. Such *interreflections* can provide a significant component of surface illumination especially in concavities or enclosures. Numerical methods for computing interreflections were developed a century ago to solve problems in heat transfer. In the 1980s, these methods were developed further by the computer graphics community, and soon after interreflections were considered in computer vision.

Interreflections are important in computer vision for methods that use exact models of image intensities. For example, shape from shading and photometric stereo methods assume direct illumination only, so these methods produce incorrect shape estimates when interreflections are present [1]. Another example is the problem of estimating surface color. Classical methods assume a planar scene under ambient illumination and so interreflections can be ignored. However, when a scene has folded or curved surfaces, interreflections will occur and can lead to incorrect estimates of surface color [2].

Theory

Interreflections can be described mathematically by writing the reflected light that leaves each surface point as a sum of two components: the first is due to the illumination arriving at the point directly from the light source, and the second is due to the illumination that arrives indirectly from other surfaces in the scene. If the scene is composed of Lambertian surfaces with albedo $\rho(\mathbf{x})$ varying across surfaces, then the total radiance $L(\mathbf{x})$ leaving \mathbf{x} can be written:

$$L(\mathbf{x}) = L_s(\mathbf{x}) + \rho(\mathbf{x}) \int_S L(\mathbf{y}) K(\mathbf{x}, \mathbf{y}) d\mathbf{y}. \quad (1)$$

Here $L_s(\mathbf{x})$ is the reflected radiance that is due to direct illumination from the source, and the second term is the component that is due to interreflections. The integral is taken over all surface points $\mathbf{y} \in S$ in the scene. The function $K(\mathbf{x}, \mathbf{y})$ is a symmetric weighting function that depends on the surface normals at \mathbf{x} and \mathbf{y} and on the distances between \mathbf{x} and \mathbf{y} . $K(\mathbf{x}, \mathbf{y})$ is zero if the \mathbf{x} and \mathbf{y} are not visible to each other. It is common to approximate Eq. (1) by using a polygonal mesh surface whose facets have constant radiance

$$\mathbf{L}_i = \mathbf{L}_i^s + \mathbf{P}_i \sum_j \mathbf{K}_{i,j} \mathbf{L}_j \quad (2)$$

where \mathbf{L}_i and \mathbf{L}_i^s are the vectors of direct and total radiance, respectively, \mathbf{P}_i is the albedo of surface facet i , and \mathbf{K} is a geometrical *form factor* matrix.

In both the continuous and discrete cases, the eigenfunctions of \mathbf{K} are radiance functions that are invariant to interreflections [3, 22]. For eigenfunctions that have relatively large eigenvalues, the support of the eigenfunctions tends to concentrate in surface concavities and at points of contact between surfaces such as a convex object resting on a plane [4].

To model interreflections when non-Lambertian surfaces are present, one needs to consider the radiance $\mathbf{L}_{i,j}$ leaving facet j in the direction of facet i . Let the weight matrix $\mathbf{W}_{i,j}$ capture the BRDF of facet i as well as the geometric relationship between facets i and j including distance and foreshortening. Then the radiance $\mathbf{L}_{c,i}$ arriving at the camera c from facet i can be written:

$$\mathbf{L}_{c,i} = \mathbf{L}_{c,i}^s + \sum_j \mathbf{W}_{i,j} \mathbf{L}_{i,j}. \quad (3)$$

An equivalent way to model interreflections is to consider how emitted light is transported through a scene via a sequence of reflections. The n^{th} reflection serves as the incident light for the $n+1^{st}$ reflection, and the sum of all reflections gives an infinite series which converges to the scene radiance. For any given scene geometry and surface reflectances, it is possible to define a sequence of linear operators that decomposes the radiance arriving at the camera into its n bounce components [5]. Related methods for decomposing the image into direct and indirect components will be discussed below.

Finally, interreflections are related to subsurface scattering and volume scattering, since these phenomena lead to multiple bounces of light between the source and camera. Although some of the methods below deal with these effects as well, we will only discuss aspects of the methods that deal with interreflections between visible surface facets whose image projection is at least as large as a pixel.

Applications

Shape from Shading and Photometric Stereo

Classical shape from shading and photometric stereo methods ignore interreflections. One can extend these methods to account for interreflections in several ways. For example, one can apply the method to obtain an approximate shape solution and then iteratively update the solution to account for interreflections. This idea has been applied to photometric stereo both for gray-level images [6] and in color [7]. The idea has also been applied to shape from shading for the special case that the surface is an unfolded book in a photocopier [8]. In these applications, it is assumed the light sources are known.

Under unknown lighting and in the absence of interreflections, there exists a family of scenes (shape, albedo, lighting) that all produce the same image – the so-called bas-relief ambiguity. When interreflections are present, this ambiguity vanishes. In this case, one can estimate the surface shape and reflectance by applying a photometric stereo method that is designed for unknown lighting and then iteratively update the shape and reflectance to account for interreflections [9].

Color

Classical color constancy methods ignore interreflections by assuming a single planar scene. When the scene contains concavities, however, interreflections sometimes cannot be ignored, especially when color bleeds from one surface to another. Consider a situation in which two planar surfaces of different colors are illuminated by the same ambient light. Under a two-bounce model (one direct plus one interreflection), these two components define a 2D subspace of RGB space for each surface. The intersection of the subspaces is the color of the indirect component. Under certain conditions, it is possible to remove this indirect component and to estimate the illuminant and reflectance spectra [10].

For the case that a surface has a single color, the problem is less constrained. Some solutions

for removing the indirect component use calibration spheres which are painted the same as the object and are viewed under the same lighting [11]. Alternatively, one can constrain the problem by using fluorescent paint and imaging the surface under different colored light sources [12]. More recent methods have attempted to learn a mapping from the image to the spectral reflectance and illuminant by training on many synthetic examples using the full infinite bounce model [13]. For further examples of interreflections in spectral estimation, see the following review [14].

Structured Light

Interreflections can also create problems for structured light methods. One method for removing interreflections is to use high-frequency illumination patterns such as checkerboards. Such patterns produce a low-frequency indirect component, and so, for example, two complementary patterns will produce essentially the same indirect component at each scene. One can measure (and then subtract) this indirect component at each scene point by using the image whose direct component is zero [15]. Several methods have been proposed to increase the robustness of this approach, for example, by using a large number of random high-frequency binary spatial patterns [16] or using patterns of different frequencies that isolate not only interreflections but also related effects such as the projector depth of field and subsurface scattering [17].

Another approach, which uses phase-shifted sinusoids, has been to avoid trying to remove the indirect component [18]. With traditional phase-shifted structured light, using only a single frequency results in a limited depth resolution because there is a 2π phase ambiguity. To resolve the ambiguity, one needs also to use a lower-frequency illumination component. However, low-frequency illumination is susceptible to errors from interreflections [17]. By using different high frequencies within a small spatial frequency band, the “micro phase shifting” [18] allows the phase information to be disambiguated

while keeping the advantage of high-frequency direct illumination, namely, that it produces a low-frequency indirect component which does not perturb the phase of the direct component.

Another approach is to separate the direct and indirect components optically [19]. The camera and projector define corresponding epipolar lines, namely, the light from a projector pixel that reaches the camera by one bounce must fall on a unique line in the image and light that reaches a pixel in the image from one bounce must have emitted from a unique line in the projection image. By synchronously masking pixels in the camera and projector at a rate much higher than the frame rate of the camera, it is possible to optically mix a selected set of light paths. For example, one can make a direct-only image, or an indirect-only image, or an indirect-invariant image, namely, the indirect component is independent of the direct component.

Time-of-Flight Imaging

For time-of-flight imaging that uses a single pulse of light, interreflections add a tail to the incoming pulse. This tail can in principle be detected and removed [20]. Often time-of-flight methods use a sequence of pulses at some temporal frequency ω , and in this case the distance to visible surfaces can only be estimated modulo the wavelength (or spatial period) of the sequence. To resolve this phase ambiguity, multiple frequencies can be used. However, this must be done with some care since interreflections can change the phase of the signal.

To deal with interreflections, one can use high frequencies, namely, the spatial period should be comparable to the interreflection path lengths. In this case, the diffuse interreflections would add roughly a DC component to the direct component which would not affect its phase. This is the temporal analog of the method described above for structured light, namely, a sufficiently high spatial frequency illumination pattern produces only low spatial frequency indirect patterns. In the time-of-flight case, there is still a phase ambiguity if one uses only one frequency. However, by using multiple high frequencies within a narrow

band, it is possible to combine the amplitude and phase information to estimate a unique depth [21].

Intrinsic Images

Marshall F. Tappen
Amazon, University of Central Florida, Seattle,
WA, USA

Definition

A set of images used to represent characteristics of a scene pictured in an image, with each image representing one particular characteristic of the scene.

Background

Vision systems have been categorized into low- and high-level processing, with high-level processing taking an object-centered approach [1]. In this categorization, the role of low-level processing is to extract basic characteristics at all locations in the image. These characteristics are then used to find objects.

Intrinsic images are a method for representing the low-level characteristics extracted from images. In the intrinsic image representation, proposed by Barrow and Tenenbaum in [2], one image represents each of the characteristics being used in the system. The value of each pixel represents the value of the characteristic at each point in the scene.

The types of characteristics that are conveniently expressed as intrinsic images include the illumination of each point in the scene, the motion at each point, the orientation of each point, the albedo, and the distance from the camera.

Application

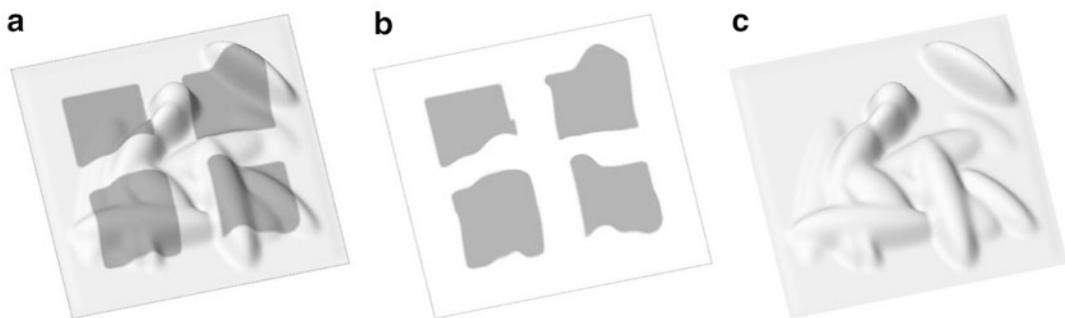

Starting with [3], the term intrinsic images have also been used to refer to an image decomposition that decomposes an observed image into intrinsic images that can be recombined to recreate the observed image. The most common decomposition is, into images, representing the shading, or illumination, and albedo of each point. Figure 1 shows an example of how the image in Fig. 1a into shading and albedo images. Mathematically, the decomposition is modeled as

$$O_p = I_p \times R_p$$

where O_p is the value of the observed image at pixel p , I is the illumination image, and R is the reflectance image.

In [3], Weiss recovers these intrinsic images from a sequence of images where the illumination varies in the scene. In [4, 5], Tappen et al. use color and gray-scale features to estimate the decomposition from a single image.

Besides image decompositions, [6] proposes using intrinsic images that represent properties like occlusion boundaries and object depth.

Intrinsic Images, Fig. 1 These images show an example of an intrinsic image decomposition. In this decomposition, the intrinsic images can be how the image in (a) can

be decomposed into the albedo and shading images shown in (b) and (c), respectively

Definition

Intrinsics, short for *intrinsic parameters*, refer to the parameters belonging to the essential nature of a thing, which is usually a camera in computer vision. The intrinsic parameters of a camera include its focal length, the aspect ratio of a pixel, the coordinates of its principal point, and the lens distortion parameters.

See entry “[Camera Parameters](#)” for more details.

Invariant Methods in Computer Vision

Definition

The term invariant methods in computer vision refers to a broad class of ideas for designing both representations and metrics that are invariant/robust to (and only to) nuisance factors in computer vision such as viewpoint, motion, defocus, etc. for different related modalities including images, videos, and point clouds.

Background

Computer vision consists of inferring geometric and semantic properties of objects and scenes, from 2D projections as seen through cameras. This theme appears in applications such as object recognition, localization, segmentation, 3D reconstruction, etc. As canonical examples, we will focus on object, scene, and action recognition. Usually, these tasks need to be performed given a single image of the object/scene or a video. That is, we usually do not have access to the full 3D structure of the object or scenes, but have 2D projections obtained using a camera. As such, a lot of important information is lost. Unknown camera intrinsics, extrinsics, sensor noise, etc. make the task more difficult. Additionally, environmental factors such as illumination, shadows, reflections, and

atmospheric conditions such as fog create more ambiguity. Furthermore, object/action categories themselves cannot be precisely defined, and there are large intra-class variations and small interclass variations for many commonly used categories. Computer vision systems should be (a) able to disregard, or at least be robust to, all these nuisance factors while performing an end task such as object/action recognition, (b) lend themselves to being interpretable, and (c) be computationally efficient. Here, we discuss issues that are relevant while designing representations/metrics that are *invariant* to these factors. Fortunately, some of these factors can be modeled mathematically leading to tractable invariances. The image/video features and metrics that arise out of these models are often described using the language of moment invariants, group theory and geometry, and topology.

Theory

Let the set of images/videos be $\mathcal{X} \subset \mathbb{R}^n$, where n is the ambient dimension of the images/videos and could be number of pixels, etc., and $x \in \mathcal{X}$ be a single datapoint on which object/action recognition is performed. The common pipeline in computer vision is as follows. First, a feature $\phi(x)$ is extracted, and then a machine learning technique such as nearest neighbors, support vector machines, neural networks, etc. is used to classify the feature into one of the predefined object/action categories. Let us now denote by $T : \mathcal{X} \rightarrow \mathcal{X}$, a set of nuisance transformations which we want to factor out. Let T be parameterized by $\theta \in \Theta$ that acts on images, and we denote $\hat{x}_\theta = T(x, \theta)$, the action of the set of transformations on an image/video. By an invariant representation of an image/video to the set of transformations T , we mean a feature $\phi : \mathcal{X} \rightarrow \mathcal{Y} \subset \mathbb{R}^d$, where d is the ambient dimension of the feature space, such that $\phi(x) = \phi(\hat{x}_\theta) = \phi(T(x, \theta)), \forall \theta \in \Theta$. It is very important to note that extracting the invariant representation is an intermediate step in the classification pipeline. Our final goal is to perform effective classification. This implies

that the process of extracting invariants should not lose any information that may be pertinent for classification, i.e., the invariants must ideally be invariant *only* to the nuisance factors. That is, for $x, y \in \mathcal{X}$, if $\phi(x) = \phi(y)$, then $\exists \theta \in \Theta$, such that $y = T(x, \theta)$. This is sometimes referred to as *completeness* of the invariant. We also note that sets of nuisance transformations T can often be equipped with a group structure, such as in the case of affine transforms for images, rate transforms for video, etc.

Another way to performing direct invariant classification is do design invariant metrics, rather than devising invariant representations. For example, if the set of transformations T can be equipped with group structure, we may be able to define a metric d so that $d(x, y) = \min_{\theta} \|x - T(y, \theta)\|_p$, under some norm over \mathbb{R}^n . Such a metric measures distances between the equivalence classes $[x] = \{\hat{x}_\theta, \theta \in \Theta\}$ and $[y] = \{\hat{y}_\theta, \theta \in \Theta\}$ or *orbits* rather than the images themselves and is invariant to the transformations T . See Vedaldi [1] and Simard et al. [2] for a longer treatment of these ideas.

For the purposes of this chapter, we will also refer to representations and metrics which are *robust* to nuisance transformations as invariant, keeping with the parlance of the community. By robust representations we mean that the representations do not change significantly under a nuisance transformation.

Examples of Factors of Variation and Associated Invariants

There are several physical factors of variation for which we want to design invariances in computer vision. Discussed below are important factors for which, under different simplifying assumptions, we can mathematically model these transformations and design invariant representations/metrics. A summary is presented in Table 1.

Blur Blurring due to resolution limitation of the sensor, defocus, motion, etc. is common in imaging, and the level of blur is usually unknown.

For image recognition, it is important to develop features/metrics that are invariant to blur. Zhang et al. [10] present a blur-invariant metric for Gaussian blurring. The blur kernel, assumed to be constant throughout the image, acts on the image via convolution and the set of all blur kernels at different levels forms a semigroup. Here, a log-Fourier representation of an image is first computed, under which the orbit of blurred versions of an image becomes a line. The Riemannian metrics defined between two images measure distances between their orbits rather than the images themselves. Instead of metrics, there are works which propose blur-invariant/robust representations. Among these are moment invariants described by Flusser et al. [9] for symmetric blur kernels, which are further shown to be *complete*. They also combine the proposed blur invariant with illumination and rotation invariance. Gopalan et al. [11] construct a geometric blur-robust descriptor for blur kernels with a predefined maximum width. For an image, they use an orthogonal basis for blur kernels and create a dictionary with each element given by the convolution of a basis function on the image. They show that, with certain assumptions on the blur kernel, the span of the elements of the dictionary of an image and its blurred variant are the same. Thus, face recognition in this framework becomes a nearest neighbor search between *spans of dictionaries* which are points on the Grassmann manifold.

Viewpoint The effect of the viewing condition, or the relative placement of the image sensor with respect to an object, leads to many difficult transforms in image space. If the object under consideration is planar, the effect of view changes can be described by projective transforms, or homographies. Invariance to projective transforms for simple objects was classically studied through geometric invariants, such as cross ratios, and local geometric invariants based on points, lines, and derivatives of curvatures [21]. For nonplanar objects, or objects with full-depth variation, any change in viewing condition results in certain parts going out of view and new parts coming into view. There are no known true invariants under

Invariant Methods in Computer Vision, Table 1

Some methods to compute invariant metrics and representations for various nuisance transformations discussed in this chapter

| Nuisance factors | Canonical applications | Mathematical models | Related works |
|------------------------------------|------------------------|--|---------------|
| View point + reparameterization | Object recognition | Affine transforms, homography | [3–7] |
| | Shape analysis | Affine transforms + diffeomorphisms | [8] |
| Blur | Object recognition | Moments, subspaces | [9–11] |
| Temporal reparameterization | Action recognition | Order-preserving diffeomorphisms | [12–15] |
| Illumination | Object recognition | Subspaces | [16–19] |
| Permutations | Point clouds | Symmetric functions | [20] |

such a case. However, under simpler assumptions of small changes in view, one can often approximate the effects of viewpoint change via global or local affine transformations. Scale variations and rotations become a special case of affine transformations. These ideas have appeared in a number of different contexts, depending on what can be robustly measured. In the field of shape analysis, where we assume that certain landmark points can always be detected, techniques for compensating for the effect rotation, scale, and affine transformations are well-developed [3, 4]. These ideas also appear in more recent developments in comparing the shapes of continuous curves and surfaces [8]. In more general situations, it is difficult to define true invariants, but the method of using local patch-level robust features is encoded even in newer algorithms for feature-point detection and matching such as SIFT [5], affine-SIFT [22], etc. In more recent developments, topological invariants for point clouds, and image patches have been gaining ground as a way to encode a far richer set of geometric deformations [23]. This area continues to see active interest and is considered an unsolved problem.

Temporal reparameterization In the case of action recognition, and more generally in the case of time-series classification problems, a common nuisance factor is execution-rate. In many applications, we want the classifier to be invariant/robust to the rate at which the activity is performed. The same activity may be performed at different rates by subjects owing to physiological, biomechanical, and other factors.

Mathematically, rate variations are modeled using order-preserving diffeomorphisms, more commonly referred to as time-warping functions. Let us consider a human action sequence each time, instant contains a human skeleton represented by 2D/3D joint locations. For two such action sequences α and β , if they only differ by execution rate, then $\alpha = \beta \circ \gamma$, where $\gamma \in \Gamma$ and $\gamma : [0, 1] \rightarrow [0, 1]$, the set of warping functions. Additionally, each $\gamma \in \Gamma$ respects the following constraints: (1) $\gamma \in C^1$, the set of differentiable functions on $[0, 1]$, (2) $\gamma(0) = 0, \gamma(1) = 1$ and (3) if $t_1 < t_2, \gamma(t_1) < \gamma(t_2)$. Γ is then easily equipped with a group structure under function composition \circ as the group action. The same model can be used to model misalignments as well as differing sampling rates between sequences. Now, we can define a metric invariant under time warps: for two sequences α and β , $d(\alpha, \beta) = \min_{\gamma \in \Gamma} \|\alpha - \beta \circ \gamma\|$. Commonly, this alignment problem is discretized and solved using dynamic programming, and the algorithm is referred to as dynamic time warping (DTW) [12]. Instead of solving alignment directly on the sequences, Srivastava et al. [13] present a Riemannian framework by first constructing the square-root velocity field (SRVF) representation using which alignment is performed. SRVF representation provides better mathematical properties and guarantees compared to DTW. In action recognition, at test time, the test sequence is aligned to a predefined template before feature extraction and classification. This leads to rate-invariant representations and improves

classification rate as shown by Veeraraghavan et al. [14] for human activities, by Vemulapalli et al. [24] using Lie group representations for human skeletons.

Illumination Chen et al. [25] showed the nonexistence of illumination invariants – given two images under unknown illumination conditions, there is no way to know with absolute certainty whether they are from the same object or not. However, with access to more images in the training set, we can avoid the ambiguity. Hallinan et al. [16] and others showed empirically that using approximately the top 5 eigenvectors explains most of the set of the images of the object under varying illumination conditions. Belhumeur and Kreigman [17] demonstrated theoretically that for a convex Lambertian object illuminated by point sources at infinity, the set of images of that object under all illumination conditions forms a convex cone with the dimension of the cone equal to the number of distinct surface normals, and determined by only three images. They conjectured and provided empirical results that the cone is flat and the set of images lies close to a low-dimensional subspace. Basri and Jacobs [18] created low-dimensional subspaces from the low-frequency spherical harmonics of the Lambertian kernel and design an effective recognition algorithm based on it. For an object or a face, its *illumination subspace* for the illumination-invariant representation. In order to perform illumination-robust face recognition, the distance of a given test face should be computed from the training illumination subspaces rather than training images if there are illumination variations [26].

Open Problems and Recent Trends

Over the last decade, employing deep neural networks has led to significant advances in solving many tasks in computer vision. The most common architecture is convolutional neural networks. Implicitly, using training data to minimize classification loss, such networks learn to develop invariant representations for images and

videos, to some extent [27]. Preliminary empirical studies demonstrate that features in deeper layers in autoencoders and convolutional deep belief networks provide better invariance to input transformations [28, 29] and further improved using data augmentation with transformed inputs [30]. However, it is not fully clear a priori to what factors the representations are invariant to, how much the architecture affects it, and if they are fully invariant (e.g., invariant to all rotations v/s invariant to rotations only present in the training data). Many times, even small perturbations of the input can break the classifier such as small amounts of Gaussian noise [31] if the network has not seen blurred images and adversarial perturbations [32].

Improving invariance properties In addition to data augmentation, regularization functions have been proposed to improve the invariance properties of neural networks for small perturbations of the input. We can regularize the norm of the Jacobian of the image/video features with respect to the input image [33]. One of the pioneering works in the field by Simard et al. [2] proposed a modified version of backpropagation (widely used to train artificial neural networks), called tangent propagation which provides some amount of invariance to small input transformations. The maxpooling operation commonly employed in convolutional neural networks (CNNs) also provides small amounts of translational invariance. Bruna and Mallat designed wavelet scattering networks [34] which are cascaded wavelet transforms and carefully designed nonlinear operators. This results in creating translation-invariant representations and provides robustness to deformations.

Hybrid model- and data-driven architectures There is a recent interest in developing hybrid data- and model-driven neural architectures that can incorporate structured layers and modules that get closer to guaranteeing invariance to some nuisance factors. Jaderberg et al. [6] propose designing a specialized neural module called a spatial transformer which takes in an input image/feature maps and outputs a spatial

transform (such as an affine transform matrix) which is then applied to the input image/feature map using a “warping layer” before feeding into the classifier layers. The authors show that this has the effect of transforming the rotated/scaled/translated input image back into a canonical form – an upright, centered image, which serves as an invariant to spatial transforms – before the classifier layers and leads to better classification accuracies. Note that all the layers here are differentiable and can be learned end-to-end by minimizing classification loss. This idea was applied for human skeletal action (time-series) classification using temporal transformers [15] where a time-warping function is generated by the transformer module and applied to the input sequence, creating a rate-invariant representation, and then fed into the classifier. These methods have the added advantage that the invariants at the outputs of the transformer modules are interpretable. Neural networks can also be trained to generate illumination subspaces which are an illumination-invariant using a single face image by posing it as a nonlinear regression problem on the Grassmann manifold as shown by Lohit and Turaga [19]. Better scale invariance has been shown to be possible using multiple columns for different scales, but using the same filters across columns with scale transformations applied on them [35]. 3D point clouds are another modality that is gaining a lot of interest recently for computer vision. Point clouds are unordered, and hence, any machine learning pipeline needs to be invariant to the order in which the 3D points are presented to it. To this end, Qi et al. [20] designed PointNet for learning permutation-invariant representations for point cloud data where a series of *symmetric functions* with learnable parameters are used and the parameters are shared for all the incoming 3D points, thus making the architecture permutation-invariant. Another related line of work is Capsule Networks and the dynamic routing algorithm by Sabour et al. [7] results in viewpoint robust classification by dividing every layer into “capsules” where each capsule is designed to encode different properties such as the pose vector.

Disentangled latent representations Well-known linear methods like principal component analysis (PCA), independent component analysis (ICA), and related approaches can provide compressed representations and disentangle factors of variation. With disentanglement, different parts of the latent space encode information about different factors of variation. Thus different partitions of the latent space provide invariances to different factors. The linear methods described above can be improved significantly in many cases using nonlinear neural architectures, especially when the datasets are larger and more challenging. For example, autoencoders and related architectures are widely employed to learn compressed/latent representations for datasets. This can be done in a supervised fashion as in the case of deep convolutional inverse graphics networks [36] where for different variations, different parts of the latent space are held constant while training. Methods based on variational autoencoders (VAEs) such as Factor VAE [37] impose independence constraints between latent variables in order to perform disentanglement. In deforming autoencoders [38], unsupervised disentanglement of spatial transforms is achieved by using spatial warping layers, and the remaining part of the latent space serves as an invariant to spatial transforms. Similar ideas are employed for designing rate-invariant representations by Koneripalli et al. [39]. Shukla et al. [40] propose product of orthogonal spheres motivated by models of physical factors of variation. Here, the latent space is split into parts such that each part is constrained to lie on a unit hypersphere.

where $\mathbf{x} = (x, y)^T$ are the pixel coordinates, $\mathbf{W}(\mathbf{x}; \mathbf{p})$ is a parameterized set of warps, and $\mathbf{W}(\mathbf{x}; \mathbf{p})$ is a vector of parameters. The Lucas-Kanade algorithm assumes that a current estimate of \mathbf{p} is known and then iteratively solves for increments to the parameters $\Delta\mathbf{p}$, i.e., approximately minimize

$$\sum_{\mathbf{x}} [T(\mathbf{x}) - I(\mathbf{W}(\mathbf{x}; \mathbf{p} + \Delta\mathbf{p}))]^2, \quad (2)$$

with respect to $\Delta\mathbf{p}$ and update the parameters

$$\mathbf{p} \leftarrow \mathbf{p} + \Delta\mathbf{p}. \quad (3)$$

Equation (2) is linearized by performing a first-order Taylor expansion:

$$\sum_{\mathbf{x}} \left[T(\mathbf{x}) - I(\mathbf{W}(\mathbf{x}; \mathbf{p})) - \nabla I \frac{\partial \mathbf{W}}{\partial \mathbf{p}} \Delta\mathbf{p} \right]^2. \quad (4)$$

In this expression, $\nabla I = \left(\frac{\partial I}{\partial x}, \frac{\partial I}{\partial y} \right)$ is the gradient of image I and $\frac{\partial \mathbf{W}}{\partial \mathbf{p}}$ is the Jacobian of the warp. Equation (4) has a closed-form solution as follows. The partial derivative of the expression in Eq. (4) with respect to $\Delta\mathbf{p}$ is

$$-2 \sum_{\mathbf{x}} \left[\nabla I \frac{\partial \mathbf{W}}{\partial \mathbf{p}} \right]^T [T(\mathbf{x}) - I(\mathbf{W}(\mathbf{x}; \mathbf{p})) - \nabla I \frac{\partial \mathbf{W}}{\partial \mathbf{p}} \Delta\mathbf{p}] . \quad (5)$$

Then denote

$$\mathbf{SD}_{lk}(\mathbf{x}) = \nabla I \frac{\partial \mathbf{W}}{\partial \mathbf{p}}, \quad (6)$$

the *steepest-descent* images. Setting the expression in Eq. (5) to equal zero and solving give

$$\Delta\mathbf{p} = H_{lk}^{-1} \sum_{\mathbf{x}} \mathbf{SD}_{lk}^T(\mathbf{x}) E(\mathbf{x}) \quad (7)$$

where H_{lk} is the $n \times n$ (Gauss-Newton approximation to the) *Hessian* matrix

$$\sum_{\mathbf{x}} [T(\mathbf{x}) - I(\mathbf{W}(\mathbf{x}; \mathbf{p}))]^2, \quad (1)$$

Inverse Compositional Algorithm

Definition

The inverse compositional algorithm is a reformulation of the classic Lucas-Kanade algorithm to make the steepest-descent images and Hessian constant.

Background: Lucas-Kanade

The goal of the Lucas-Kanade algorithm is to minimize the sum of squared error between a template image $T(\mathbf{x})$ and a warped input image $I(\mathbf{x})$:

Inverse Compositional Algorithm, Fig. 1 A schematic overview of the inverse compositional algorithm. Steps 3–6 (*light-color arrows*) are performed once as a precomputation. The main algorithm simply consists of iterating image warping (Step 1), image differencing

(Step 2), image dot products (Step 7), multiplication with the inverse of the Hessian (Step 8), and the update to the warp (Step 9). All of these steps can be performed efficiently

and the Hessian must therefore be recomputed in every iteration [1, 2].

$$H_{lk} = \sum_x \mathbf{SD}_{lk}^T(x) \mathbf{SD}_{lk}(x) \quad (8)$$

and

$$E(x) = T(x) - I(W(x; p)) \quad (9)$$

is the *error image*. The Lucas-Kanade algorithm consists of iteratively applying Eqs. (7) and (3). Because the gradient ∇I must be evaluated at $W(x; p)$ and the Jacobian $\frac{\partial W}{\partial p}$ at p , they both depend on p . Both the steepest-descent images

The Inverse Compositional Algorithm

Baker and Matthews [3] proposed the inverse compositional algorithm as a way of reformulating image alignment so that the steepest descent images and Hessian are constant. Although the goal of the inverse compositional algorithm is the same as the Lucas-Kanade algorithm (e.g.,

minimizing Eq. (1)), the inverse compositional algorithm iteratively minimizes

$$\sum_x [T(\mathbf{W}(\mathbf{x}; \Delta\mathbf{p})) - I(\mathbf{W}(\mathbf{x}; \mathbf{p}))]^2, \quad (10)$$

with respect to $\Delta\mathbf{p}$ and then updates the warp

$$\mathbf{W}(\mathbf{x}; \mathbf{p}) \leftarrow \mathbf{W}(\mathbf{x}; \mathbf{p}) \circ \mathbf{W}(\mathbf{x}; \Delta\mathbf{p})^{-1}. \quad (11)$$

The expression

$$\mathbf{W}(\mathbf{x}; \mathbf{p}) \circ \mathbf{W}(\mathbf{x}; \Delta\mathbf{p}) \equiv \mathbf{W}(\mathbf{W}(\mathbf{x}; \Delta\mathbf{p}); \mathbf{p}) \quad (12)$$

is the composition of 2 warps, and $\mathbf{W}(\mathbf{x}; \Delta\mathbf{p})^{-1}$ is the inverse of $\mathbf{W}(\mathbf{x}; \Delta\mathbf{p})$. The inverse compositional algorithm iterates Eq. (10) and (11) and can be shown to be equivalent to the Lucas-Kanade algorithm to first order in $\Delta\mathbf{p}$ [3].

Performing a first-order Taylor expansion on Eq. (10) gives

$$\sum_x \left[T(\mathbf{W}(\mathbf{x}; 0)) + \nabla T \frac{\partial \mathbf{W}}{\partial \mathbf{p}} \Delta\mathbf{p} - I(\mathbf{W}(\mathbf{x}; \mathbf{p})) \right]^2. \quad (13)$$

Assuming that $\mathbf{W}(\mathbf{x}; \mathbf{0})$ is the identity warp, the minimum of this expression is

$$\Delta\mathbf{p} = -H_{ic}^{-1} \sum_x \mathbf{SD}_{ic}^T(\mathbf{x}) E(\mathbf{x}), \quad (14)$$

where $\mathbf{SD}_{ic}^T(\mathbf{x})$ are the steepest-descent images with I replaced by T :

$$\mathbf{SD}_{ic}(\mathbf{x}) = \nabla T \frac{\partial \mathbf{W}}{\partial \mathbf{p}}, \quad (15)$$

H_{ic} is the Hessian matrix computed using the new steepest-descent images:

$$H_{ic} = \sum_x \mathbf{SD}_{ic}^T(\mathbf{x}) \mathbf{SD}_{ic}(\mathbf{x}), \quad (16)$$

and the Jacobian $\frac{\partial \mathbf{W}}{\partial \mathbf{p}}$ is evaluated at $(\mathbf{x}; \mathbf{0})$. Since there is nothing in either the steepest-descent images or the Hessian that depends on \mathbf{p} , they can

both be precomputed. The inverse composition algorithm is illustrated in Fig. 1.

Application

The inverse compositional algorithm can be used almost anywhere the Lucas-Kanade can be. It can be applied to anything from simple translational motion to dense optical flow. Perhaps the most significant application is its use to speed-up the fitting or tracking of active appearance models [4, 5].

Definition

Light transport describes how the light propagates into a known 3D scene. The inverse light transport problem takes a set of images of an unknown scene as input and infers the light transport process in the scene.

Background

Although the light transport simulation and acquisition have been well studied in computer graphics, the inverse light transport is still an open problem and hasn't been systematically investigated. This is due to the complexity of the paths of light propagation in the scene, as well as variations of surface BRDFs along each light path. The problem becomes even more challenging when the scene geometry and illumination are unknown.

A set of inverse light transport methods [3, 10, 14] decompose the light transport into the direct lighting and indirect lighting parts. Most of these methods make some assumptions about the scene reflectance or lighting conditions. Several methods [2, 11, 15] first capture the light transport matrix of a scene and then decompose the images of the scene as a set of light transport components that correspond to different number of light bounces in the scene. Other methods leverage the time-of-flight imaging [13] or optical computing [12] to obtain the light transport of a scene with different number of bounces.

Different from the inverse rendering problem that mainly focuses on direct illumination effects and ignores the interreflection in the scene, the inverse light transport problem focuses on deriving the interreflections of the light in the scene (i.e., the multiple bounces of the light between scene surfaces). The inverse light transport techniques can be combined with the inverse rendering approaches for recovering scene geometry [9] and reflectance [16] from the images that consists of global illumination effects of the scene.

Theory

The light transport can be modeled by the rendering equation [7]

$$\begin{aligned} L(x, x') = & L_e(x, x') \\ & + \int_S \rho(x, x', x'') G(x', x'') L(x', x'') dx'', \end{aligned} \quad (1)$$

where $L(x, x')$ is the radiance from a surface point x' to another point x , $L_e(x, x')$ is the light emitted from x' toward x , $\rho(x, x', x'')$ is the BRDF (i.e., surface reflectance) at x' , $L(x', x'')$ is the incident light from another surface point x'' in the scene to x' , and $G(x', x'')$ is the geometry factor between x' and x'' . The integration is performed over all surface points S .

Seitz et al. [15] proved that for image captured from an unknown scene under unknown illumination, there are a set of linear operators that can remove the N-bounce interreflections from the image. By assuming the scene geometry is composed of a set of small surface patches, the rendering equation can be discretized as [15]

$$L_o[i] = L_o^1[i] + \sum_j A[i, j] L_o(j), \quad (2)$$

where $L_o[i]$ is the outgoing radiance from surface patch i of x' , $L_o^1[i]$ is the outgoing radiance with the first surface bounce (i.e., the radiance caused by the direct lighting), and $A[i, j]$ represents the light transport from surface patch j to i , which is determined by the BRDF of patch i and the geometry factor between patch i and j . So we can formulate the light transport in the matrix form and solve the light transport by [7]

$$L_o = L_o^1 + AL_o = (I - A)^{-1} L_o^1. \quad (3)$$

Given this equation, we can define a set of linear operators

$$C^1 = I - A \quad (4)$$

$$C^n = C^1(I - C^1)^{n-1} \quad (5)$$

to remove the N-bounce interreflections L_o^n from the image recursively

$$L_o^1 = C^1 L_o \quad (6)$$

$$L_o^n = C^n L_o \quad (7)$$

Durand et al. [5] provided a frequency analysis framework for light transport in a scene. Bai et al. [2] analyzed the duality of forward and inverse light transport and formulated the inverse light transport as a Neumann series.

Applications

Since most vision algorithms assume the scene is directly illuminated by the light sources, one application of inverse light transport is to remove the interreflections from the input images of these vision algorithms. Also, the inverse light transport can work with this vision algorithms for recovering shape [9], reflection [16], or illumination compensation [2].

Another application of inverse light transport is the image manipulation, where the users could change the albedo or reflectance properties of the objects in the image and keep the interreflections between different objects consistent, such as the color bleeding between the diffuse surfaces [3] or mirrorlike reflection of a diffuse surface [4].

In time-of-flight imaging, the interreflections of the light between scene surfaces (i.e., multiple path interference) will result in the bias of the measured depth. Therefore, the inverse light transport technique is very important for removing the effect of interreflections in time-of-flight imaging [1, 6, 8].

Open Problems

Similar to the inverse rendering problem, the inverse light transport problem is ill-conditioned when only one among three scene properties (i.e., geometry, reflectance, and illumination) is known while the other two are unknown. Different from many inverse rendering problems where the color

of each surface point can be determined by the geometry, reflectance, and incoming lighting at this surface point, the light transport in a scene takes the interreflection between surfaces in consideration. As a result, the color of a surface point is determined by the properties of all surface points along the light paths passing through this surface point. Therefore, the inverse light transport with single unknown (one of the lighting, scene geometry, or surface reflectance) is still a challenging problem.

Definition

The rendering refers to the procedure that generates an image of a 3D scene from its geometry, surface reflectance, and lighting. The inverse rendering is the reverse process of the rendering that derives unknown surface reflectance, lighting, and scene geometry from images of a 3D scene.

Background

Inverse rendering is a fundamental problem in 3D vision and covers almost all research topics that derive the physical properties of a 3D scene from its images. Specifically, an image of a 3D scene can be determined by the geometry and layout of 3D objects in the scene, reflectance properties of the objects, as well as the lighting conditions of the scene. According to the number of unknown factors (i.e., geometry, reflectance, and lighting) computed in the inverse rendering, we could classify these research topics into several categories.

Inverse rendering with one unknown Shape from shading techniques [19] assume the lighting and surface albedo are known and recover the surface geometry from single image with known viewpoint.

Surface reflectance acquisition approaches [17, 20] assume the surface geometry and lighting are known and recover the spatially varying BRDF (SVBRDF) over the surface from images taken from fixed or different viewing directions.

For light estimation and calibration [8], most approaches assume the scene is lit by point or directional light sources and then estimate the position and intensity of each light source from images of a 3D scene with known geometry and surface reflectance.

Inverse rendering with two unknowns Photometric stereo techniques [1] and other multiple-view-based methods [16] reconstruct surface geometry and reflectance from images captured with known lighting conditions.

A set of methods [2, 4, 14] assume the scene geometry is known and estimate both SVBRDF and lighting from the images of the scene.

Inverse rendering with all three unknowns Many methods have been presented for recovering all three unknowns (i.e., lighting, surface geometry, and reflectance) from images captured from a scene.

Intrinsic image decomposition [11] assumes the surface is Lambertian and decomposes an input image as the product of surface albedo and

shading that fuses the normal and lighting information at each surface point. Based on the same assumption, later techniques [3] further recover surface geometry, albedo, and low-frequency illumination from single input image.

For the scenes with arbitrary surface reflectance, a set of methods automatically reconstruct all three unknowns from single image [10, 15] or a set of images [18].

Theory

Problem Formulation Given a 3D scene, the outgoing radiance $L(x, x')$ from a surface point x' to another point x in the scene is determined by the rendering equation [9]

$$\begin{aligned} L(x, x') = & L_e(x, x') \\ & + \int_S \rho(x, x', x'') G(x', x'') L(x'', x'') dx'', \end{aligned} \quad (1)$$

where $L_e(x, x')$ is the light emitted from x' toward x , $\rho(x, x', x'')$ is the BRDF (i.e., surface reflectance) at x' , $L(x', x'')$ is the incident radiance from another surface point x'' to x' , and $G(x', x'')$ is the geometry factor determined by the local geometry of around x' and x'' . The integration in the rendering equation is performed over all surface points S . Please refer to [9] for more details.

For inverse rendering, we focus more on the appearance of a scene surface lit by the light source and reflected radiance of surrounding scenes. To this end, we ignore the interreflections in the scene and reparameterized the rendering equation and related terms as

$$\begin{aligned} L(x_p, \omega_o) = & \int_{\Omega^+} \rho(x_p, \omega_i, \omega_o) (n(x_p) \cdot \omega_i) \\ & V(x_p, \omega_i) L(x_p, \omega_i) d\omega_i, \end{aligned} \quad (2)$$

where x_p is a surface point visible at pixel p and $n(x_p)$ is its surface normal, ω_o is the viewing direction from x_p to pixel p , and $\rho(x_p, \omega_i, \omega_o)$ is the BRDF (i.e., surface reflectance) at x_p . $L(x_p, \omega_i)$ is the incident radiance from a light

source or other surface point to x_p along the direction ω_i , and $V(x_p, \omega_i)$ is the visibility of x_p along ω_i . The integration is performed over the upper hemisphere Ω^+ over x_p .

Signal Processing Framework of Inverse Rendering Ramamoorthi and Hanrahan [12, 13] formulated the inverse rendering as a deconvolution of the reflected light field. Based on this formulation, they provided a theoretical analysis of inverse rendering and discussed the well-posedness of various inverse rendering tasks. The conclusion is that with the known geometry and high-frequency BRDF or lighting, the inverse rendering with the one unknown is well-posed.

Priors of 3D Scenes for Inverse Rendering All inverse rendering problems could be solved by minimizing the difference between the images rendered from the reconstructed unknowns and the captured images. Due to the illposedness of the inverse rendering, some priors of the scene geometry, reflectance, or lighting should be applied in optimization as constraints. A key effort in inverse rendering is to develop new and efficient priors. Here, we summarize the priors frequently used in the existing inverse rendering solutions.

- **Geometry prior.** The shape smoothness and spatial distribution of the surface normals are often used to constrain the reconstructed surface shapes [3] in inverse rendering. For a family of objects with similar shapes (e.g., human faces), the parametric model (e.g., morphable model) of shape space is an efficient constraint for inverse rendering [7].
- **SVBRDF prior.** For each surface point, the compact parametric BRDF model is always applied to simplify the SVBRDF reconstruction [18]. For SVBRDF, the coherence of BRDFs on all surface points in spatial domain [11] or BRDF domain [20] has also been exploited in inverse rendering. For human faces with similar shapes and appearances, the PCA model of face albedo map pre-computed from a 3D face dataset can be used for recovering face shape, albedo, and illumination from single face image [7].

- Lighting prior. A common practice is to simplify the lighting as a sparse set of point or directional light sources. For natural environmental lighting, the smoothness of an environmental lighting in angular domain [4] and the statistics of the real environmental lightings [14] are served as priors in different inverse rendering solutions.

With the recent advances of deep learning techniques, a set of methods [5, 6, 10, 15] automatically learn the priors of scene geometry, reflectance, and lighting from the training dataset and solve the inverse rendering problem via deep learning.

Open Problems

The inverse rendering problem is still an open and challenging problem in computer vision due to its illposedness. The key problem is how to develop or learn effective priors of lighting, scene geometry, and reflectance, as well as their relationships from real-world observations.

Irradiance, Fig. 1 Geometric setting

Related Concepts

► RADIANCE

Definition

Irradiance E is defined as the incident power of electromagnetic radiation on a surface per unit surface area. It is expressed in watt per square meter ($\text{W} \cdot \text{m}^{-2}$).

Background

Irradiance is a concept from radiometry, the science of measuring radiant energy transfer [1]. The equivalent concept in photometry is illuminance, with the key difference being that illuminance is adjusted to account for the varying sensitivity of the human eye to different wavelengths of light.

Theory

The irradiance at a surface point x is proportional to the radiance $L(x, \theta, \phi)$ arriving at x from direction (θ, ϕ) with a geometric foreshortening factor $\cos \theta$. Taking into account the whole hemisphere above the surface point, the irradiance is the integral over all incoming directions

$$E(x) = \int_{\theta, \phi} L(x, \theta, \phi) \cos \theta \, d\theta d\phi. \quad (1)$$

θ denotes the angle between the surface normal and the incident direction (θ, ϕ) (see Fig. 1).

Application

For a camera with an optical lens and an aperture, the image irradiance at a camera sensor is proportional to the radiance L emitted from a small scene patch in the form that

$$E = L \frac{\pi}{4} \left(\frac{d}{f} \right)^2 \cos \alpha^4 \quad (2)$$

where d is the aperture and f the focal length of the lens. α is the angle between the direction to the observed patch and the principal ray of the camera. For wide-angle lenses, the influence of α often results in a reduction of an image's brightness at the corners compared to the image center. This effect is also called vignetting.

The pixel values of digital images are directly related to the irradiance at the sensor of the camera via the camera's response curve [2, 3]. Many computer vision techniques such as photometric stereo use this fact to recover information about the scene from the irradiance. Early works in this field include [4] and [5].

Definition

In many settings the conventional Euclidean differential geometry is not appropriate. A common case involves “graphs,” an instance being images where the carrier may be modeled as the Euclidean plane, but the intensity domain is incommensurate. Isotropic differential geometry allows one to deal with such cases.

Background

Isotropic differential geometry became highly developed during the first half of the twentieth century, mainly in German-speaking countries. The bulk of the literature is still in German.

Theory

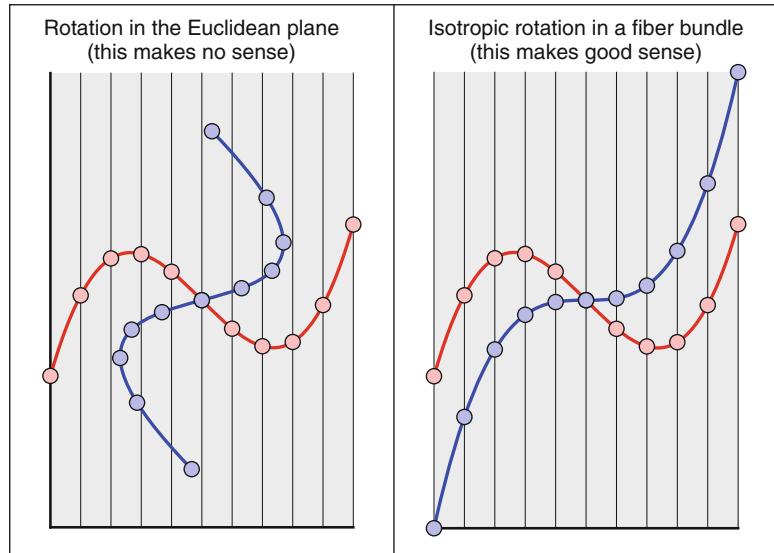

There are frequent cases in computer vision and image processing in which the Euclidean \mathbb{E}^3 setting from classical differential geometry is not appropriate. A simple example is an image, which may be thought of as the Euclidean plane \mathbb{E}^2 , augmented with some “intensity domain.” Intensities are nonnegative quantities that somehow reflect photon-catches in, e.g., CCD devices. Usually the physical dimension is unclear and considered irrelevant to the problem. Then the structure of the intensity domain is most appropriately modeled by the affine line \mathbb{A}^1 , by considering the logarithm of the intensity modulo some arbitrary constant. But the $\mathbb{E}^2 \times \mathbb{A}^1$ -space is quite unlike \mathbb{E}^3 as becomes evident when one considers Euclidean rotations about some axis in the image plane. Such rotations make no sense because photon catches and lengths are incommensurable physical quantities. The correct way to proceed is to consider “image space” to be a fiber bundle with base space \mathbb{E}^2 and fibers \mathbb{A}^1 . Permissible transformations do not “mix” fibers, and Euclidean rotations about axes in the image plane are not among them.

This situation is typical in many contexts. The simplest example is perhaps a graph $y = f(x)$, where x and y are incommensurable physical quantities. Although the graph is evidently a curve in the xy -plane, it makes no sense to compute its Euclidean curvature as the result will depend on irrelevant transformations of the y -domain (Fig. 1).

A formal way to deal with such problems is to treat the y -axis as an isotropic dimension. Then the metric in the plane is essentially the separation in the x -dimension, the y -separation being treated as isotropic, i.e., nil. Thus the distance of points $\{x_1, y_1\}$ and $\{x_2, y_2\}$ is taken to be $x_2 -$

Isotropic Differential Geometry in Graph Spaces

Fig. 1 At left a graph in red, and the graph after a Euclidean rotation (in blue). This obviously makes no sense at all: the blue curve is not even a graph anymore! This is not a fiber bundle. At right the red graph has been subjected to an isotropic rotation. This makes perfect sense, one obtains another graph. Notice that the points move up and down along the fibers of the fiber space, they never leave their fiber, fibers “do not mix”

x_1 . Notice that this implies that points $\{x, y_1\}$ and $\{x, y_2\}$ with $y_1 \neq y_2$ are at mutually zero distance, yet different. One denotes such points “parallel” and assigns them the “special distance” $y_2 - y_1$. Only parallel points have a special distance, generic points only a proper distance. The group of “isotropic motions”:

$$x' = x + t_x, \quad (1)$$

$$y' = \alpha x + y + t_y, \quad (2)$$

conserves proper distance and, in the case of parallel points, special distance. This group is fit to replace the group of Euclidean movements:

$$x' = x \cos \alpha - y \sin \alpha + t_x, \quad (3)$$

$$y' = x \sin \alpha + y \cos \alpha + t_y, \quad (4)$$

and indeed has a somewhat similar (with important differences!) structure.

One obtains this group if the xy -plane is interpreted as the dual number plane. Dual numbers are complex numbers $z = x + \varepsilon y$, where the imaginary unit ε is defined as a nontrivial (i.e., not equal zero) solution of the quadratic equation $\varepsilon^2 = 0$. Thus $\varepsilon \neq 0$ whereas $\varepsilon^2 = 0$, from which one derives that neither $\varepsilon > 0$, nor $\varepsilon < 0$.

Thus one is forced to use intuitionistic logic, for instance dropping the law of the excluded middle. A concrete representation is by way of matrices:

$$z = x + \varepsilon y = \begin{pmatrix} x & y \\ 0 & x \end{pmatrix}, \quad (5)$$

then addition and multiplication of dual numbers may be done by matrix algebra, similar to the conventional complex numbers $x + iy$ with imaginary unit $i^2 = -1$, which are modeled through matrix algebra with the matrices:

$$z = x + iy = \begin{pmatrix} x & -y \\ y & x \end{pmatrix}. \quad (6)$$

However, although perhaps less scary, these matrix models are an unnecessary pain in hand calculations.

A linear transformation $z' = az + b$ with $a = 1 + \varepsilon\alpha$ and $b = t_x + \varepsilon t_y$ becomes:

$$\begin{aligned} z' &= (1 + \varepsilon\alpha)(x + \varepsilon y) + (t_x + \varepsilon t_y) \\ &= (x + t_x) + \varepsilon(\alpha x + y + t_y), \end{aligned} \quad (7)$$

(using $\varepsilon^2 = 0$), i.e., exactly the transformation given above. Apparently the dual imaginary unit is an “infinitesimal.” Indeed, the full Taylor expansion of a function F about x is:

$$F(x + \varepsilon h) = F(x) + \varepsilon h F'(x). \quad (8)$$

$$k(x) = \frac{y_{xx}(x)}{(1 + y_x(x)^2)^{3/2}}. \quad (13)$$

Specifically, one has:

$$\sin \varepsilon \xi = \varepsilon \xi, \quad (9)$$

$$\cos \varepsilon \xi = 1, \quad (10)$$

$$e^{\varepsilon \xi} = 1 + \varepsilon \xi, \quad (11)$$

thus trigonometry becomes really convenient. The polar representation of a dual number becomes:

$$z = x + \varepsilon y = x \left(1 + \varepsilon \frac{y}{x} \right) = |z| e^{\varepsilon \arg z}. \quad (12)$$

The dual angle is $y/x = y/x$ (notice that an isotropic angle equals its tangent!), thus the angle measure is parabolic instead of elliptic. Angles do not repeat with period 2π as in the Euclidean plane, but run between $\pm\infty$. Rotating the point 1 (that is $1 + \varepsilon 0$) about the origin over an angle α yields $1 + \varepsilon \alpha$, thus the line $x = 1$ is (part of) a unit circle. This brings one back to the original construction, and the rotations do not “mix” the x and y dimensions in a way that would be nonsense from the perspective of physics.

The group of proper motions (translations and rotations) of the dual plane leads to a differential geometry of curves that differs from that of the Euclidean plane. Consider the curve $z(x) = x + \varepsilon y(x)$. It is evidently parameterized by arc length, for $|z_x|^2 = 1$. The tangent is $t(x) = z_x = 1 + \varepsilon y_x(x)$, and is a unit vector, for $|t(x)| = 1$. The unit normal is ε , for $t_x(x) = \varepsilon y_{xx}(x)$ with (special) length $y_{xx}(x)$. Thus the normal is constant along the curve and useless for the purposes of differential geometry. The slope of the tangent is well defined though, the tangent subtends an angle $y_x(x)$ with the x -axis. The derivative of this angle with arc-length is $y_{xx}(x)$, thus one concludes that the curve has curvature $k(x) = y_{xx}(x)$. Notice that it is a much simpler expression than one has in the Euclidean plane, which is:

As expected, the Euclidean and the dual curvatures agree to first order, and for very shallow curves (infinitesimally near the x -axis) the Euclidean curvature degenerates to the dual curvature.

A curve:

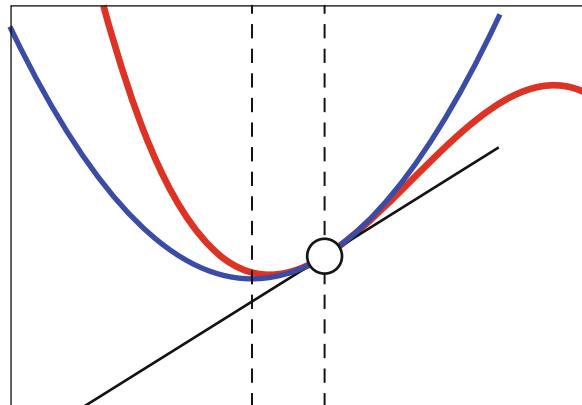

$$z(x) = \varepsilon \frac{(x - c)^2}{2R}, \quad (14)$$

has curvature $1/R$, thus a radius of curvature R and is centered on $x = c$. It is evidently a circle in some sense, though different from the circle encountered above. One denotes $x = \pm 1$ a unit circle of the first kind, with center at the origin, $\varepsilon x^2/2$ a unit circle of the second kind, centered at the origin. The local second-order Taylor expansion of a curve is illustrated in Fig. 2. It is a parabola with isotropic axis, thus a “circle of the second kind.” It is the osculating circle to the curve in the isotropic geometry. The radius of the osculating circle is evidently the reciprocal of the second derivative, thus a curve $x + \varepsilon y(x)$ has curvature $y_{xx}(x)$ as argued above.

The differential geometry of curves and surfaces in a fiber bundle $\mathbb{E}^2 \times \mathbb{A}^1$ can be handled in a similar manner. All expressions are much simpler than those in Euclidean differential geometry, which is a very useful property, apart from the advantage that they make sense for a change. (Inappropriate applications of expressions taken from Euclidean differential geometry occur very frequently in computer vision and image processing. Although they certainly yield numerical results, they strictly speaking make no sense.) Thus the mean curvature of a surface $\{x, y, z(x, y)\}$ in Monge form becomes $2H = z_{xx} + z_{yy}$, the Gaussian curvature $K = z_{xx}z_{yy} - z_{xy}^2$, and so forth. Like in the planar case discussed above, the normal is constant, and thus useless. One uses the spatial attitude of the tangent plane instead. Any point of the surface may be mapped on the unit sphere of the second kind $z(x, y) = (x^2 + y^2)/2$ through parallelity of tangent planes. Even more conveniently, one notices that the xy -plane $\{x, y$

Isotropic Differential Geometry in Graph Spaces, Fig. 2

Consider the local Taylor expansion of the *red curve* at the point indicated by the *white dot*. The first order is the drawn *black line*, the second-order approximation is the *blue parabola*. The center of this “circle of the second kind” is indicated by the leftmost *dotted line*. The other *dotted line* is the normal direction

$0\}$ is the stereographic projection of this sphere, thus conformal, but most remarkably – because different from the Euclidean case – also isometric. Thus the Gauss map becomes

$$\{x, y, z(x, y)\} \in \mathbb{E}^2 \times \mathbb{A}^1 \mapsto \begin{cases} -z_x(x, y), \\ -z_y(x, y) \end{cases} \in \mathbb{R}^2, \quad (15)$$

a map that is familiar in computer vision as “gradient space.” Gradient space is often used by way of a “linear approximation,” but it is really the exact Gauss map (or “spherical image”) in terms of the appropriate differential geometry.

The geometry of single isotropic space is well understood, although almost all of the literature is in German. The paper by Pottmann is the only reference in English on the general (space) setting, the book by Yaglom (translated into English from Russian) is an excellent introduction to the geometry of the dual plane.

Open Problems

This section introduced a very simple setting. In general one may have to deal with a graph over a curved surface. The paper by Pottmann gives some leads as how to handle such more general cases.

Iterative Closest Point (ICP)

Zhengyou Zhang

Tencent AI Lab & Robotics X, Shenzhen, China

Synonyms

ICP

Definition

Iterative closest point (ICP) is a popular algorithm employed to register two sets of curves, two sets of surfaces, or two clouds of points.

Background

The ICP technique was proposed independently by Besl and McKay [1] and Zhang [2] in two different contexts. Besl and McKay [1] developed the ICP algorithm to register partially sensed data from rigid objects with an ideal geometric model, prior to shape inspection. So this is a subset–set matching problem because each sensed point has a correspondence in the ideal model. Zhang [2] developed the ICP algorithm in the context of autonomous vehicle navigation in rugged terrain based on vision. His algorithm is used to register a sequence of sensed data in order to build a complete model of the scene and to plan a free path for navigation. So this is a subset–subset matching problem because a fraction of data in one set does not have any correspondence in the other set. To address this issue, Zhang's ICP algorithm has integrated a statistical method based on the distance distribution to deal with outliers, occlusion, appearance, and disappearance. However, both algorithms share the same idea: iteratively match points in one set to the closest points in another set and refine the transformation between the two sets, with the goal of minimizing the distance between the two sets of point clouds.

Theory

The ICP algorithm is very simple and can be summarized as follows:

- *Input:* two point sets, initial estimation of the transformation
- *Output:* optimal transformation between the two point sets
- *Procedure:* Iterate the following steps:
 - (i) Apply the current estimate of the transformation to the first set of points.
 - (ii) Find the closest point in the second set for each point in the first transformed point set.

- (iii) Update the point matches by discarding outliers.
- (iv) Compute the transformation using the updated point matches, until convergence of the estimated transformation.

Here are a few comments on this general algorithm:

- Depending on the nature of the point sets, various pose estimation techniques described in the earlier sections can be used to compute the transformation between the two sets.
- The step of finding the closest point to a given point is generally the most time-expensive one. However, this step can be easily parallelized.
- Many data structures can be used to accelerate the finding of the closest point. They include k-D tree and octree.
- Instead of using all points from the first set, a selected subset of points (such as high curvature points) can be used to speed up the process, with only moderate sacrifice of the final accuracy.
- The above algorithm is not symmetric. Let point \hat{p}'_i in the second set be the closest point to a point p_i in the first set. In the other direction, point p_i is, in general, not necessarily the closest point to \hat{p}'_i . In order to make the algorithm symmetric, we can find the closest point in the first transformed point set for each point in the second set and add these point matches to the overall set of matches. Better results can then be obtained at the expense of additional computational cost.
- When the ICP algorithm is applied to register curves or surfaces, they need to be sampled. The final accuracy depends on the density of sampling. The denser the sampling is, the higher the registration quality will be, but the more the computation will be required.

For more detailed and extensive discussions on ICP, the interested reader is referred to Sects. 7 and 8 of Zhang's paper [2].

There are several variants to the ICP algorithm. A useful variation is to substitute the point-to-point distance with point-to-plane distance [3]. The point-to-plane distance allows one surface to slide tangentially along the other surface, making it less likely get stuck in local minima. Consider a point p_i in the first set. Let point \hat{p}'_i in the second set be its closest point. Let the surface normal at point p_i be n_i (a unit vector). Then, the point-to-plane distance measure is given by

$$d_i = n_i^T (\hat{p}'_i - p_i).$$

Surface normals can be precomputed to save computation.

Definition

The Kalman filter is a set of mathematical equations that provides an efficient computational (recursive) means to estimate the state of a process, in a way that minimizes the mean of the squared error. The filter is very powerful in several aspects: it supports estimations of past, present, and even future states, and it can do so even when the precise nature of the modeled system is unknown.

Background

In 1960, Rudolf E. Kalman published his famous paper describing a recursive solution to the discrete-data linear filtering problem [1]. Since that time, due in large part to advances in digital computing, the Kalman filter has been the subject of extensive research and application, particularly in the area of autonomous or assisted navigation. The goal of the filter is to produce evolving optimal estimates of a modeled process from noisy measurements of the process.

Theory

The Kalman filter addresses the general problem of trying to estimate the state $x \in \mathbb{R}^n$ of a discrete-time controlled process that is governed by the linear stochastic difference equation

$$x_k = Ax_{k-1} + Bu_{k-1} + w_{k-1} \quad (1)$$

at time step k , with a measurement $z \in \mathbb{R}^m$ that is

$$z_k = Hx_k + v_k. \quad (2)$$

The random variables w_k and v_k represent the *process noise* and *measurement noise*, respectively. They are assumed to be independent of each other, white, and with normal probability distributions

$$p(w) \sim N(0, Q), \quad \text{and} \quad (3)$$

$$p(v) \sim N(0, R). \quad (4)$$

The $n \times n$ matrix A in the difference Eq. (1) relates the state x at the previous time step $k - 1$ to the state x at the current step k , in the absence of either a driving function or process noise. The $n \times l$ matrix B relates an optional control input $u \in \mathbb{R}^l$ to the state x . The $m \times n$ matrix H in the measurement Eq. (2) relates the state to the measurement z_k .

One usually does not know the true form of the process (1) and associated noise parameter (3) nor the true measurement model (2) and associated noise parameter (4), but in practice one can often arrive at useful models via analytical formulations and laboratory-based measurements.

Using the process and measurement models (1)–(4), and real (noisy) measurements \hat{z}_k at each time step k , the *Kalman filter* is used to recursively estimate the first two statistical moments of the process: the mean \hat{x}_k and the error covariance P_k .

The filter is typically implemented in two steps, a *time update* step and a *measurement update* step, as follows:

Time update:

$$\begin{aligned}\hat{x}_k^- &= A\hat{x}_{k-1} + Bu_{k-1} \\ P_k^- &= AP_{k-1}A^\top + Q\end{aligned}$$

Measurement update:

$$\begin{aligned}K &= P_k^- H^\top (HP_k^- H^\top + R)^{-1} \\ \hat{x}_k &= \hat{x}_k^- + K(\hat{z}_k - H\hat{x}_k^-) \\ P_k &= (I - KH)P_k^-\end{aligned}$$

Repeatedly applying these steps recursively estimates the process mean \hat{x}_k and the error covariance P_k . Because the measurements can vary in form and timing, the filter is often characterized as a tool for *sensor fusion*.

The *Kalman filter* is optimal in that the $n \times m$ *Kalman gain* matrix K minimizes the trace of a posteriori error covariance P_k .

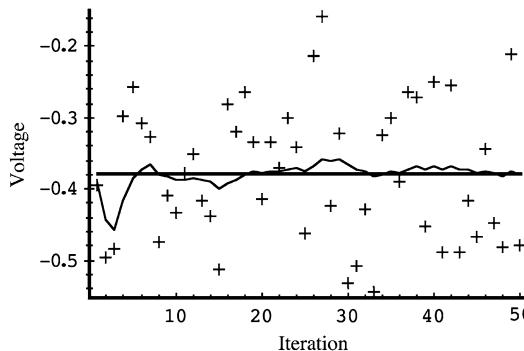

An accessible high-level introduction to the general idea of the Kalman filter can be found in Chap. 1 of [2]. A more complete introduction can be found in [3] and in [4] which also contains some interesting historical narrative. More extensive references include [2, 5–9].

Application

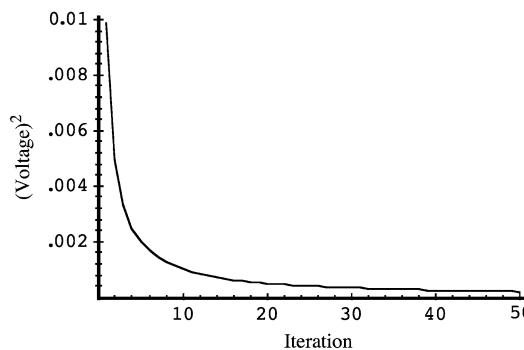

Despite the fact that employed process models rarely match the corresponding true systems, and the noise models rarely exhibit the characteristics required for optimality (zero mean, normally distributed, and independence over space and time), the Kalman filter remains popular – perhaps due to its relative simplicity and robustness. It continues to be used widely in diverse application areas such as electronics, robotics, localization, navigation, and even economics. In computer vision, variations of the Kalman filter are typically used to estimate structure, motion, and camera parameters. Early examples include [10–13]. Both the OpenCV software project [14, 15] and the Matlab numerical computing environment [16] include Kalman filter functions.

Experimental Results

A relatively simple example of using the Kalman filter to estimate a scalar random constant is given in [3], with complete details for the structure of the filter, the parameters, the initial conditions, and various results. The example presumes access to noisy measurements of a voltage that is corrupted by a 0.1 volt RMS white measurement noise. Referring back to Eqs. (1) and (2), the value to be estimated is presumed constant so $A = 1$, there is no control input so $u = 0$ (and B is irrelevant), and the noisy measurements are of the state (the voltage) directly so $H = 1$. For a true voltage of $x = -0.37727$, $Q = 1 \times 10^{-5}$, and $R = (0.1)^2 = 0.01$, plots for the true voltage x_k , noisy measurements, and estimated voltage \hat{x}_k are shown in Fig. 1; and the error covariance P_k is shown in Fig. 2.

Kalman Filter, Fig. 1 An example: estimating a random constant from noisy measurements. The true random constant x_k (solid line), the noisy measurements \hat{z}_k (cross marks), and the filter estimate \hat{x}_k

Kalman Filter, Fig. 2 The error covariance P_k associated with the estimates in Fig. 1. After 50 iterations, the covariance has settled to a relatively small 0.0002 volts²

Definition

Kinematic motion models are mathematical models that describe the motion of objects without consideration of forces.

Background

Although kinematics is in general more broadly defined, in computer vision, the term kinematic motion model is usually used synonymously with kinematic chain motion models, a term that comes from the field of robotics. Such a model defines a set of rigid objects (called links) that are connected with joints. The motion of the links is constraint by the degrees of freedom of the joints. For instance, a link can only rotate relative to

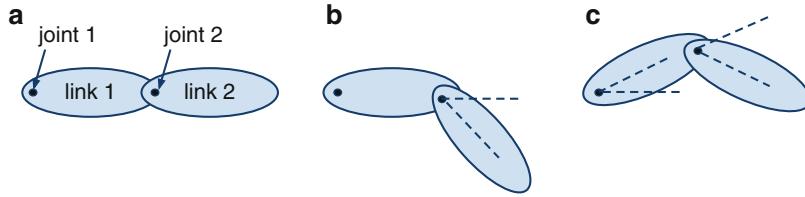

another link around a joint axis. These models are most commonly used to describe human and animal skeletal models or robotic manipulators. The motion constraints can be used for robust visual tracking of skeletal configurations in single-view or multi-view video. Other kinematic models include special cases like one single rigid object, or more general motion models like deformable models, often called nonrigid models. A kinematic motion model does not consider mass distributions and forces that influence the motion. This is described by so-called dynamical models.

Theory

A kinematic chain is a sequence of rigid links l_i that are connected by joints at location j_i (Fig. 1). There are different types of joints (Fig. 2). The simplest is a “revolute joint,” which has one axis of rotation α_i . Other possible joint types are “prismatic joints” (sliding along an axis) and joints with two or three axes of rotations (sometimes called “ball joints” or “spherical joints”). The configuration of the kinematic chain is defined by the relative joint angles between links. For instance, Fig. 1a shows a chain model with all angles set to 0 and another configuration (Fig. 1b, c) with different angle values. The first link in the chain is called the base link l_0 . To represent a human skeleton, the base link is usually the hip, and several chains originating from l_0 define spine, head, arms, and legs. Connecting several chains this way leads to a kinematic tree, but for simplicity only chains are discussed. The base joint l_0 is either fixed or can move with any arbitrary translation T_0 and rotation R_0 . The configuration $\theta = [R_0, T_0, \alpha_1, \dots, \alpha_k]$ of all $k + 6$ degrees of freedom (local joint angles and l_0 translation and orientation) is often called the pose.

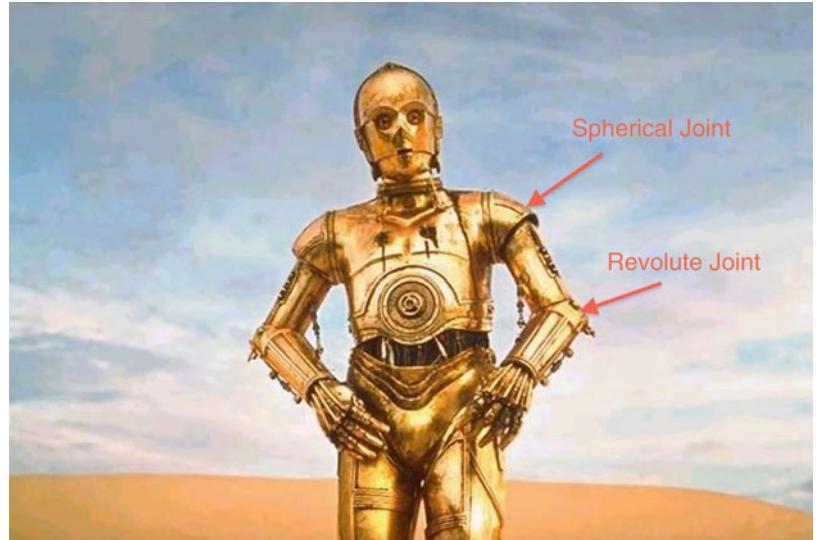

Forward Kinematics

Mathematically the kinematic model (M) can be defined in terms of how points P_i on a specific link in the rest pose are moved to points Q_i by a new kinematic configuration θ (Fig. 1):

Kinematic Motion Models, Fig. 1 Example of a kinematic chain representation. (a) Rest pose. (b) Joint 2 rotates. (c) Joint 1 rotates

Kinematic Motion Models, Fig. 2 Different kinematic joint types

$$Q_i = M(\theta, P_i) \quad (1)$$

A very important aspect of kinematic chain models is that a rotation of a link l_a affects all link motions further down the chain l_b with $a > b$. For example, a rotation of a shoulder joint affects the global elbow position and rotation of the wrist link. But a local rotation of the elbow will not affect links further up. Starting with the scenario of changing the joint angle α_k of the last link l_k only (Fig. 1b), the motion of a point P_i on l_k to Q_i can be calculated by the following translation and rotation using homogeneous coordinates for P_i and $Q_i = [x, y, z, 1]^T$:

$$\begin{aligned} Q_i &= \begin{bmatrix} \mathbf{R}_k & (j_k - R_k \cdot j_k) \\ 0 & 0 & 0 & 1 \end{bmatrix} \\ P_i &= G_k \cdot P_i \end{aligned} \quad (2)$$

The rotation matrix R_k can be parameterized using Euler angles or the exponential map of a twist [1]. The exponential map of a twist leads to simpler computation of derivatives in tracking equations (as described below):

$$G_k(\alpha) = \exp \left(\begin{bmatrix} 0 & -\omega_z & \omega_y & v_1 \\ \omega_z & 0 & -\omega_x & v_2 \\ -\omega_y & \omega_x & 0 & v_3 \\ 0 & 0 & 0 & 0 \end{bmatrix} \cdot \alpha \right)$$

with twist $\xi_k = \begin{bmatrix} v_1 \\ v_2 \\ v_3 \\ \omega_x \\ \omega_y \\ \omega_z \end{bmatrix}$

(3)

For a single axis joint (1 DOF), the twist ξ_k defines the axis at joint j_k (with $\omega_x^2 + \omega_y^2 + \omega_z^2 = 1$). α is the angle around the axis. The twist is

constant, and α is the only varying parameter. For ball joints, it is modeled as a sequence on single axis joints around the same location j_k . Alternatively it can be modeled as letting all directional components for the twist vary.

Rotations of links further up the chain can be incorporated link by link. For instance, all points that are affected by a rotation around link location l_{k-1} are defined by G_{k-1} , including the points Q_i that have been moved by G_k already (Fig. 1c):

$$Q'_i = G_{k-1}(\alpha_{k-1}). \quad (4)$$

$$Q_i = G_{k-1}(\alpha_{k-1}) \cdot G_k(\alpha_k) \cdot P_i$$

Working all the way backward to the base link l_0 results in a product of G_0 to G_k :

$$Q''_i = G_0 \cdot G_1 \cdot \dots \cdot G_k \cdot P_i \quad (5)$$

$$= M_k(R_0, T_0, \alpha_1, \dots, \alpha_k) \cdot$$

$$P_i = M(\theta) \cdot P_i \quad (6)$$

The position and motion M_i of links further up the chain ($i < k$) can be modeled in the same way, as the product of G_0 to G_i . Using for G_0 to G_k the exponential map of twist representation, this equation is referred to as the “product of exponential map” representation [1]. An alternative representation is the more traditional Denavit-Hartenberg representation [2], which does not allow such an easy construction of the motion model or simple computation of derivatives and linearizations (more advantages of the product of exponential map representation are discussed in [1]).

Application

Kinematic Tracking

As mentioned earlier, kinematic chain models are commonly used in computer vision to track the articulated poses of humans. If visual markers are identified with high accuracy, either using a motion capture system or patterns that are easy to track, estimating the pose $\theta = [R_0, T_0, \alpha_1, \dots, \alpha_k]$ can be done with an

error minimization technique. For instance, a marker-based motion capture system estimates 3D reconstructions of body markers \hat{Q}_i . The function $M(\theta)$ in Eq.(6) can be easily linearized [1] and used in estimating the 3D pose θ with the Newton-Raphson method or any other optimization technique. If 2D points are located in an image, the same can be applied to video tracking in single or multi-view footage using a camera model that relates 3D points to 2D projections. The $M(\theta)$ model can even be incorporated in optical flow models, and a direct estimation of θ is possible from spatiotemporal image gradients [3]. An earlier historic paper that uses an alternative formulation is reported by [4]. Since the comeback of deep learning models, many new architectures have been proposed that implicitly model kinematic constraints [5–10]. Most recent state-of-the-art models are usually the winners of the COCO Keypoint Challenge (<http://cocodataset.org>).

Model Estimation

Estimating the geometry of the kinematic chain (the point locations P_i in the rest pose, or other geometric shape representations) and all joint axes ξ_k in the rest pose can also be done with optimization techniques. This requires collecting a sequence of different poses that ideally go through the entire “range of motion” of a person or articulated object, a common procedure for motion capture systems, called “subject calibration.” The same can be also done for computer vision systems. Once a sufficient number of frames with different pose configurations are collected, jointly the poses θ_t for each frame t and the common model parameters ξ_k and P_i (that are constant over time) are estimated. Some example techniques are described in [11, 12].

Animation

Kinematic chain models are also used extensively in computer graphics and computer animation. Animating a character efficiently requires locally controlling the joint angles in the same way as previously outlined. All major 3D graphics packages support skeletal models that are based on kinematic chain motion models.

[Lambertian model](#); [Lambert's law](#)

Related Concepts

- ▶ [Diffuse Reflectance](#)
- ▶ [Photometric Stereo](#)

Background

Local reflectance can be defined by the four-dimensional bidirectional reflectance distribution function (BRDF), where the four dimensions are the angles for viewing direction and incident illumination. Lambertian reflectance has no dependency on viewing direction and is therefore a two-dimensional function. This simplicity has made it popular, but like all local models, it does not account for cast shadows or specularities. The Lambertian model is widely used due to both its computational tractability and its fidelity to many scenes, especially when the captured image data is of low resolution. Finally, the Lambertian model is an example of diffuse reflectance, which means it acts as a low-pass filter to incident illumination [1]. An artificial chemical called Spectralon is the real-world material with the closest appearance to the Lambertian ideal.

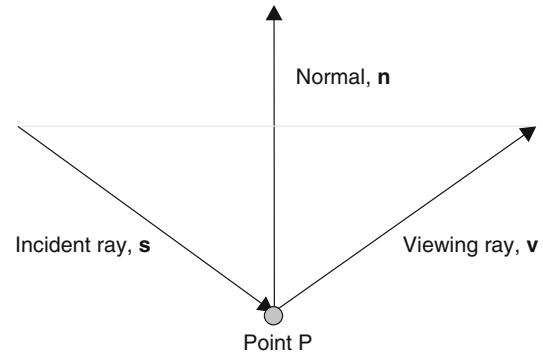

Theory

A scene point is said to exhibit Lambertian reflectance [2,3] when the measured intensity E can be expressed in terms of the surface normal

\mathbf{n} and incident illumination direction \mathbf{s} as

$$E = I\rho \max(\mathbf{n} \cdot \mathbf{s}, 0) \quad (1)$$

where I is the intensity of the light (which may be attenuated by falloff) and ρ is the scene point albedo (which is the ratio of the reflected and incident energies). Note that since the surface normal and illumination directions are unit vectors, Lambertian reflectance is a clamped cosine function, and this allows the model to account for attached shadows. In some applications, the raw dot product $\mathbf{n} \cdot \mathbf{s}$ is used as the reflectance model, and a nonnegativity constraint for irradiance is applied separately.

Lambertian Reflectance, Fig. 1 Reflection occurs when the incident ray, the surface normal, and the reflected lie in the same plane and, in addition, the angle between the incident ray and the normal is identical to that between the reflected ray and the normal

Extensions

A variety of extensions to Lambertian reflection exist to remove its most glaring deficiencies. The most common of these is a “diffuse + specular” extension [4],

$$E = I\rho_d \max(\mathbf{n} \cdot \mathbf{s}, 0) + I\rho_s \delta(\mathbf{v} - \mathbf{s} - 2\|\mathbf{n} \cdot \mathbf{s}\|\mathbf{n}) \quad (2)$$

where ρ_d and ρ_s are the diffuse and specular albedos of the scene and the δ function denotes when the viewing, incident, and surface normal vectors are aligned according to the Law of Reflection, as illustrated in Fig. 1.

Oren and Nayar [5] have generalized the Lambertian model to include microfacets, which model surface roughness by a Gaussian distribution of the orientations of microstructure within any scene point. This extended model explains the visual appearance of rough diffuse Lambertian surfaces (such as the moon) and analytically reduces to the Lambertian model for a smooth surface whose microfacet orientation distribution is a delta function.

Application

The popularity of Lambertian models is due to its linearity. Consider a scene whose surface points

are indexed by $i = 1, 2, \dots, k$. Without loss of generality, let the maximum value of the image intensity I and albedo ρ both be in unity. If the viewing position is fixed and if t images are taken of the scene under different lighting directions, indexed by $j = 1, 2, \dots, t$, the images create a matrix whose analytic form is just a row-wise stacking of Eq. (2) as

$$\begin{pmatrix} E_{11} & E_{12} & \dots & E_{1k} \\ E_{21} & E_{22} & \dots & E_{2k} \\ \vdots & & & \\ E_{t1} & E_{t2} & \dots & E_{tk} \end{pmatrix} = \begin{pmatrix} s_1(x) & s_1(y) & s_1(z) \\ s_2(x) & s_2(y) & s_2(z) \\ \vdots & & \\ s_t(x) & s_t(y) & s_t(z) \end{pmatrix} \begin{pmatrix} n_1(x) & n_2(x) & \dots & n_k(x) \\ n_1(y) & n_2(y) & \dots & n_k(y) \\ n_1(z) & n_2(z) & \dots & n_k(z) \end{pmatrix} \quad (3)$$

which we can rewrite in matrix notation as $\mathbf{E} = \mathbf{S} \cdot \mathbf{N}$. Therefore, images taken of the scene can be linearly separated into a surface normal matrix and a light-source direction matrix. This separation allows many applications such as the following:

Explanations of Ambiguities From the above equation, it is clear that many combinations of normals and light-source directions can create the same image data, since $\mathbf{E} = \mathbf{S} \cdot \mathbf{Q} \cdot \mathbf{Q}^{-1} \cdot \mathbf{N}$, for any

invertible Q . Belhumeur et al. [6] have shown that this ambiguity follows a closed form under orthographic viewing and distant illumination.

Scene Reconstruction In classical photometric stereo [7], three or more images are taken of the scene with known illumination. Since the matrix S is known, the surface normal matrix can be obtained by $N = (S^{-1} \cdot E)$. Extensions to these methods have also been presented, where the illumination is unknown. In these cases, the matrix E is decomposed using well-known linear methods such as QR decomposition or SVD under constraints such as smooth motion for the light source [8] or low rank [9]. Finally, we note that most extensions to the Lambertian model lose their linearity, and therefore, photometric stereo methods that model interreflections [10], microfacets [5], scattering [11], or near lighting [12] either apply nonlinear optimizations or require some form of calibration.

Subspace Methods Since the rows and columns of S and N lie in \mathcal{R}_3 , the intensity matrix E is of at most rank 3. Belhumeur and Kriegman [13] further explain that, under fixed viewing and varying illumination, the set of images under Lambertian reflectance lies in a conical subspace. Such an argument underlines the success of dimensionality reduction methods, such as PCA, in representing large collections of images of objects, such as faces. It also explains the existence of good recognition algorithms for scenes under varying illumination.

Relighting Scenes Data-driven methods for relighting under distant illumination exploit the additivity of light [14]. For the Lambertian case, such relighting can be modeled as creating new illumination directions. For example, consider the addition of images created by two sets of illumination directions S_1 and S_2 . The resultant data can be described as $E = S_1 \cdot N + S_2 \cdot N = S_3 \cdot N$, where $S_3 = S_1 + S_2$: that is, the relit Lambertian scene can be modeled as being illuminated by a third, new set of illumination directions.

Definition

This entry gives an overview of learning from a neuroscience perspective by highlighting some key chronological findings in neuroscience that have given rise to various theories of learning and have particularly inspired major developments in artificial intelligence.

Background

Learning has been a central question in psychology and neuroscience, spanning various theories and explanations from the behavioral level to the neuronal scale. Even though many of these theories are strengthened by experimental evidence, understanding how learning is performed by the brain is still an open problem and subject of numerous ongoing research efforts. Nevertheless, the neuroscience perspective on learning has heavily influenced artificial intelligence and machine learning, hallmarked by early instances

such as the Perceptron, to the more recent advent of convolutional neural networks and neuromorphic processing hardware. In this article, we give a brief overview of some of the key notions of learning from a neuroscience perspective.

Theory

We consider three different accounts of learning from a neuroscience perspective, namely, reinforcement and conditioning, Hebbian learning, and feature extraction.

Reinforcement and Conditioning

Historically, the earliest efforts in explaining how the brain learns go back to the pioneering works of psychologists such as Edward Thorndike, Ivan Pavlov, and B. F. Skinner, among others. Their theories of learning revolve around the notion of “reinforcement,” which is defined as the strengthening of the association between a pair of stimuli or between the stimulus and response. According to Pavlov’s classical conditioning (often referred to as Pavlovian conditioning), learning is the strengthening of the association between two stimuli: an unconditioned stimulus (such as food), which is rewarding for the learner, and a conditioned stimulus (such as a bell ring), which is neutral. In a variant introduced by Thorndike and further developed by Skinner, namely, instrumental learning or operant conditioning, learning pertains to an increase in the frequency of the responses that accompany satisfying results and a decrease in those that result in unpleasant outcomes.

These theories have been instrumental in describing various behaviors elicited by humans and animals since their inception in the early 1900s. They also inspired the mathematical theory of reinforcement learning, in which a learner aims at optimizing a cost function through a balance between exploration (trying new actions) and exploitation (using previously tested actions) [1,2]. Another related development is the Bellman equation for Markov decision processes, in which a learner recursively optimizes an overall cost function [3]. However, it took

researchers nearly a century to pinpoint the neural basis and circuit mechanisms of these theories in the brain [4–7]. In particular, it is now widely accepted that the activation of groups of neurons, known as dopaminergic projections, mediates reinforcement and reward-motivated behavior through the release of a neurotransmitter called dopamine [8].

Neural Encoding of Sensory Stimuli and the Hebbian Theory of Learning

Shortly after the advent of the various theories of learning in the psychology community, physiologists were able to record the activity of neurons in the nervous system. The most notable such effort is due to Edgar Adrian in 1926, who recorded the electrical activity of a nerve cell in response to sensory stimulation [9].

The nerve cells, or neurons, are typically composed of three main components: the soma, the dendrites, and the axon [8]. The soma is the cell body of the neuron. The dendrites are treelike extensions of the soma that receive electrical signals from the other nerve cells. The axon is a long fiber that propagates electrical signals from the soma toward other neurons. The axons connect to the dendrites via the so-called synapses, which are chemical or electrical junctions that transmit signals from one neuron to another. It is known the rapid depolarization of a neuron's soma (presynaptic neuron) results in the so-called action potential, which travels in the form of an electrical impulse along the axon and reaches a synapse located in a receiving neuron's dendrites, thereby changing the membrane potential of the receiving neuron (postsynaptic neuron). The rate at which a neuron produces action potentials is known as the firing rate.

Based on his observations, Adrian postulated that the intensity of a stimulus affecting a neuron is encoded as its firing rate and not necessarily the precise timing of each individual spike. Various experiments that followed the pioneering work of Adrian showed that the precise timing of individual spikes of a neuron could also carry information about the sensory stimuli (see, e.g., [10]).

The foregoing observations further led to the Hebbian theory of learning, named so in recognition of Donald Hebb, who summarized these findings in the form of a learning rule in 1949 [11]. In the Hebbian theory, learning corresponds to the consolidation of synaptic weights in a network of neurons, as a result of repetitive firing patterns that arise from multiple presentations of stimuli. Hebbian learning is often summarized in the form of the following adage: *The neurons that fire together, wire together; the neurons that fail to sync, fail to link.*

The simplest form of the Hebbian learning rule states that if presynaptic and postsynaptic neurons get activated simultaneously, the strength of the synapse is increased. Let w_i and x_i , $i = 1, 2, \dots, N$ denote the synaptic strengths and activity of N presynaptic neurons to a target neuron, respectively. In a linear neuronal model, let $y = \sum_{i=1}^N w_i x_i$ be the postsynaptic potential of the target neuron. Then, the Hebbian learning rule states that

$$\Delta w_i \propto x_i y,$$

where the proportionality accounts for the learning rate. Various generalizations of this simplified learning rule have been proposed and studied in the computational neuroscience literature [12]. One notable form of Hebbian learning is the spike-timing-dependent plasticity (STDP) [13–17], in which the delay between the pre- and postsynaptic activities plays a key role in the learning rate of the synaptic update rule. Let τ_i denote the delay between the spiking of the i th presynaptic and the postsynaptic neuron. Then, the simplest form of STDP specifies that

$$\Delta w_i \propto W(\tau_i),$$

where $W(\tau)$ is a weighting function that penalizes positive delays (i.e., presynaptic neuron firing after the postsynaptic neuron) and promotes negative delays (i.e., postsynaptic neuron firing after the presynaptic neuron). Another notable generalization of Hebbian learning is the Bienenstock-Cooper-Munro (BCM) theory [18]. In addition to the timing

between the pre- and postsynaptic responses, the BCM learning rule also takes into account the nonlinear dependence of the weight update on the intensity of the postsynaptic response y .

Apart from being a topic of active research in computational neuroscience, Hebbian learning has also been utilized in hardware implementations of neuromorphic chips [19, 20], with a recent example of Intel's Loihi neuromorphic processor [21].

Sensory Neurons as Feature Extractors

Pioneering work by David Hubel and Torsten Wiesel in 1959 [22, 23] showed that neurons in the mammalian primary visual cortex have a unique functional characteristic known as the receptive field. The receptive field is a mapping from the parameter space of the sensory stimuli (e.g., visual or auditory stimuli) to the activity of the neuron. In the case of the primary visual cortex, it was shown that neurons preferentially exhibit higher spiking rate when particular patterns are present in the visual field. Similar characteristics have been shown to exist in the primary auditory cortex, in which neurons exhibit selective activity to certain patterns in the spectrotemporal domain [24], as well as in the somatosensory cortex, in which neurons selectively respond to tactile stimulation of different skin regions [25]. These findings suggested that some sensory neurons in primary cortical areas act as feature extractors, as they selectively respond to specific patterns in the feature space of the sensory stimuli.

Hubel and Wiesel also postulated that connections of neurons from the primary sensory areas to higher-level cortical areas result in a hierarchical combination of receptive fields and contribute to the emergence of complex receptive fields that can learn complicated features of the stimuli. This hierarchical feature extraction viewpoint of the visual cortex inspired the development of the multilayer perceptron [26] and together with the concept of receptive fields led to the advent of convolutional neural networks [27]. Obtaining a complete functional mapping of the architecture of the visual cortex, however, is still the topic of active research in neuroscience.

It is worth noting that the spectacular success of deep learning methodologies in recent years has motivated researchers to examine the architectural parallels between artificial neural networks and the visual cortex to gain insight on the functional roles of higher-order visual cortical areas [28].

Open Problems

In closing, we outline three areas of active research aimed at solving open problems in the domain of learning from a neuroscience perspective:

Biologically Plausible Computation and Learning

Given that neural networks are originally inspired by neural circuitry in the brain, the success of backpropagation in training artificial neural networks motivated researchers to examine whether a similar procedure is carried out by biological neural networks. Computation of the derivatives in backpropagation, however, is a global operation and is not consistent with the predominantly local connections of the neurons in the brain. Finding biologically plausible algorithms for neuronal computation and learning has been an active topic of research [29–32]. Another hallmark of brain function is its robust and adaptive learning capability. These features of brain function are often attributed to recurrent connections across various brain regions, resulting in top-down control. However, such control mechanisms require the availability of global information at the controller. Recent results have shown that it is indeed possible to construct robust and adaptive learning algorithms that can be implemented with local and neurally plausible circuits [33]. For the most part, constructing computational models and training algorithms that are both neurally plausible and exhibit performance on par with backpropagation and other successful, yet neurally implausible computational and control methodologies, remains an open question to this day.

Dendritic Learning

As mentioned earlier, most prevalent theories of learning at the neuronal level are based on the adaptations of the synaptic weights. Recent evidence, however, suggests that computation carried out at the level of dendrites is significant in learning and memory [34–36]. Developing a dendritic theory of learning has thus become an active area of research and remains an open question to this day.

From Single Neurons to Recurrent Networks and Population Representations

Studies of neuronal circuits are predominantly carried out under the paradigm of hierarchical cortical organization: primary cortical areas act as simple feature extractors, and higher-order areas learn more complex attributes of the stimuli. However, it is now widely accepted that recurrent connections in the cortex are a staple of neuronal circuitry [37]. An important open question is to go beyond the hierarchical feature extraction models and address how learning is performed in such recurrent networks. A notable development in this area is FORCE learning, which suggests a learning mechanism by which chaotic neuronal networks can produce a wide range of behaviors that are observed experimentally [38]. In addition, recent evidence shows that when populations of neurons in a primary area are considered together (as opposed to being independent feature extractors), they encode the more complex attributes of the stimuli that were believed to only exist in higher-order areas (see, e.g., [39, 40]). Constructing a theory of learning that is consistent with these findings remains an open problem.

Imitation learning; Learning from demonstration; Programming by demonstration

Definition

Learning-from-Observation is the framework to generate robot's (or other agent's) movement to achieve a target task with less user's programming effort. In this framework, a user just demonstrates the target task and a robot learns the method to reproduce the target task from the observation.

Background

One goal in robotics and artificial intelligence (AI) fields is to achieve any target tasks by a robot with less user's programming efforts. To achieve this purpose, *Learning-from-Observation* (LFO) framework attracts an attention. In this framework, a user just demonstrates the target task and a robot learns the method to reproduce the target task from the observation. The user is not required to have special skills on robotics.

Note that an agent that the user teaches is not limited to a robot.

In a scientific point of view, it is important to clarify the methodology to achieve the LFO framework. Only primates including human beings have the ability to learn tasks from observation, and ones think that the mirror neuron that primates have is related to LFO [1]. The mirror neuron fires not only when it acts some task (e.g., grasp an object) but also when it observes the same task by others.

Theory

A LFO method formalizes the observed task and reproduces it. Thus, the LFO methods are categorized based on the following two aspects:

- how to observe demonstration
- how to formalize demonstration

Modalities in Observation

It is interesting to use vision to observe the task as if human beings do. Another choice is to additionally use linguistic instruction. Considering the maximization of the effects of the demonstration, it is reasonable to use various types of modalities, such as haptic information and kinesthetic demonstration; skills in dexterous manipulation appear in force interaction. Note that human beings cannot share haptic information directly.

The space of the demonstration is not limited to the real world; the virtual reality (VR) space is one of the candidates (e.g., [2]). Though the advantage to use the VR space is that everything in the space can be captured, the demonstrator should get used to executing tasks in the VR space.

The target tasks are from manipulation and body movements, such as gestures and dances. Thus the target objects and/or body movements of the demonstrator should be observed. The level of details of the observation depends on the method to formalize the target tasks. The finest level of the observation, for example, is 6D pose

trajectories of objects and trajectories of all body joints in 3D. To simplify the observation, the AR marker (e.g., [3]), a motion capture system, and a sensor glove are employed.

Formalization of Target Tasks

As described in [4], there are three levels of LFO:

1. Appearance level
2. Action level
3. Purposive task level

When a child learns a garden cleaning task using a broom, she/he begins by imitating the movement of a broom. She/he finally learns how to clean a garden using a broom, such as collecting the falling leaves. In LFO, it is a final goal to learn the method to achieve the purpose of the task. Furthermore, the mirror neuron fires when observing the achievement of the purpose and does not fire even when observing the imitated movement that does not achieve the purpose.

One idea to realize LFO is to formalize tasks by recognizing the purpose of the task. Then the robot reproduces the task from the purpose only (e.g., [5]). Though such realization of LFO looks plausible, this complicates reproduction of the target tasks. In the worst scenario, the movement should be generated from the scratch; this is equivalent to the path planning [6].

Several research methods [7–10] divide the purpose into several sub-purposes. To do so, the methods define the symbolic representation of the states and analyze the feasible state transitions; each transition corresponds to a sub-purpose, and the purpose is to achieve the final state. Since the purpose is represented as a set of small sub-purposes, the reproduction is simplified. Since the purpose is symbolically represented, the methods can recognize the success of the tasks under various situations.

Another idea is that the method copies all the movements of the demonstration. Many of LFO-related methods follow this idea [11–13]. Fortunately, the copy of the movement achieves the purpose under the *same* environment as in the demonstration. This idea can be implemented

using machine learning technique, such as classification and regression.

There are several research methods to handle the change of the environments. The intuitive idea is to learn the relationship between the environment and the corresponding movement (e.g., [14, 15]); the information of the environment is also included in the input of the classifier/regressor. Schulman et al. [16] uses the non-rigid registration to derive the relationship between the current environment and that in the demonstration and transforms the demonstrated movement using this relationship. Ye and Alterovitz [17] use motion planning, where the demonstration movement guides the search region. Kramberger et al. [18] use states and their transitions and estimate the constraints from the demonstration in assembly tasks.

Open Problems

In the former idea for the formalization, it is necessary to pursue the generic method to generate the robot motion in various kinds of tasks, given the purpose and the current environment. In the latter idea, it is necessary to pursue the generic method to handle the environmental changes from the demonstration. If the kinesthetic demonstration is not used, the difference of the body size between the demonstrator and a robot should be considered. Finally, in order to reduce the user's effort, the number of required demonstrations should also be considered (e.g., one-shot learning).

- ▶ Camera Calibration
- ▶ Lens Distortion, Radial Distortion

Definition

Lens distortion is a form of optical aberration that causes lenses to deviate from rectilinear projection. Commonly, it is caused by defects in lens design and manufacturing.

Background

In many cameras, optical errors or the construction of the lens by nature itself does not allow for rectilinear projection (projection that maps 3D lines onto 2D lines). The deviation from rectilinear projection is termed lens distortion.

In most common lens systems designed for rectilinear projection, this occurs because of optical errors and is primarily radial in nature. This phenomenon, also called radial distortion, is of two types: barrel distortion (Fig. 1) and pincushion distortion (Fig. 2). In barrel distortion, image magnification increases nonlinearly with distance from the optical axis resulting in lines “bulging

outward.” Pincushion distortion has the opposite effect (lines bend radially inward), caused by decrease in image magnification with distance from the axis. Radial distortion is corrected by calibrating the camera using a planar “checkerboard” pattern.

The second, less damaging cause of distortion is the misalignment of optical elements in a compound lens. This is called tangential distortion or decentering distortion.

Some wide-angle lenses, like fish-eye lenses, have distortion as a product of the construction of the lens (sometimes in addition to radial distortion). Fish-eye lenses capture images that appear to be barrel distorted (Fig. 3).

Other Aberrations

Other common aberrations in lenses include chromatic aberration (wavelength-specific distortion) and spherical aberration (imperfect focusing of light rays incident at lens periphery).

L

Theory

The most common representation of radial and tangential distortion (for correction) is Brown’s distortion model [1, 2, 6], which represents the distorted image coordinate as

$$\mathbf{r} = \begin{pmatrix} r_x \\ r_y \end{pmatrix} = \mathbf{x_u} - \mathbf{cc}, \quad r = |\mathbf{r}| \quad (1)$$

$$\begin{aligned} \mathbf{x_d} = & \left(1 + k_1 r^2 + k_2 r^4 + k_3 r^6 \right) \mathbf{x_u} \\ & + \begin{pmatrix} 2k_4 r_x r_y + k_5 (r^2 + 2r_x^2) \\ k_5 (r^2 + 2r_y^2) + 2k_4 r_x r_y \end{pmatrix} \end{aligned} \quad (2)$$

where $\mathbf{x_u}$, $\mathbf{x_d}$ are the undistorted and distorted point coordinates, $k_{(1,2,3,4,5)}$ the distortion coefficients (first three radial and the rest tangential), and \mathbf{cc} the principal point.

Once estimated, images can be corrected for distortion by warping by a function that maps

Lens Distortion, Radial Distortion, Fig. 1 Effects of barrel distortions respectively on lines (Distortions in these images have been exaggerated for visualization)

Lens Distortion, Radial Distortion, Fig. 2 Effects of pincushion distortions respectively on lines (Distortions in these images have been exaggerated for visualization)

Definition

Lens glare or lens flare is a global light transport phenomenon which occurs due to reflections and scattering of light in the optical elements and body of the camera and leads to decrease in the contrast of the image.

Background

Glare is a phenomenon caused due to bright light source (either narrow or extended) in or near the field of view of the camera. It is typically caused when stray light reaches the sensor and could be either due to reflections at the air-glass interface of the lens or due to scattering in the lens. The effect of glare is a decrease in contrast of the image and thereby its dynamic range and is often considered undesirable. Sometimes glare is used artistically in graphics or outdoor filming to convey a sense of realism. A simple way to decrease glare is to use lens hood to prevent stray light from entering the lens and by using antireflective coating on lens which decreases the reflections at the lens surface.

Glare can also be mitigated by first estimating it and then removing it from the image. This can be done in a passive fashion post capture or in an active fashion where the sensed image is modified for better glare estimation and removal.

L

Theory

While there is some confusion in the literature regarding the classification and terminology of different kinds of lens glare, glare can be broadly classified into three kinds as shown in Fig. 1. Two of these, aperture ghosting and lens flare, are caused by reflections at the air-glass interface of the lens. The third, veiling glare, is caused by the scattering of light in the lens.

Aperture ghosting is caused due to Fresnel reflection at the air-glass interface resulting in a number of aperture shaped reflections in the image as shown in Fig. 1. These aperture-shaped reflections or ghosts occur in the image at the symmetrically opposite end of the light source. If there are n lens surfaces, the number of ghosts are $n(n - 1)/2$ [2].

Lens flare appears as fogging of a large image area as shown in Fig. 1 and is prominent when the aperture is large and the camera has a wide field of view. The effect is that region surrounding the bright light source is also bright due to reflections in the lens system as shown in Fig. 2.

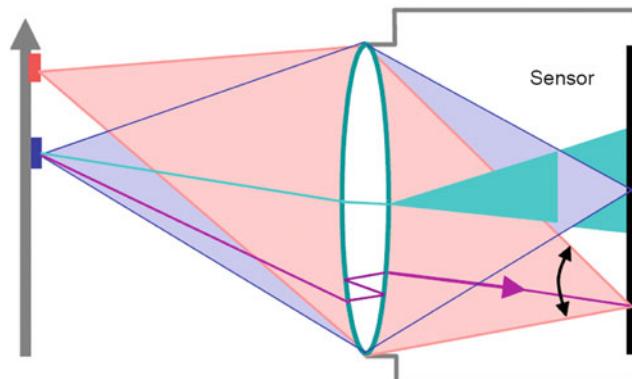

Lens Flare and Lens Glare

Glare, Fig. 1 Different kind of lens glare in the image. Aperture ghosting can be seen as hexagonal parasitic images symmetrically opposite the light source. Lens flare is the fogging seen around the light source. Veiling glare is the cause for decrease in contrast on the person's jacket and the wall behind. (Figure courtesy [1])

Lens Flare and Lens Glare

Glare, Fig. 2 The red and blue spot are focused on the sensor. The purple ray from the blue light source is undergoing reflection, which results in either aperture ghosting and/or lens flare. The cyan ray is scattering due to weak diffusion caused by the lens resulting in veiling glare. (Figure courtesy [1])

Veiling glare is caused by scattering of light in the lens since lens acts as a weak diffuser as shown in Fig. 2. This results in a foggy appearance in the entire image with a distinct loss in contrast as shown in Fig. 1. Veiling glare is caused due to bright scene and not necessarily due to bright light sources close to the field of view.

In practice it is hard to distinguish and separate lens flare from veiling glare. Superior optics helps in mitigating glare by reducing the reflections at the lens surface.

Measuring glare: There are various ways of measuring glare. The standard way of measuring glare is to photograph a white board with a black target in the center [3, 4]. The ratio of the luminance of the black target to the luminance in the white region is defined as veiling glare

index (VGI) by the ISO standard 9358 (year 1994).

Glare spread function (GSF) is another measure defined by ISO standard to quantify glare. It is defined as the glare intensity as function of distance from the center of an image of a centered point light source. If the glare intensity is invariant to the location of the point light source in the image, then GSF can be represented by a convolution operation like the point spread function (PSF).

Traditional methods of removing glare involve assuming a shift invariant GSF, estimating it, and performing deconvolution. This has been used in removing veiling glare in X-ray imaging [5]. The methods using deconvolution are passive where the glare is estimated and removed after capture. Active methods to remove glare have also been

proposed, and they involve modifying the imaging architecture for better glare estimation and removal.

Talvala et al. [6] estimate veiling glare by taking multiple images of a scene by shifting a mask. This method allows the glare to be estimated even when the glare is significantly dominant. Other active approach involves estimating aperture ghosting and lens flare due to point light source by inserting a mask near the sensor and capturing a light field [1]. This method treats glare as high-frequency phenomenon in ray space as opposed to image space and defines a 4D glare ray spread function (GRSF) that characterizes how much an incident ray on lens contributes to outgoing rays. Please refer the above entries for technical details.

Application

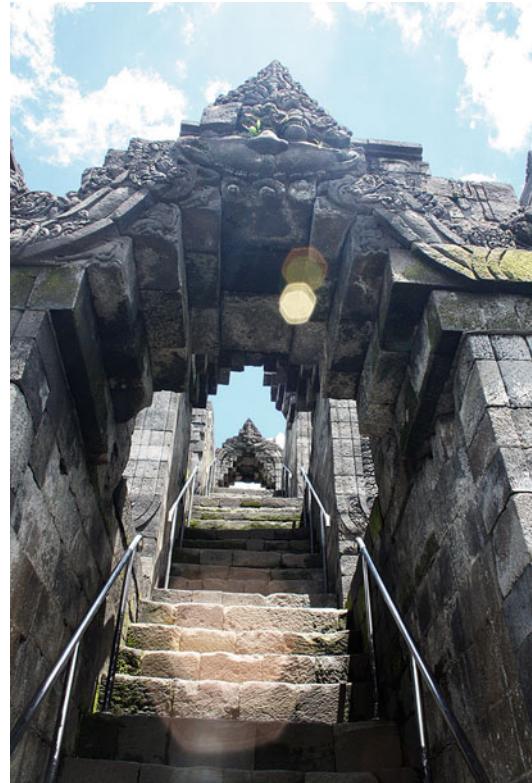

Glare is used in photography and videography to enhance the scene by conveying a sense of realism as shown in Fig. 3.

Glare estimation and removal is an important step in HDR imaging since the presence of glare in captured images reduces the dynamic range. Glare removal techniques in HDR are described in [7]. In multi-exposure HDR imaging, it has been used in [8]. Glare removal techniques are also used in X-ray imaging [5, 9]. They are also used in astronomical imaging where scattering effects cause a degradation in the image. Glare removal has been used to remove glare caused by water droplets sticking to the lens [10].

Since aperture ghosting is symmetrically opposite to the light source, techniques have been proposed to estimate the light source location and the optical center of the camera using this fact [11].

and inverse (\mathbf{X}^{-1}) are analytic (read smooth or differentiable) mappings. We will only consider finite-dimensional Lie groups also known as matrix groups, i.e., $\mathbf{X} \in \mathbb{G}$ and $\mathbf{x} \in \mathfrak{g}$ are $n \times n$ square matrices with real entries. For matrix groups, the Lie bracket becomes the commutator $[\mathbf{x}, \mathbf{y}] = \mathbf{xy} - \mathbf{yx}$. The commutator signifies the degree to which the Lie bracket deviates from commutativity and equals zero when elements commute under composition.

Lie algebras are intuitively understood as corresponding to the set of infinitesimal transformations. Any finite transformation can be thought of as the composition of repeated infinitesimal transformations. Consider the set of transformations in the neighborhood of \mathbf{I} , i.e., $\mathbf{I} + \epsilon \mathbf{x} + O(\epsilon^2)$. For small enough ϵ , we note that $\mathbf{XY} \approx (\mathbf{I} + \epsilon \mathbf{x})(\mathbf{I} + \epsilon \mathbf{y}) \approx \mathbf{I} + \epsilon(\mathbf{x} + \mathbf{y})$. Using this it can be shown that the set of infinitesimal transformations form a linear space. Further, owing to its non-commutativity, left and right matrix multiplication have different implications. This is seen by considering the *conjugation* mapping $C_{\mathbf{X}} \mathbf{Y} = \mathbf{XYX}^{-1}$ which is \mathbf{Y} only for commutative groups. Dropping mathematical details, the *adjoint* action for infinitesimal transformations gives

$$\begin{aligned} Ad_{\mathbf{X}}(\mathbf{y}) &= \mathbf{XYX}^{-1} \\ &\approx (\mathbf{I} + \epsilon \mathbf{x})\mathbf{y}(\mathbf{I} + \epsilon \mathbf{x})^{-1} \\ &\approx (\mathbf{I} + \epsilon \mathbf{x})\mathbf{y}(\mathbf{I} - \epsilon \mathbf{x}) \\ &= \mathbf{y} + \epsilon(\mathbf{xy} - \mathbf{yx}). \end{aligned} \quad (2)$$

Definitions and Properties

Lie algebras can be interpreted in a number of ways: the set of infinitesimal transformations, tangent space about the identity element of a group, and a linear space with special properties. Formally, a Lie algebra (denoted \mathfrak{g}) is a vector space equipped with a bilinear, non-associative map $[\cdot, \cdot] : \mathfrak{g} \times \mathfrak{g} \rightarrow \mathfrak{g}$ known as the Lie bracket. The Lie bracket satisfies the following relationships:

$$[\mathbf{x}, \mathbf{y}] = -[\mathbf{y}, \mathbf{x}] \text{ (anti-symmetry)}, \quad (1)$$

$$[\mathbf{x} + \mathbf{y}, \mathbf{z}] = [\mathbf{x}, \mathbf{z}] + [\mathbf{y}, \mathbf{z}] \text{ (bilinearity)},$$

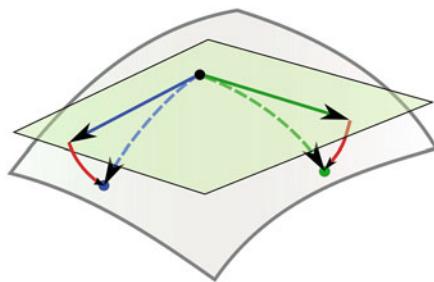

$$[\mathbf{x}, [\mathbf{y}, \mathbf{z}]] + [\mathbf{y}, [\mathbf{z}, \mathbf{x}]] + [\mathbf{z}, [\mathbf{x}, \mathbf{y}]]$$

$$= \mathbf{0} \text{ (Jacobi identity)}.$$

In computer vision, Lie groups play an important role in representing geometric transformation models such as rotations and Euclidean motions. Lie groups are groups that are also smooth manifolds. Specifically for elements \mathbf{X}, \mathbf{Y} in Lie group \mathbb{G} , composition $(\mathbf{X} \circ \mathbf{Y})$

Thus, the Lie algebra is a vector space endowed with the Lie bracket $[\mathbf{x}, \mathbf{y}] = \mathbf{xy} - \mathbf{yx}$. In the above we have discussed the Lie algebra (equivalently tangent space) about the identity element \mathbf{I} . But we can also consider the Lie algebra as a left-invariant vector field at \mathbf{I} . It can be shown that if $\mathbf{x} \in \mathfrak{g}$ is a tangent vector at \mathbf{I} , then \mathbf{Yx} is tangent to $\mathbf{Y} \in \mathbb{G}$. Accumulating these tangent vectors on an integral curve gives us the ordinary differential equation

$$\frac{d\mathbf{X}(s)}{ds} = s\mathbf{x}. \quad (3)$$

Lie Algebra, Fig. 1 Schematic illustration of the mapping from the Lie algebra \mathfrak{g} to the Lie group \mathbb{G} using the exponential function

The solution for this relationship yields the important exponential mapping

$$\mathbf{X}(s) = \exp(s\mathbf{x}) = \sum_{k=0}^{\infty} \frac{(s\mathbf{x})^k}{k!} \quad (4)$$

The exponential mapping $\exp : \mathfrak{g} \rightarrow \mathbb{G}$ allows us to directly move from the Lie algebra \mathfrak{g} to the Lie group \mathbb{G} as schematically illustrated in Fig. 1. It will also be noted that varying s traces out a line in the Lie algebra which maps to a one-dimensional subgroup of \mathbb{G} . This subgroup is Abelian as its elements are commutative under multiplication.

Conversely, we can define a logarithm mapping $\log : \mathbb{G} \rightarrow \mathfrak{g}$ that maps from the Lie group to its corresponding Lie algebra element. While the exponential mapping is absolutely convergent, the $\log(\cdot)$ mapping is only valid in a suitable ball around \mathbf{I} and also has a series expression.

Examples

To satisfy group properties, we require that \mathbf{X} be invertible, i.e., $|\mathbf{X}| \neq 0$. The set of invertible matrices is an open set and under matrix multiplication forms the General Linear Group $\text{GL}(n) = \{\mathbf{X} \in \mathbb{R}^{n \times n} \mid |\mathbf{X}| \neq 0\}$. This group has two connected components corresponding to positive and negative determinants, and one cannot smoothly move from one component to the other. We can also identify the corresponding

Lie algebra $\mathfrak{gl}(n)$ with the set of all real $n \times n$ matrices.

All matrix groups of interest to us can be obtained by specifying constraints to obtain appropriate subgroups of $\text{GL}(n)$. For instance if we consider affine transformations of a vector space $x \mapsto \mathbf{A}x + \mathbf{b}$, we get

$$\mathbb{A}(n) = \left\{ \begin{pmatrix} \mathbf{A} & \mathbf{b} \\ \mathbf{0} & 1 \end{pmatrix} \mid |\mathbf{A}| \neq 0, \mathbf{b} \in \mathbb{R}^{n-1} \right\} \quad (5)$$

where \mathbf{A} are all invertible matrices of dimensions $(n-1)$. It will be recognized that $\mathbb{A}(n) \subset \text{GL}(n)$ and is closed under matrix multiplication.

We can obtain Lie groups of interest by imposing two types of specifications. In the first instance, we consider only matrices $\mathbf{X} \in \text{GL}(n)$ with a determinant of +1. This yields the Special Linear Group $\text{SL}(n) = \{\mathbf{X} \in \text{GL}(n) \mid |\mathbf{X}| = +1\}$. The corresponding Lie algebra $\mathbf{x} \in \mathfrak{sl}(n)$ can be obtained using the trace identity of matrix exponentials

$$\begin{aligned} \det(e^{\mathbf{X}}) &= e^{\text{tr}(\mathbf{X})}, \\ \det(e^{\mathbf{X}}) &= +1 \quad \forall \mathbf{x} \in \mathfrak{sl}(n), \\ \Rightarrow \text{tr}(\mathbf{x}) &= 0 \end{aligned} \quad (6)$$

where $\text{tr}(\cdot)$ is the trace of a matrix. Thus the Lie algebra $\mathfrak{sl}(n)$ consists of all matrices with trace zero.

In the second instance, another Lie group of interest is the Orthogonal Group $\text{O}(n) = \{\mathbf{X} \in \text{GL}(n) \mid \mathbf{X}\mathbf{X}^T = \mathbf{X}^T\mathbf{X} = \mathbf{I}\}$ under which distances are preserved. However we can note that the determinant of an orthogonal transformation matrix equals ± 1 , i.e., it includes reflections. $\text{O}(n)$ consists of two disconnected components corresponding to determinant values of +1 and -1. We can combine the above two restrictions and specify that matrices be orthogonal and have a determinant of +1. This yields the Special Orthogonal Group $\text{SO}(n) = \{\mathbf{X} \in \text{GL}(n) \mid \mathbf{X}\mathbf{X}^T = \mathbf{X}^T\mathbf{X} = \mathbf{I}, |\mathbf{X}| = +1\}$ which corresponds to orientation preserving rigid rotations in n -dimensions. In computer vision, the 3D rigid rotations group $\text{SO}(3)$ is of special interest.

Finally, in Eq. 5 if we impose a further restriction that \mathbf{A} is a rigid rotation (denoted \mathbf{R}), we get rigid Euclidean transformations that preserve angles between vectors. In computer vision, the absolute or relative motions of cameras are specified by 3D Euclidean motions, i.e., they are elements of the Special Euclidean Group $\text{SE}(3)$.

Any 3D rotation can be defined by an axis \mathbf{n} about which we rotate by an angle θ . Defining $\boldsymbol{\omega} = \theta\mathbf{n}$, we can show that the corresponding 3D rotation matrix $\mathbf{R} \in \text{SO}(3)$ is given by

$$\mathbf{R} = \exp([\boldsymbol{\omega}]_{\times}) \quad (7)$$

where $[\cdot]_{\times}$ is the skew-symmetric cross-product form such that $[\mathbf{a}]_{\times}\mathbf{b} = \mathbf{a} \times \mathbf{b}$. Conversely, we can extract the skew-symmetric representation of a 3D rotation by the logarithm operation, i.e., $[\boldsymbol{\omega}]_{\times} = \log(\mathbf{R})$. We also note we can specify a canonical basis for $\mathfrak{so}(3)$ as the skew-symmetric cross-product matrix forms for the canonical direction vectors $\mathbf{e}_1 = [1\ 0\ 0]^T$, $\mathbf{e}_2 = [0\ 1\ 0]^T$, and $\mathbf{e}_3 = [0\ 0\ 1]^T$. Finally, $\text{SO}(3)$ is non-commutative since multiplication of skew-symmetric matrices is not commutative.

Optimization Using Lie Algebras

Many problems in computer vision involve the optimization of cost functions on Lie groups. Here the vector space properties of the corresponding Lie algebra play a key role. To optimize a function on a Lie group, we need two concepts: a distance metric on the Lie group and a means to take a step on the Lie group without moving away from the manifold.

Distance Metrics For Lie groups, we may define an *intrinsic* distance metric $d(\cdot, \cdot) : \mathbb{G} \times \mathbb{G} \rightarrow \mathbb{R}^+$. The natural distance metric between two 3D rotations \mathbf{R}_1 and \mathbf{R}_2 is the magnitude of the angle of the rotation that takes us from \mathbf{R}_1 to \mathbf{R}_2 or vice-versa, i.e., $d(\mathbf{R}_1, \mathbf{R}_2) = \frac{1}{\sqrt{2}} \|\log(\mathbf{R}_1 \mathbf{R}_2^{-1})\|_F = \frac{1}{\sqrt{2}} \|\log(\mathbf{R}_2 \mathbf{R}_1^{-1})\|_F$, where $\|\cdot\|_F$ is the Frobenius norm. We can also define an intrinsic distance metric on $\text{SE}(3)$.

While the intrinsic metric on $\text{SO}(3)$ is bi-invariant, there cannot be a bi-invariant metric on $\text{SE}(3)$ which has implications for problems in robotic planning [1].

Optimization Consider minimization of a cost function $f(\mathbf{v})$ for $\mathbf{v} \in \mathbb{R}^n$. We could obtain an iterative step $\Delta\mathbf{v}$ via a Taylor series expansion of the cost function

$$\begin{aligned} f(\mathbf{v}) &\approx f(\mathbf{v}_0) + \mathbf{g}^T \Delta\mathbf{v} + \Delta\mathbf{v}^T \mathbf{H} \Delta\mathbf{v} \\ &\Rightarrow \mathbf{v} \leftarrow \mathbf{v} - \mathbf{H}^{-1} \mathbf{g} \end{aligned} \quad (8)$$

where \mathbf{g} and \mathbf{H} denote the first and second derivatives of f with respect to \mathbf{v} evaluated at \mathbf{v}_0 . Using only a first-order approximation in Eq. 8 yields the gradient descent solution.

Now let us consider the minimization of a cost function defined on $\text{SO}(3)$, i.e., $f(\mathbf{R})$. In this case, to move in a descent direction while remaining on the Lie group, we need to consider infinitesimal rotations. This is where the optimization problem becomes one of solving a linear problem on the Lie algebra $\mathfrak{so}(3)$. Analogous to our update in Eq. 8 $\mathbf{v} \leftarrow \mathbf{v} + \Delta\mathbf{v}$, for the rotation at the current iteration \mathbf{R} , we can write the updated rotation as $(\mathbf{I} + [\Delta\boldsymbol{\omega}]_{\times})\mathbf{R}$. Note that here $\Delta\boldsymbol{\omega} \in \mathbb{R}^3$, i.e., a three-dimensional vector representing the axis-angle parameters and $[\Delta\boldsymbol{\omega}]_{\times}$ is an element of the Lie algebra $\mathfrak{so}(3)$. Analogous to Eq. 8, we can define the cost function to be minimized as

$$\begin{aligned} f((\mathbf{I} + \Delta\boldsymbol{\omega})\mathbf{R}) &= f(\mathbf{R}) + \mathbf{g}^T \Delta\boldsymbol{\omega} + \Delta\boldsymbol{\omega}^T \mathbf{H} \Delta\boldsymbol{\omega} \\ &\Rightarrow \Delta\boldsymbol{\omega} = -\mathbf{H}^{-1} \mathbf{g} \end{aligned} \quad (9)$$

The crucial difference from the vector space problem is that given the descent step $\Delta\boldsymbol{\omega}$, we update the 3D rotation as

$$\mathbf{R} \leftarrow e^{[\Delta\boldsymbol{\omega}]_{\times}} \mathbf{R} \quad (10)$$

which ensures that at all times our current estimate of \mathbf{R} is an element of the Lie group $\text{SO}(3)$.

Example Applications

In this section a representative sample of applications based on estimation on the Lie algebra are presented.

Averages A problem of interest is the mean or average of a number of 3D rotations $\{\mathbf{R}_1, \dots, \mathbf{R}_N\}$. Analogous to the definition of the mean in vector spaces as the variational minimizer, for estimating the intrinsic average, we can define the minimization problem as

$$\min_{\mathbf{R}} f(\mathbf{R}) = \sum_{i=1}^N d^2(\mathbf{R}_i, \mathbf{R}) \quad (11)$$

where $d(\cdot, \cdot)$ is the intrinsic metric on $\mathbb{SO}(3)$ [2]. If all rotations \mathbf{R}_i lie within a ball of radius less than $\frac{\pi}{2}$, it can be shown that the intrinsic average approach will converge [3]. In practice we often have statistical outliers in the observations, i.e., some \mathbf{R}_i could be grossly incorrect. In such a scenario, the cost function can be made robust to outliers using an appropriate loss function [4, 5]. We also note that while Eq. 9 states a second-order approach, the methods described in [2, 4] only use a first-order gradient estimate in the optimization.

When describing the statistical properties of a population or set of observations, we need to capture different modes of variation using methods such as principal component analysis. For articulated or deformable shapes, this translates to distributions on Lie groups. In computational anatomy, Lie groups are used in characterizing statistical variations in medially-defined anatomical objects such as kidneys [6]. A similar analysis of variability in human body shape is presented in [7].

Motion Averaging In structure-from-motion, given feature correspondences across many images, we estimate both 3D camera motions and 3D structure points. In recent years the approach of rotation averaging (more generally motion averaging) has been used for this problem.

Consider a viewgraph representing a network of camera-camera relationships. Given relative rotations \mathbf{R}_{ij} for available edges, we seek the vertex rotation values $\mathcal{R} = \{\mathbf{R}_1, \dots, \mathbf{R}_N\}$ using the consistency relationship $\mathbf{R}_{ij} = \mathbf{R}_j \mathbf{R}_i^{-1}$ that needs to be satisfied. This translates to a minimization problem in a least squares sense, i.e.,

$$\min_{\mathcal{R}} \sum_{(i,j) \in \mathcal{E}} d^2(\mathbf{R}_{ij}, \mathbf{R}_j \mathbf{R}_i^{-1}).$$

This is the approach proposed in [2], and a robust version is in [4]. Given the individual rotation estimates, a number of approaches are available to recover camera translations as well as the 3D structure. A similar Lie algebra based motion averaging on $\mathbb{SE}(3)$ can also be developed for 3D registration problems.

Visual Tracking and Servoing A problem of visual servoing is addressed in [8] where visual feedback is used to drive the control of a robotic arm to achieve a desired position. In this work, a non-rigid contour is tracked using the Lie algebra of affine transformations. In turn this is used to drive the rigid motion ($\mathbb{SE}(3)$) control of a robotic arm. A key step in this process is the estimation of an affine-to-robot Jacobian using the Lie algebra $\mathfrak{se}(3)$. Visual tracking and servoing using a homography representation is proposed in [9]. Here the Lie algebra $\mathfrak{sl}(3)$ is used for estimation of the updates for the homography. Another work of relevance is [10].

Interpolation In many applications in control or graphics, we wish to obtain a smooth trajectory of intermediate motions given two or more motions. This is achieved by smoothly interpolating between an ordered set of $\mathbb{SE}(3)$ elements in a manner analogous to splines in vector space [11–14].

Further Reading The literature on Lie algebras and Lie groups is enormous. Useful and accessible introductions are available in [15–18]. Of more direct relevance are the following volumes written with computer vision and engineering researchers in mind [19–21].

Definition

The light field is a function that describes the amount of light in radiance along light rays traveling in every direction through every point in empty space.

Background

The term light field was coined in a paper by A. Gershun [6] for studying surface illumination with artificial lightings. A similar concept was introduced to the computer graphics community as the light field in [8] and lumigraph in [7]. The motivation is to render new views or images of objects or scenes from densely sampled images previously taken to avoid building or capturing complicated 3D models. Light field or lumigraph rendering is a special representation of image-based rendering (IBR), and they require either no geometry [8] or limited geometry in terms of depth maps [7]. The light field and lumigraph are also four dimension (4D) simplification of the plenoptic function for static scenes.

Theory

In geometric optics, light propagation is modeled as rays which travel in straight lines in free space. The amount of light along a ray is measured in radiance which is the power transmitted per unit area perpendicular to the direction of travel, per unit solid angle. It is denoted by l in watts (W) per steradian (sr) per meter squared (m^2). The function that describes the radiance along light rays traveling in every direction through every point is called the plenoptic function.

A ray in free space can be parameterized by three coordinates, x , y , and z and the elevation (θ) and azimuth (ϕ) angles as shown in Fig. 1. Therefore, for a static scene, the radiance of all the light rays observed is a 5D function $l(x, y, z, \theta, \phi)$, which is a special case of the seven-dimensional plenoptic function which also includes time and wavelengths. Here, it is assumed that only the three color components, instead of all the wavelengths, are of interest, and hence the dimension of wavelengths in the plenoptic function is dropped.

If $l(x, y, z, \theta, \phi)$ can be captured by an imaging device, it is possible to select the required rays from $l(x, y, z, \theta, \phi)$ to obtain a projected image at any location (x, y, z, θ, ϕ) as if a picture is taken at this location. Very often, it is the exterior of an object which is of interest, and therefore the viewing locations can be restricted to the convex hull of the object. In this case, the plenoptic function can be captured by a digital camera, which captures the rays at the viewing locations. Since the radiance along rays in free space remain constant, this one-dimensional redundancy in the plenoptic function allows us to reduce it to the 4D light field or lumigraph. The light field concept can be similarly extended to time-varying or dynamic scenes, which results in a 5D plenoptic function.

Parameterization

The collection of light rays in a 4D static light field can be parameterized in a number of ways as shown in Fig. 2. A commonly used parameterization is the two-plane parameterization, where

a light ray in the light field is parameterized as its intersections or coordinates with two parallel planes, which are denoted by (u, v) and (s, t) . Usually, one of the plane, say the (u, v) plane, is chosen as the camera plane where images are to be taken. All the rays passing through a given point in the (u, v) plane will then correspond to an image taken by a camera at that location, which can be parameterized by the image coordinate (s, t) . Therefore, (s, t) is usually called the image plane, or vice versa.

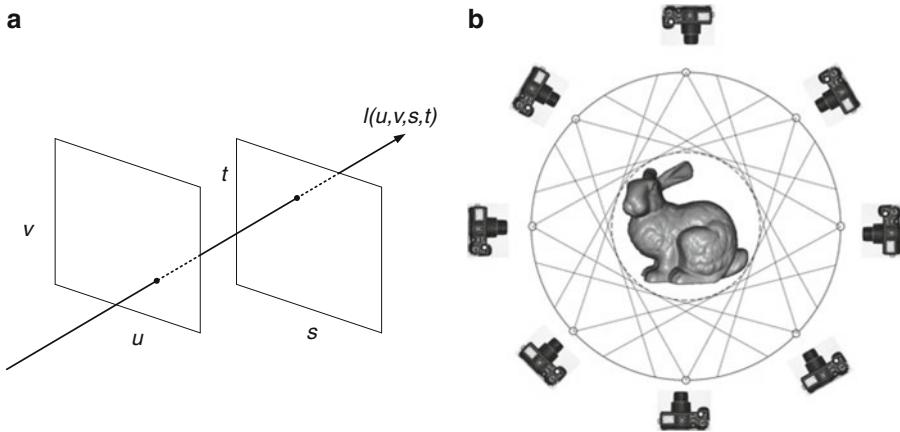

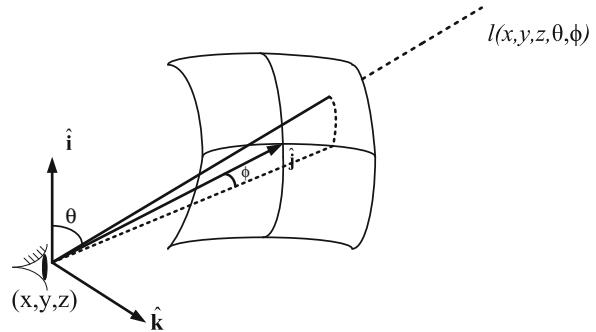

Both the light field in [8] and the lumigraph [7] use the parallel plane parameterization due to its simplicity. Other possible parameterizations include intersections with surface of a sphere or the intersections between a plane/sphere with a convex surface. These parameterizations can be further simplified by restricting the camera locations to line, line segments, circle, circular arc, etc. to reduce hardware complexity of the capturing system. This gives rise to a wide range of image-based representations specified by different camera geometry. See [19] for a review up to 2007 and a quick summary in the image-based rendering and plenoptic function sections.

For time-varying or dynamic scenes, similar parameterization can be employed. This can be done by an array of video cameras or specially design capturing devices. It can be shown from the sampling analysis of light field [3] that geometry information can be employed to reduce the sampling rate of light field. Therefore, recent research has focused on the estimation of geometry of objects using stereo or multiview vision techniques, special depth sensing devices and lighting techniques as in photometric stereo. This has been shown to improve significantly the rendering quality as illustrated in lumigraph, pop-up light [18] and object-based plenoptic videos, etc. If complete 3D model can be reconstructed, interactive relighting is also possible [24].

Creating/Capturing Light Fields

Light fields can be created by rendering 3D models using computer graphic techniques or captured naturally using imaging devices such as cameras. The former can be used

Light Field, Fig. 1 Light field describes the amount of light in radiance along light rays traveling in every direction through every point in empty space

Light Field, Fig. 2 (a) 2-plane and (b) spherical parameterization of light fields

to record densely spaced images of a very complicated scene rendered off-line by computer graphic techniques. New novel views can then be rendered in real-time using the recorded image-based representations. In [22], real-time relighting of panoramas has also been demonstrated. For real and static scenes, it can be captured by placing a digital still camera at the desired locations of the image-based representations using a robot arm or at general locations using unstructured lumigraph rendering [2]. The light field can also be captured using specially designed cameras called the plenoptic cameras [1], where an optical element, such as a lenticular lens array [1, 14] or a coded aperture [10, 21], is placed in front of a sensor array to map rays from different directions at a location to neighboring pixels in the sensor array. In other words, the recorded images consist of an array of macro-pixels; each contains a set of

neighboring pixels recording rays from a given set of directions. By integrating appropriately these 4D samples in a light field, one can approximate the view that would be captured by a camera having a finite aperture. In the handheld light field camera [14], an array of microlens is placed in front of the sensors of a handheld digital camera, and photographs can be refocused after they are taken, a process called synthetic aperture photography. In principle, a light field video can be obtained in a similar manner.

To achieve a larger disparity, multiple camera systems are frequently used, especially in dynamic scenes. Much research effort has been devoted to the construction of 2D camera arrays (see the section of plenoptic function for more references in capturing systems). To simplify the capturing hardware, light field captured on line segments and circular arc have also been reported.

Sampling

An important problem in capturing, display, and rendering light fields is “how many samples of the plenoptic function and how much geometrical and textural information are needed to generate a continuous representation of the plenoptic function?” This problem was first studied for the light fields in [3] using the concept of Fourier transform, which provides valuable insight in the design of IBR systems and 3D display.

Assuming (u, v) and (s, t) are respectively the image and camera planes as in the lumigraph [7, 19]. Let $l(u, v, s, t)$ represent the continuous light field, $p(u, v, s, t)$ the pattern in sampling the light field, and $r(u, v, s, t)$ the combined filtering and interpolating low-pass filter. The output image after reconstruction is then given by

$$i(u, v, s, t) = r(u, v, s, t) * [l(u, v, s, t) p(u, v, s, t)], \quad (1)$$

where $*$ represents the convolution operation. Taking the Fourier transform of (Eq. 1), one gets

$$I(u, v, s, t) = R(u, v, s, t) [L(u, v, s, t) * P(u, v, s, t)], \quad (2)$$

$$l_S(u, v, s, t) = l(u, v, s, t) \sum_{m_1, m_2, m_3, m_4 \in \mathbb{Z}} \delta(u - n_1 \Delta u) \times \delta(v - n_2 \Delta v) \delta(s - n_3 \Delta s) \delta(t - n_4 \Delta t), \quad (4)$$

where I , R , L , and P denote, respectively, the Fourier transforms of $i(u, v, s, t)$, $r(u, v, s, t)$, $l(u, v, s, t)$, and $p(u, v, s, t)$. It is important to study how the spectrum $L(u, v, s, t)$ varies with the geometry of the scene, from which the minimum sampling density and the reconstruction filter $r(u, v, s, t)$ can be determined. For Lambertian surfaces, the radiance received at the camera position (s, t) is given by

$$l(u, v, s, t) = l\left(u - \frac{fs}{z(u, v, s, t)}, v - \frac{ft}{z(u, v, s, t)}, 0, 0\right) \quad (3)$$

with Fourier transform $L(\Omega_u, \Omega_v, \Omega_s, \Omega_t) = \int_{\mathbf{x} \in R^4} l(u, v, s, t) e^{-j\Omega^T \mathbf{x}} d\mathbf{x}$ where $\mathbf{x} = (u, v, s, t)$ and $\Omega = (\Omega_u, \Omega_v, \Omega_s, \Omega_t)$ and f is the focal length. For rectangular sampling, lattice, $p(u, v, s, t) = \sum_{n_1, n_2, n_3, n_4 \in \mathbb{Z}} \delta(u - n_1 \Delta u) \delta(v - n_2 \Delta v) \delta(s - n_3 \Delta s) \delta(t - n_4 \Delta t)$ where $\delta(\cdot)$ is the Dirac delta function and Δu , Δv , Δs , and Δt are the corresponding sampling intervals. The sampled light field $l_S(u, v, s, t)$ is

$$L_S(\Omega) = \sum_{m_1, m_2, m_3, m_4 \in \mathbb{Z}} L\left(\Omega_u - \frac{2\pi m_1}{\Delta u}, \Omega_v - \frac{2\pi m_2}{\Delta v}, \Omega_s - \frac{2\pi m_3}{\Delta s}, \Omega_t - \frac{2\pi m_4}{\Delta t}\right). \quad (5)$$

It can be seen that $L_S(\Omega)$ consists of replicas of the original spectrum, which are shifted to the 4D grid points $\left(\frac{2\pi m_1}{\Delta u}, \frac{2\pi m_2}{\Delta v}, \frac{2\pi m_3}{\Delta s}, \frac{2\pi m_4}{\Delta t}\right)$. For scene with a constant depth z_0 , it is noted from (Eq. 3) that $l(u, v, s, t)$ is a shifted version of the image $l(u, v, 0, 0) = l'(u, v)$ at $(s, t) = (0, 0)$ by an

and its Fourier transform is

amount $(-fs/z_0, -ft/z_0, 0, 0)$. Consequently, $L(\Omega)$ is simplified to

$$L(\Omega) = 4\pi^2 L'(\Omega_u, \Omega_v) \delta$$

$$\times \left(\frac{f}{z_0} \Omega_u, \Omega_s\right) \delta\left(\frac{f}{z_0} \Omega_v, \Omega_t\right), \quad (6)$$

where $L'(\Omega_u, \Omega_v)$ is the 2D Fourier transform of $l(u, v)$. Equation (Eq. 6) suggests that the projection of $L(\Omega)$ on the (Ω_v, Ω_t) (Ω_u, Ω_s) plane lies on a straight line passing through the origin with a slope of $-z_0/f$ (Fig. 3a). After sampling, the spectrum will be shifted to grid points $\left(\frac{2\pi m_1}{\Delta u}, \frac{2\pi m_2}{\Delta v}, \frac{2\pi m_3}{\Delta s}, \frac{2\pi m_4}{\Delta t}\right)$ (Fig. 3b). If z_{\min} and z_{\max} denote the minimum and maximum depth values of the scene, then the spectrum will be bounded by the two lines with slopes $-z_{\min}/f$ and $-z_{\max}/f$, respectively, as shown in Fig. 3c. From Fig. 3b, the minimum interval, by which the replicas of spectral support can be packed without overlapping or aliasing, is $2\pi K_{\Omega_v} f \left(\frac{1}{z_{\min}} - \frac{1}{z_{\max}} \right)$, where K_{Ω_v} is the maximum frequency of the light field in v plane, which depends on the maximum frequency of texture variations B_v and the resolutions of the sampling camera $1/\Delta v$ and the rendering camera $1/\delta v$ as $K_{\Omega_v} = \min(B_v, 1/(2\Delta v), 1/(2\delta v))$. The maximum camera spacing is thus $K_{\Omega_v} = 1/\left(2\pi K_{\Omega_v} f \left(\frac{1}{z_{\min}} - \frac{1}{z_{\max}} \right)\right)$. To reduce the sampling rate and avoid dense sampling, the value of K_{Ω_v} can be decreased by reducing B_v and $1/(2\Delta v)$, through pre-filtering the light field images, to the desired rendering resolution. Similar results apply to the (Ω_u, Ω_s) plane. A more thorough discussion on the effect of geometry on this minimum sampling density or rate can be found in [3, 19]. It was found that the sampling rate can be reduced by decomposition of the light fields into depth layers.

Ideally, if the depth map can be computed from stereo or multiview matching algorithm, then the number of images required can be significantly reduced. Despite considerable advances in depth estimation algorithm, finding correspondences in multiple images is still fundamentally limited by textureless region, reflections, and large variations of the imaging content itself. In pop-up light field [18], a sparse light field is modeled using a set of coherent layers with each layer being a collection of corresponding planar regions in the light field images with the help of an easy to use user interface. The number of layers, segmentation, and matting are done with the help of user

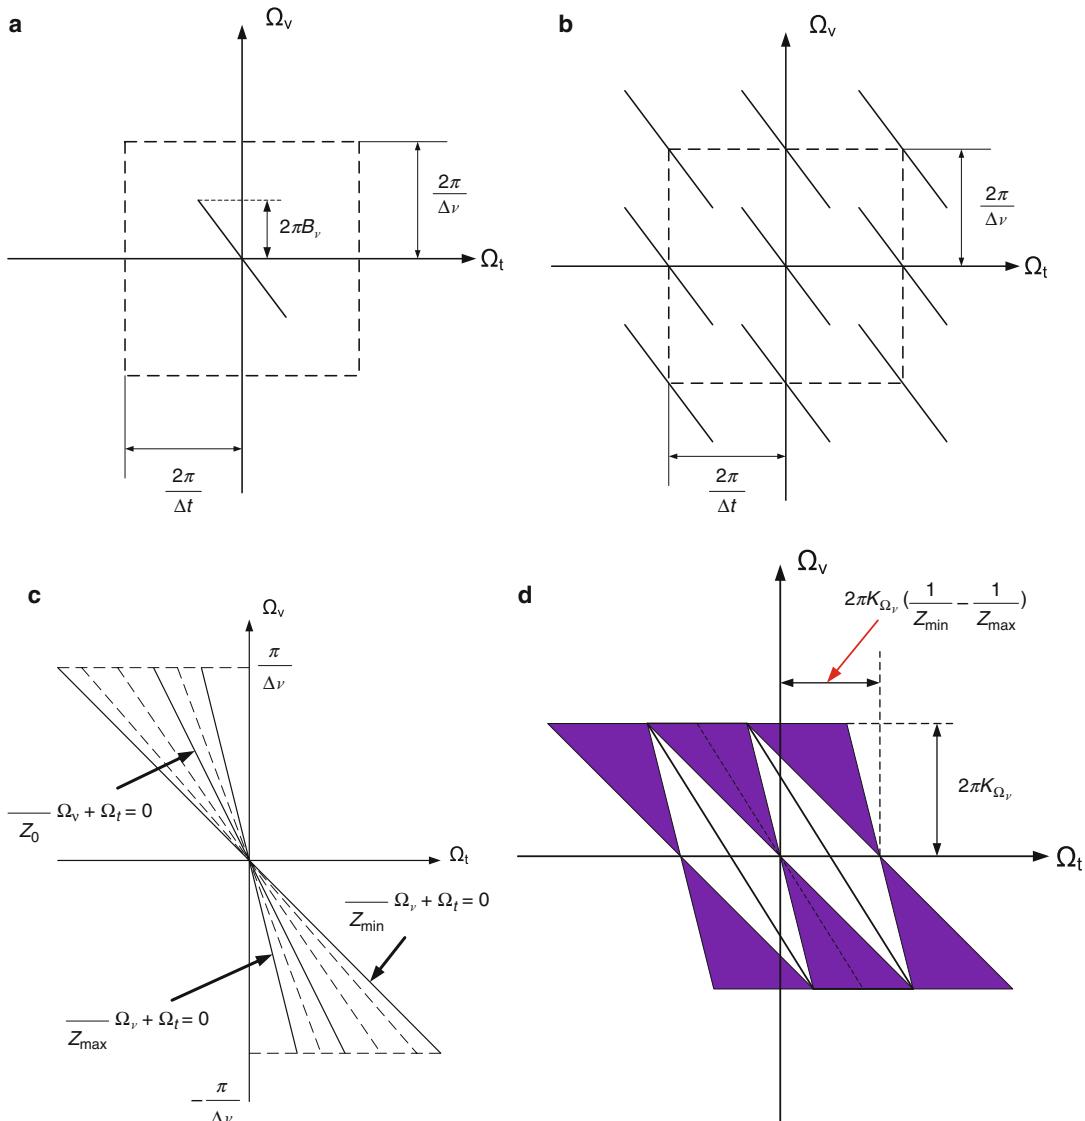

interface so that the user can supply the information needed for refining the above processes. Each coherent layer can then be rendered free of aliasing by itself or with other background layers.

The effects of occlusion, and lighting and reflection on light field spectrum can be found in [4, 16].

Compression

Since adjacent light field images appear to be shifted relative to each other, there is considerable redundancy in the 4D data set, which can be compressed to save storage and transmission bandwidth. Earlier approaches on light field or lumigraph compression were mostly based on conventional pixel-based methods such as vector quantization (VQ) [8, 20], discrete cosine transform (DCT)-based coding, and wavelet coding. Subsequently, disparity compensation prediction (DCP) [11], model-based/model-aided, and object-based methods were proposed to improve the compression ratio and rendering quality. In DCP, the light field images is divided into I- (intra) and P- (predicted) pictures, and the P-pictures can be predicted by disparity compensation from the nearest encoded I-pictures, which are evenly distributed. In [23], a multiple reference frame (MRF) prediction coding method was proposed for lumigraph compression. Anchor frames (A frames) which are similar to the I-pictures are used as reference for predicting the remaining P-images, and a two-level index table is incorporated into the bit stream for quick access to individual picture and macroblocks. This helps to simplify the “random access problem” to improve rendering speed (see the image-based rendering section for more details and references). A caching stream is also incorporated to speed up the rendering.

Model-based coding makes use of the scene geometry to convert the images from a spherical light field to view-dependent texture maps, which are more amenable to coding using a wavelet-based set partitioning in hierarchical trees (SPIHTs) 4D codec. Model-aided predictive coding makes use of geometry information to morph and predict new views from already encoded

Light Field, Fig. 3 Spectral support of light field: (a) spectrum of a light field with constant depth on the (v, t) plane, (b) spectrum after sampling, and (c) spectrum of a light field signals with depth bounded by z_{\min} and z_{\max} .

The mean depth is z_0 ; (d) Optimal reconstruction filter (black parallelogram in the middle) and optimal spacing of spectrum without aliasing

images, and the prediction residuals are encoded using DCT-based coding. Experimental results showed that the model-aided approach is more robust to variations in the geometric models [12]. In object-based light field compression [15], the light field images are segmented into image-based objects, or IBR objects in short, each with its image sequences, depth maps, and other relevant information such as shape information. They

are compressed using an MPEG-4-like compression algorithm so as to provide content-based functionalities such as scalability of contents, error resilience, and interactivity with individual IBR objects. Rendering scene with depth layers or IBR objects also reduce the artifacts due to depth discontinuities. For more information of IBR and light field compression, see also the survey [5, 19].

Applications

Like the plenoptic function, light field serves an important concept for describing visual information in our world. Its sampling analysis also serves as a basic for designing light field cameras and automultiscopic displays for capturing and displaying such high-dimensional function, respectively. Light fields have also found many other applications in computational photography, microscope [9], glare reduction in camera [17], 3DTV [13], etc.

Open Problems

Since the light field is a special case of the plenoptic function, most of their open problems are similar. For instance, the efficient capturing and processing of light fields are important problems in visual computing and vision research. A detailed analysis of the light field for complicated scene is difficult because the function itself may not even be bandlimited. A general analysis involving all these components is again difficult. Moreover, how to achieve high-quality rendering and display light fields with a wide range of viewpoints in large-scale environmental modeling remains open.

Definition

Light transport describes how the light emitted from light sources propagates into a 3D scene and bounces between object surfaces. The light transport in a scene can also be presented by a reflectance field that directly encodes the mapping between the incident light field to the outgoing light field of the scene caused by the light transport.

Background

The physical process of light transport in a 3D scene has been well studied in computer graphics

since 1980s. In theory, the light transport in a scene can be formulated by the rendering equation [5]. In practice, simulating the light transport in a 3D scene (i.e., global illumination effects) is the essential task of various rendering techniques in computer graphics. To this end, a set of global illumination algorithms, such as Monte Carlo ray tracing, photon mapping, and radiosity, have been developed for efficiently simulating the light transport in a synthetic 3D scene and generating photo-realistic images of the scene from arbitrary viewpoints [2]. These rendering techniques can faithfully reproduce all kinds of light transport effects with the high computational cost and long rendering time. Later, Precomputed Radiance Transfer (PRT) techniques [9, 10] have been developed for rendering the global illumination effects of a synthetic scene in real time.

With the development of computational imaging devices, some methods [4, 11] directly capture the light transport process in a real scene via ultrafast imaging.

The light transport in a 3D scene can also be modeled as an 8D reflectance field [1], which represents the light transport from incident light field to outgoing light field of the scene. Compared to physically based representation (i.e., the rendering equation), this image-based representation requires no scene modeling and thus can be directly captured from real world scenes and used for rendering images of the scene under new lighting conditions. Based on this representation, a set of image-based relighting techniques [8, 12, 14] have been developed for efficiently capturing the reflectance field of a real scene and generating images of the scene under new illuminations.

Theory

Light transport describes the light propagation in a 3D scene, where the light emitted from a light source passes through the empty space along a ray and is scattered toward different directions after hitting a surface point. For each scattered ray, this process is repeated until the light is absorbed by the scene surfaces or reaches the image plane of a virtual camera. The light

transport in the scene can be described by the following rendering equation: [5]

$$L(x, x') = L_e(x, x') + \int_S \rho(x, x', x'') G(x', x'') L(x', x'') dx'' \quad (1)$$

where $L(x, x')$ is the radiance from a surface point x' to another point x , $L_e(x, x')$ is the light emitted from x' toward x , $\rho(x, x', x'')$ is the bidirectional reflectance distribution function (BRDF) (i.e., surface reflectance) at x' , $L(x', x'')$ is the incident light from another surface point x'' in the scene to x' , and $G(x', x'')$ is the geometry factor between x' and x'' . The integration is performed over all surface points S . Please refer to [5] for more details.

The rendering equation can be solved in two ways. One is to integrate the light transport along all possible paths, each of which starts from the light source and ends with the path (x', x) and has arbitrary number of bounces in between:

$$L(x, x') = L_e(x, x') + \sum_P P_i(x, x', \dots, x_0, x_e) L_e(x_0, x_e) \quad (2)$$

where $L_e(x_0, x_e)$ is the light emitted from the light source x_e to a surface point x_0 , $P_i(x, x', \dots, x_0, x_e)$ represent the probability of the light propagation path from x_e to x , and P is all the possible light paths in the scene.

The other solution is to solve the rendering equation with the Neumann series: [5]

$$L(x, x') = L_e + M L_e + M^2 L_e + M^3 L_e \dots + M^n L_e \dots \quad (3)$$

which is the sum of the radiance transfers from x to x' with different number of bounces between the surfaces. Specifically, L_e refers to the direct radiance transfer without any bounce, $M L_e$ represents the radiance transfer with one bounce, and $M^n L_e$ is the radiance transfer with n bounces [5].

The light transport in a scene can also be formulated as an 8D reflectance field: [1]

$$R(u_i, v_i, \theta_i, \phi_i, u_r, v_r, \theta_r, \phi_r) \quad (4)$$

where $(u_i, v_i, \theta_i, \phi_i)$ represents the incident light field and $(u_r, v_r, \theta_r, \phi_r)$ represents the outgoing light field of a scene or object. The ray in each light field is parameterized by a point (u, v) on a virtual cube surrounding the scene and its direction (θ, ϕ) . Since capturing this high-dimensional reflectance field is very expensive, many methods simplify this 8D reflectance field into a lower-dimensional one. This can be achieved by fixing the viewpoint and thus simplifying the outgoing 4D light field to a 2D image (u_i, v_i) or simplifying the 4D incident light field as 2D directional lighting or a set of point light sources that lie in a 2D plane.

Based on the reflectance field representation of the light transport in a scene, image-based relighting can be formulated by the following matrix vector multiplication: [8]

$$b = T \cdot l \quad (5)$$

where b is a vector of the outgoing radiance observed from an image with m pixels, l is illumination condition represented by a vector of incident radiance from n light sources, and T is the $m \times n$ light transport matrix that records the light transport from n light sources to m camera pixels. The light transport matrix T represents discrete samples of the reflectance field of the scene. Since the 8D reflectance field is difficult to be captured and processed, most of image-based relighting methods focus on 4D reflectance field with a fixed viewpoint and light sources that lie in a 2D plane or hemisphere. The core task of image-based relighting is to acquire the light transport matrix T from the scene.

A set of methods [1, 13] directly measure the light transport matrix from the scene, which always require tens of thousands of images taken under the controlled lighting. Other methods exploit the sparsity [8] or coherence [7, 12] of the light transport matrix to reduce the number of images required for constructing

the light transport matrix. Recently, the deep neural network-based methods [14] exploit the coherence of the light transports among various scenes for image-based relighting.

Image-based relighting techniques have been successfully used in movie production for relighting the performance of real characters [13]. For synthetic 3D scenes, many-light methods [3] model the global illumination with the same matrix-vector multiplication formulation and leverage the sparsity or coherence of light transport matrix for speeding up the rendering.

Open Problems

How to efficiently capture the full 8D reflectance field is still an open and challenging problem in computer graphics and computer vision. Due to the high computational cost, simulating the light transport of a 3D scene in real time is still an open problem in computer graphics.

Experimental Results

For light transport simulation, the Mitsuba 2.0 (<http://www.mitsuba-renderer.org/>) and PBRT (<https://www.pbrt.org/>) provide good frameworks and implementations of many global illumination algorithms.

For image-based relighting, the source code or data of several methods (e.g., [7, 14]) can be found in their project pages.

Definition

Line drawing labeling is an assignment of labels to lines in a line drawing according to the interpretation of the line drawing as a three-dimensional scene.

Background

Machine interpretation of a line drawing as a three-dimensional scene is one of the fundamental problems in computer vision. However, a line drawing is a collection of line segments in the plane and has no direct information about three-dimensional structures. Line drawing labeling is an effective method to find candidates of interpretations as three-dimensional scenes. Hence, this method is used as the first step for interpreting a line drawing. Once the labeling is obtained, the associated candidate of interpretation is analyzed in details to judge whether it is a correct interpretation.

Theory

The most basic version of line drawing labeling is an interpretation of a line drawing as a polyhedral scene viewed from a general angle. This framework is based on the next four assumptions.

Assumption 1 A scene is a collection of opaque polyhedrons.

Assumption 2 The view point is in general position in the sense that no accidental alignment happens in the picture plane (for example, nonparallel edges do not fall into parallel lines, or noncollinear edges do not fall into collinear lines).

Assumption 3 Every vertex of a polyhedron is incident to exactly three faces.

Assumption 4 Visible edges only are drawn in the line drawing.

Under these assumptions, lines in the line drawing are classified into three categories.

1. Convex line. An image of an edge forming a ridge whose two side faces are both visible; this line is represented by “+” label.
2. Concave line. An image of an edge forming a valley; this line is represented by “–” label.
3. Silhouette line. An image of an edge forming a ridge, one of whose side faces is invisible; this line is represented by an arrow label so that the associated faces are to the right of the arrow.

Then, [1] showed that the allowed combinations of labels around junctions are restricted to only 12 types shown in Fig. 1. Clowes [2] found essentially the same property with different notations.

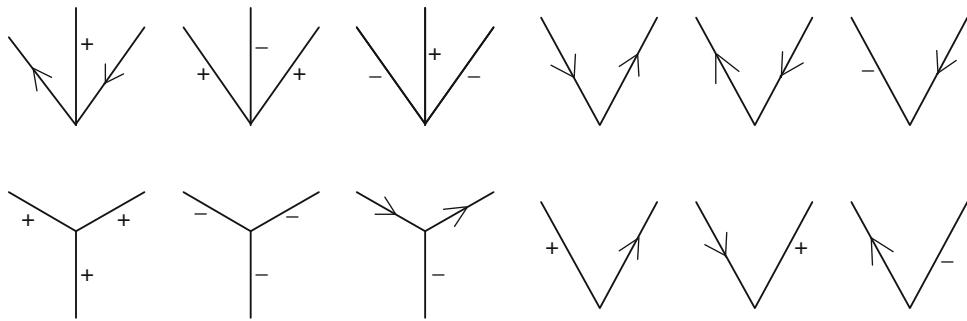

An assignment of the three labels, one label to each line, is called a *consistent labeling* if the resulting combinations around the vertices all belong to Fig. 1. A line drawing is called *labelable* if it admits a consistent labeling. Then, the next property holds.

Property 1 If a line drawing does not admit a consistent labeling, it cannot represent a three-dimensional scene under Assumptions 1–4.

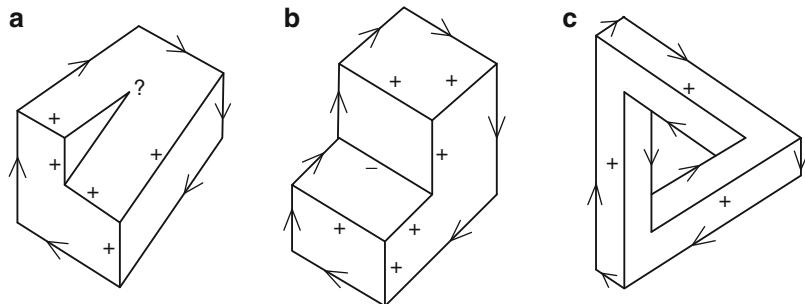

For example, the line drawing in Fig. 2a does not admit a consistent labeling, and hence it cannot represent a polyhedral scene. On the other hand, a consistent labeling sometimes corresponds to a correct interpretation as in Fig. 2b, but sometimes does not correspond to a correct interpretation as in Fig. 2c.

To find a consistent labeling is in general a hard problem; actually it was proved to be NP-hard by [3]. On the other hand, for many line drawings observed in ordinary scenes, consistent labeling can be found efficiently by a constraint propagation method [4] and a relaxation method [5].

The list of allowed combinations of labels in Fig. 1 is called a *junction dictionary*; this is because a line drawing is a language to convey solid information, and the list in Fig. 1 can be

Line Drawing Labeling, Fig. 1 Allowed combinations of labels around junctions

Line Drawing Labeling, Fig. 2 Labelable and unlabelable line drawings

considered as a dictionary to understand this language.

The junction dictionary in Fig. 1 is obtained under Assumptions 1–4. If some of the assumptions are changed, different sets of allowed combinations are obtained. Waltz [6] constructed a junction dictionary for line drawings with shadow lines and cracks. Sugihara [7] constructed a dictionary for engineering line drawings in which hidden lines are represented by broken lines. Kanade [8] constructed a dictionary for origami world in which the objects are made of thin sheets such as paper. Sugihara [9] considered a junction dictionary for range image in which the line categories are known from range data, and hence the dictionary is used for predicting missing edges.

Open Problems

It is known to be NP-hard to find a consistent labeling in general. It is natural to ask what

subclasses of pictures can admit polynomial-time algorithms, but it is still open.

Figure 1 is the junction dictionary for the simplest world, defined by Assumptions 1–4. If we change the assumptions, the associated junction dictionary also changes. It is open to construct the junction dictionaries for other worlds and to evaluate their performance. Important worlds include, to mention a few, the world of the three-view drawings used in engineering, and the world with curved surface objects.

Application

A consistent labeling gives a candidate of interpretation of a line drawing as a polyhedral scene. Usually, the set of all consistent labelings is small, and hence the line drawing labeling can effectively prune the possible candidates of interpretation for more detailed analysis. Thus, it can be a first step for machine interpretation of

line drawings. A method for judging whether a consistent labeling corresponds to a correct interpretation was established by [10].

LP

Definition

A *linear programming problem* (also termed *linear program*) is an optimization problem to

minimize or maximize a linear objective function subject to linear equality/inequality constraints. *Linear programming*, often abbreviated as *LP*, is a methodology initiated by G. Dantzig, J. von Neumann, L. V. Kantorovich, and others in the 1940s [1–10]. It includes:

- Modeling techniques to formulate real-world problems into linear programs
- Theory about the mathematical structure of linear programs
- Algorithms for numerically solving linear programs

Background

For theoretical treatment and software development, it is convenient to use a specific form to describe linear programs. Often adopted for use is:

$$\begin{aligned} & \text{Minimize } c^\top x \\ & \text{subject to } Ax = b \\ & \quad x \geq \mathbf{0}, \end{aligned} \tag{1}$$

called the *standard form*, although the terminology varies in the literature. It should be clear that:

- An instance of the optimization problem is specified by a matrix A and vectors b and c . It is assumed that A is an $m \times n$ matrix, b is an m -dimensional vector, and c is an n -dimensional vector.
- Symbol $^\top$ means the transpose, and $c^\top x$ denotes the inner product of c and x , that is, $c^\top x = \sum_{j=1}^n c_j x_j$.
- The inequality between vectors means componentwise inequality; $x \geq \mathbf{0}$ for $x = (x_1, \dots, x_n)$ means $x_j \geq 0$ for $j = 1, \dots, n$.
- The variable x , an n -dimensional vector, is the variable for optimization. It is required to find an *optimal solution* x that minimizes the *objective function* $c^\top x$ under the *equality constraint* $Ax = b$ and the *inequality constraint* $x \geq \mathbf{0}$.

Any linear program can be put in the standard form by introducing auxiliary variables,

changing maximization to minimization, etc. The transformation to the standard form, however, is not unique.

Example 1 A linear program of the form

$$\text{Minimize } c^\top x \quad \text{subject to } Ax \geq b, x \geq \mathbf{0} \quad (2)$$

can be put in the standard form (1) by rewriting $Ax \geq b$ to $Ax - s = b, s \geq \mathbf{0}$ with a vector $s = (s_1, \dots, s_m)$ of *slack variables* s_1, \dots, s_m . Conversely, a linear program in the standard form (1) can be recast into the form of (2) by rewriting $Ax = b$ to $Ax \geq b, -Ax \geq -b$. It is mentioned that (2) is often called the *canonical form*. ■

Example 2 A linear program of the form

$$\text{Maximize } c^\top x \quad \text{subject to } Ax \leq b \quad (3)$$

can be put in the standard form (1) as follows. First, $Ax \leq b$ is rewritten as $Ax + s = b, s \geq \mathbf{0}$. Then, the vector x of *free variables*, which are free from sign-constraint, is expressed as $x = y - z$ with $y \geq \mathbf{0}$ and $z \geq \mathbf{0}$. Finally, maximization is turned into minimization by changing the sign of the objective function. The resulting linear program is

$$\begin{aligned} & \text{Minimize } -c^\top y + c^\top z \\ & \text{subject to } Ay - Az + s = b, \quad y, z, s \geq \mathbf{0}, \end{aligned}$$

which is in the standard form (1) with A, b, c replaced by

$$\begin{aligned} \tilde{A} &= [A \quad -A \quad I], \quad \tilde{b} = b, \\ \tilde{c} &= [-c^\top \quad c^\top \quad \mathbf{0}^\top]^\top. \end{aligned} \quad (4)$$

Given a linear program, say, in the standard form (1), a vector x is called a *feasible point* or a *feasible solution* if it satisfies all the constraints. In the literature of optimization, “solution” is often used as a synonym of “point,” and therefore, “solution x ” may or may not be a “solu-

tion” to the given optimization problem, the latter being termed an *optimal solution*. By definition, an optimal solution minimizes the objective function among all feasible solutions (points). A linear program is said to be *feasible* if it has a feasible solution; otherwise, it is *infeasible*. The set of feasible solutions is called the *feasible region*. For instance, $S = \{x \mid Ax = b, x \geq \mathbf{0}\}$ is the feasible region of the problem (1).

A linear program is said to be *unbounded* if the objective function can become indefinitely small toward $-\infty$; otherwise, it is *bounded*. It is a fundamental fact in linear programming that a bounded problem has an optimal solution, which means that there exists a feasible solution $x^* \in S$ such that $c^\top x^* = \inf\{c^\top x \mid x \in S\}$, where S denotes the feasible region. Note that this is not the case in nonlinear optimization; for example, no x^* exists such that $\exp(-x^*) = \inf\{\exp(-x) \mid x \geq 0\}$.

L

Theory

In the standard form (1), it can be assumed, without loss of generality, that the $m \times n$ matrix A has independent rows. This implies that $m \leq n$ and $\text{rank } A = m$. Note $b \in \mathbf{R}^m$, $c \in \mathbf{R}^n$, and $x \in \mathbf{R}^n$, where \mathbf{R} denotes the set of real numbers.

Let B be the set of column numbers that corresponds to a basis of the column vectors of A and N be the set of remaining column numbers; $B \cap N = \emptyset$ and $B \cup N = \{1, \dots, n\}$. The $m \times m$ submatrix of A corresponding to B is denoted as A_B , and, similarly, the $m \times (n-m)$ submatrix corresponding to N is A_N . If $B = \{1, \dots, m\}$ and $N = \{m+1, \dots, n\}$, for example, then $A = [A_B \quad A_N]$. Accordingly, the vector x is partitioned into two parts: $x = (x_B, x_N)$ with $x_B = (x_i \mid i \in B) \in \mathbf{R}^m$ and $x_N = (x_j \mid j \in N) \in \mathbf{R}^{n-m}$. Variables x_i contained in x_B are *basic variables*, and those in x_N are *nonbasic variables*.

The equality constraint $Ax = b$ can be rewritten as

$$x_B + A_B^{-1} A_N x_N = A_B^{-1} b, \quad (5)$$

which is satisfied by

$$\bar{x} = (\bar{x}_B, \bar{x}_N) = (A_B^{-1}b, \mathbf{0}). \quad (6)$$

A solution \bar{x} induced from a basis B in this manner is called a *basic solution*. The basic solution \bar{x} is feasible if

$$A_B^{-1}b \geq \mathbf{0}. \quad (7)$$

A *basic feasible solution* means a basic solution that is feasible. A basis B is called a *feasible basis* if it satisfies the condition (7). Two different bases can possibly determine the same basic solution (6). This is called *degeneracy*.

The following theorem reveals a combinatorial nature of linear programs. Note that, for a given linear program, there exist only finitely many bases, at most $\binom{n}{m} = n!/(m!(n-m)!)$ in number.

Theorem 1 *For a linear program in (1), the following hold:*

- (1) *A basic feasible solution exists if it has a feasible solution.*
- (2) *A basic optimal solution exists if it has an optimal solution.*

With reference to a basis B , x and c are represented as $x = (x_B, x_N)$ and $c = (c_B, c_N)$. The basic solution corresponding to B is given by (6). It follows from (5) that

$$x_B = A_B^{-1}b - A_B^{-1}A_N x_N. \quad (8)$$

Then

$$\begin{aligned} f &= c^\top x = c_B^\top x_B + c_N^\top x_N \\ &= c_B^\top A_B^{-1}b + (c_N^\top - c_B^\top A_B^{-1}A_N)x_N \\ &= \bar{f} + \bar{c}_N^\top x_N, \end{aligned} \quad (9)$$

which is an expression of the objective function as a function in x_N , where

$$\bar{f} = c_B^\top A_B^{-1}b = c_B^\top \bar{x}_B = c^\top \bar{x}, \quad (10)$$

$$\bar{c}_N^\top = c_N^\top - c_B^\top A_B^{-1}A_N. \quad (11)$$

Expressions (8) and (9) are reformulations of the equality constraint and the objective function, respectively, in terms of the nonbasic variable x_N at a basic solution. They are often referred to as the *basic forms*.

With the notation

$$\bar{a}_{ij} = (A_B^{-1}A_N)_{ij}, \quad \bar{b}_i = (A_B^{-1}b)_i \quad (i \in B, j \in N) \quad (12)$$

for the coefficients in (8), and $\bar{b} = (\bar{b}_i \mid i \in B) \in \mathbf{R}^m$, the condition (7) for the feasibility of basic solution \bar{x} can be rewritten as

$$\bar{b}_i \geq 0 \quad (i \in B) \quad [\text{i.e., } \bar{b} \geq \mathbf{0}]. \quad (13)$$

The modified cost vector $\bar{c} = (\bar{c}_B, \bar{c}_N) = (\mathbf{0}, \bar{c}_N) \in \mathbf{R}^n$ is defined using \bar{c}_N in (11).

Theorem 2 *Let B be a feasible basis for a linear program (1). Then the basic solution \bar{x} corresponding to B is an optimal solution if*

$$\bar{c}_j \geq 0 \quad (j \in N) \quad [\text{i.e., } \bar{c}_N \geq \mathbf{0}]. \quad (14)$$

Proof. Since $x_N \geq \mathbf{0}$ for any feasible solution, it follows from $\bar{c}_N \geq \mathbf{0}$ and (9) that $f = \bar{f} + \bar{c}_N^\top x_N \geq \bar{f}$. \square

A feasible basis B that satisfies the condition (14) is called an *optimal basis*. Theorem 2 states that an optimal basis induces an optimal solution; note, however, that, in case of degeneracy, not every basis associated with an optimal basic solution meets the condition (14).

Suppose that B is a feasible basis that is not optimal. As the optimality condition (14) fails at B , the set $J = \{j \in N \mid \bar{c}_j < 0\}$ is nonempty. Choose a nonbasic variable x_{j^*} with $j^* \in J$ and consider increasing x_{j^*} from zero to a positive value, while fixing other nonbasic variables to zero. It is expected that the objective function decreases since \bar{c}_{j^*} is negative.

As for the equality constraint, (8) is written componentwise as

$$x_i = \bar{b}_i - \sum_{j \in N} \bar{a}_{ij} x_j \quad (i \in B). \quad (15)$$

In increasing x_{j^*} , the basic variables x_i ($i \in B$) can be determined by (15) to maintain the equality constraint.

For the inequality constraint, define $I = \{i \in B \mid \bar{a}_{ij^*} > 0\}$. To maintain $x_i \geq 0$ for $i \in I$, the value of x_{j^*} must be chosen as $x_{j^*} \leq \bar{b}_i / \bar{a}_{ij^*}$, whereas any nonnegative value of x_{j^*} results in $x_i \geq 0$ for $i \notin I$. Therefore, if $I = \emptyset$, the given linear program is unbounded. Hence, suppose $I \neq \emptyset$. With

$$\xi = \min_i \{\bar{b}_i / \bar{a}_{ij^*} \mid \bar{a}_{ij^*} > 0\} \quad (\geq 0), \quad (16)$$

a new point \hat{x} is defined by

$$\begin{aligned}\hat{x}_{j^*} &= \xi, \quad \hat{x}_i = \bar{b}_i - \bar{a}_{ij^*}\xi \quad (i \in B), \\ \hat{x}_j &= 0 \quad (j \in N \setminus \{j^*\}),\end{aligned}$$

which is a basic feasible solution associated with another basis

$$\hat{B} = (B \setminus \{i^*\}) \cup \{j^*\},$$

where i^* designates the index i that attains the minimum on the right-hand side of (16). This basis \hat{B} is a neighbor to B in the sense that $|\hat{B} \setminus B| = 1$. It is remarked that $\xi = 0$ means $B \neq \hat{B}$ and $x = \hat{x}$ (degeneracy).

The objective function is nonincreasing, since $\bar{c}_{j^*} < 0$, $\xi \geq 0$, and

$$f(\hat{x}) - f(x) = c^\top (\hat{x} - x) = \bar{c}_{j^*}\xi.$$

It is strictly decreasing if $\xi > 0$ (i.e., in a nondegenerate case).

This is the fundamental idea of the simplex method, which repeats updating bases as above until it finds an optimal basis. So long as no degeneracy occurs, the objective function decreases monotonically, and the minimum value is reached in finite steps. In the case of degeneracy, however, it can happen that distinct bases corresponding to the same basic solution are visited infinitely many times – a phenomenon called *cycling*. A judicious choice of j^* and i^* avoids cycling.

Duality

For a linear program in the standard form (1) described by an $m \times n$ matrix A , an m -dimensional vector b , and an n -dimensional vector c , another linear program may be considered:

$$\begin{array}{ll}\text{Maximize } & b^\top y \\ \text{subject to } & A^\top y \leq c.\end{array}$$

This is called the *dual problem*; in contrast, the original problem (1) is referred to as the *primal problem*. The pair of linear programs read as

| | |
|---|--|
| $\begin{array}{ll}\text{Problem P} & \\ \text{Minimize } & c^\top x \\ \text{subject to } & Ax = b \\ & x \geq \mathbf{0}\end{array}$ | $\begin{array}{ll}\text{Problem D} & \\ \text{Maximize } & b^\top y \\ \text{subject to } & A^\top y \leq c.\end{array}$ |
|---|--|

(17)

Since any linear program can be put in the standard form, the dual of the standard form equivalent to Problem D, which is called the dual of Problem D, may be conceived. Problem D is equivalent to the standard form (1) with A , b , and c replaced by

$$\begin{aligned}\tilde{A} &= [A^\top \quad -A^\top \quad I], \quad \tilde{b} = c, \\ \tilde{c} &= [-b^\top \quad b^\top \quad \mathbf{0}^\top]^\top;\end{aligned}$$

see (4) in Example 2 and replace $A \rightarrow A^\top$, $b \rightarrow c$ and $c \rightarrow b$. The dual problem of Problem D is

$$\text{Maximize } c^\top \tilde{y} \quad \text{subject to} \quad \begin{bmatrix} A \\ -A \\ I \end{bmatrix} \tilde{y} \leq \begin{bmatrix} -b \\ b \\ \mathbf{0} \end{bmatrix},$$

which can be rewritten with $\tilde{x} = -\tilde{y}$ as

$$\text{Minimize } c^\top \tilde{x} \quad \text{subject to} \quad A\tilde{x} = b, \quad \tilde{x} \geq \mathbf{0}.$$

This coincides with Problem P. In this sense, the linear program dual to the dual problem coincides with the primal problem.

Example 3 For the canonical form, the dual pair is given as

$$\begin{array}{ll} \text{Minimize } c^\top x & \text{Maximize } b^\top y \\ \text{subject to } Ax \geq b & \text{subject to } A^\top y \leq c \\ x \geq \mathbf{0} & y \geq \mathbf{0}. \end{array}$$

■

The *linear programming duality* is stated in the following theorem, where the feasible regions of Problems P and D in (17) are denoted as

$$\begin{aligned} P &= \{x \in \mathbf{R}^n \mid Ax = b, x \geq \mathbf{0}\}, \\ D &= \{y \in \mathbf{R}^m \mid A^\top y \leq c\}. \end{aligned} \quad (18)$$

In (19) below, we follow the convention that the infimum over an empty set is equal to $+\infty$ and the supremum over an empty set is equal to $-\infty$.

Theorem 3 *For the dual pair of linear programs in (17), the following hold.*

- (1) [Weak duality] $c^\top x \geq b^\top y$ for any $x \in P$ and $y \in D$.
- (2) [Strong duality] If $P \neq \emptyset$ or $D \neq \emptyset$, then

$$\inf\{c^\top x \mid x \in P\} = \sup\{b^\top y \mid y \in D\}. \quad (19)$$

This common value is finite if and only if both P and D are nonempty, and in that case, the infimum and the supremum are attained by some $x \in P$ and $y \in D$, respectively.

Proof. (1) For $x \in P$ and $y \in D$, it holds that $y^\top b = y^\top Ax \leq c^\top x$. The essence of this theorem lies in (2), which can be derived from a fundamental fact known as Farkas' lemma. □

An optimality criterion in terms of complementarity can be derived from the duality theorem above. For any $x \in P$ and $y \in D$, it holds that

$$\begin{aligned} c^\top x - b^\top y &= c^\top x - y^\top Ax = (c - A^\top y)^\top x \\ &= \sum_{j=1}^n (c - A^\top y)_j x_j \geq 0. \end{aligned} \quad (20)$$

Here, the inequality " ≥ 0 " turns into equality " $= 0$ " if and only if the *complementarity condition*:

$$x_j = 0 \text{ or } (A^\top y)_j = c_j \quad \text{for each } j = 1, \dots, n \quad (21)$$

is satisfied. Hence, (21) is sufficient for the optimality of x and y . The necessity follows from Theorem 3(2). Hence, follows the next theorem.

Theorem 4 *Assume $x \in P$ and $y \in D$. Then x is optimal for Problem P and y is optimal for Problem D if and only if they satisfy the complementarity condition (21).* ■

Another implication of Theorem 3 is that solving Problem P is equivalent to finding (x, y) that satisfies a system of linear equalities/inequalities:

$$Ax = b, \quad x \geq \mathbf{0}, \quad c^\top x \leq b^\top y, \quad A^\top y \leq c. \quad (22)$$

Thus, the duality theorem transforms the optimization problem to a feasibility problem.

Integrality

Linear programming acquires combinatorial flavors through integrality [9, 11]. A linear program described by integer data (an integer matrix A and integer vectors b and c) may or may not have an integer optimal solution. A major interest in this context is under which condition an integer optimal solution is guaranteed.

An integer matrix is *totally unimodular* if every minor (subdeterminant) is equal to 1, -1, or 0. Each entry of a totally unimodular matrix is 1, -1, or 0.

A typical example of a totally unimodular matrix is the incidence matrix of a (directed) graph. Let $G = (V, E)$ be a directed graph with vertex set V and edge set E , where no self-loops exist. The *incidence matrix* of G is a matrix such that the row-set is indexed by V , the column-set by E , and

$$(v, e)\text{-entry} = \begin{cases} +1 & (v \text{ is the initial vertex of edge } e) \\ -1 & (v \text{ is the terminal vertex of edge } e) \\ 0 & (\text{otherwise}), \end{cases}$$

where $v \in V$ and $e \in E$.

The following theorem relates the total unimodularity of the coefficient matrix to the integrality of optimal solutions of linear programs. The set of integers is denoted as \mathbf{Z} .

Theorem 5 *Let A be a totally unimodular matrix.*

- (1) *If b is integral, Problem P in (17) has an integral optimal solution $x \in \mathbf{Z}^n$, as long as it has an optimal solution.*
- (2) *If c is integral, Problem D in (17) has an integral optimal solution $y \in \mathbf{Z}^m$, as long as it has an optimal solution.*

Algorithms

Algorithms for solving linear programs are divided into three categories: the *simplex method* [1, 2, 9], the *interior-point method* [12–18], and the *ellipsoid method* [19]. The simplex method, proposed by G. Dantzig, 1947, has long been the standard algorithm. The interior-point method, initiated by N. Karmarkar, 1984, is getting more and more important. The ellipsoid method, due to L. G. Khachiyan, 1979, is of theoretical importance but of little practical value; it is the first polynomial-time algorithm and has deep implications in the theory of combinatorial optimization.

Open Problems

The simplex method, with some pivoting rule, is known to be a finite algorithm, but not a polynomial-time algorithm. A major open problem is to find, if possible, a pivoting rule that renders the simplex method a polynomial-time algorithm.

The ellipsoid method is a polynomial-time algorithm, but it is weakly polynomial in that the running time depends on the size of the input numerical data. Another major open problem is to design a strongly polynomial-time algorithm, which, by definition, runs in time polynomial in the number of constraints and the number of variables.

Linear Shape and Appearance Models

► Active Appearance Models

Linguistic Techniques for Event Recognition

Vlad I. Morariu

Computer Vision Laboratory, College Park, MD, USA

Definition

Linguistic techniques for event recognition use elements of language such as vocabulary, grammar, expressions, syntax, and semantics to represent and recognize events.

Background

Visual event recognition systems use linguistic techniques to describe complex events by the composition of primitive sub-events according

certain rules (spatial, temporal, logical, etc.). This allows systems to represent a large set of events while modeling a much smaller set of primitive events by low-level processing. Representational and computational properties of these systems depend on the types of allowable relationships between sub-events. Some systems also aim for representations that are closer to natural language to facilitate user interaction, i.e., to describe events, make queries, or interpret results.

Theory and Applications

Hidden Markov Models (HMMs) [10] are statistical Markov models that decompose temporal sequences into discrete time steps, each with an associated unobserved discrete state variable and an observed continuous or discrete variable. Each state has a probability distribution over the output variable and another over the transition to a new state in the next time step. These models have been successful in the field of speech recognition and have also been widely used for gesture [7] and event recognition [6, 16]. More general Dynamic Bayesian Networks (DBNs) [3] have also been applied to event recognition (e.g., [8]) and some extensions such as Propagation Nets (P-Nets) model duration of temporal subintervals [13] for recognition of complex events.

Logical languages such as First-Order Logic have been used to represent qualitative spatial and temporal constraints, with temporal constraints often expressed using Allen's temporal primitives [1]. Allen and Ferguson [2] proposed a framework for using these temporal primitives to create a representation motivated by natural language that is able to reason about complex patterns such as external events, simultaneous activities, and mutually exclusive activities for the purpose of planning and natural language understanding systems. Siskind's formal language of *event logic* [14], which also uses Allen's temporal primitives, reasons about simple spatial verbs observed from animated images. To deal with the computa-

tional complexity with Allen's temporal primitives, Pinhanez and Bobick propose Past-Now-Future Propagation (PNF) [9], which constructs a three-valued PNF constraint network designed to answer only the question of whether an action is currently happening or not. Nevatia et al. [5] also use Allen's interval logic for relating event intervals to each other using the Event Recognition Language (ERL). ERL hierarchically represents single and multiple threads of composite events and is intended to simplify user interaction through its similarity to existing programming languages. Tran and Davis more recently [15] combined logical and probabilistic event reasoning via Markov Logic Networks (MLNs), which relax hard rules in First-Order Logic and perform probabilistic inference using Markov networks.

Grammars, which have been used in analyzing static images (e.g., picture languages [11]), have also been used for event recognition. Ivanov and Bobick [4] propose a system that recognizes events using a stochastic context-free grammar (SCFG) parsing mechanism which allows for long range temporal constraints, uncertain low-level detections, as well as concurrency of events. Their approach combines the statistical detection of primitives using uncertain low-level detectors, with long-term structural interpretation by stochastic context-free parsing. Ryoo and Aggarwal [12] combine Bayes Nets at the lowest layer to infer pose, HMMs that the middle layer to extract gesture symbols, and context-free grammars (CFGs) combined with Allen's interval logic to extract composite actions and interactions from primitive (or atomic) actions. Their system was applied to the recognition of two-person interactions.

LSTM

Related Concepts

► Recurrent neural network

Definition

Long short-term memory (LSTM) is a variation of recurrent neural network (RNN) for processing long sequential data. To remedy the gradient vanishing and exploding problem of the original RNN, constant error carousel (CEC), which models long-term memory by connecting to itself using an identity function, is introduced.

Background

Sequential data processing is a key technology for a wide range of applications such as natural language comprehension, speech recognition, and video recognition. The goal is to predict the conditional probability $p(O_1, \dots, O_{T'} | I_1, \dots, I_T)$ where $(O_1, \dots, O_{T'})$ is an output sequence and (I_1, \dots, I_T) is its corresponding input sequence. Note that the length T' and T may be different from each other.

A well-known approach is applying RNN. It computes the probability of an output sequence $(O_1, \dots, O_{T'})$ given an input sequence (I_1, \dots, I_T) as follows:

$$p(O_1, \dots, O_{T'}) = \prod_{t=1}^{T'} p(O_t | \mathcal{O}_t), \quad (1)$$

where $\mathcal{O}_t = \{I_1, \dots, I_T, O_1, \dots, O_{t-1}\}$ for $t > 2$ and $\mathcal{O}_1 = \{I_1, \dots, I_T\}$. Let $\mathbf{x}_t \in \mathbb{R}^{d_x}$ and $\mathbf{y}_t \in \mathbb{R}^{d_y}$ be, respectively, the representation of I_t and O_t , e.g.,

$$\mathbf{x}_t = f(I_t), \quad (2)$$

where f is a feature extractor for the inputs. Typically, the dimension of output representation d_y is set to be equal to the number of “vocabulary” \mathcal{V} for the target prediction. Let \mathcal{V}_i and $y_{(t+l)i}$ be the i -th member of the set \mathcal{V} and the i -th element of $\mathbf{y}_{(t+l)}$, respectively. With a latency constant $l \in \mathbb{Z}_{\geq 0}$, the outputs are then predicted as:

$$O_t = \mathcal{V}_j, \text{ where } j = \operatorname{argmax}_i y_{(t+l)i}. \quad (3)$$

Typically, $T = T'$ and $l = 0$ for name entity recognition, $T' = 1$ and $l = T - 1$ for sentiment classification, and $l = T$ for machine translation. RNN preserves sequential information in a hidden state vector $\mathbf{h}_t \in \mathbb{R}^{d_h}$ and predicts \mathbf{y}_t as:

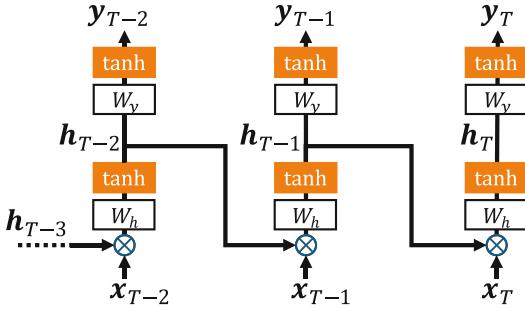

$$\mathbf{h}_t = \tanh(W_h(\mathbf{h}_{t-1}^\top \mathbf{x}_t^\top)^\top + \mathbf{b}_h), \quad (4)$$

$$\mathbf{y}_t = \tanh(W_y \mathbf{h}_t + \mathbf{b}_y), \quad (5)$$

where $W_h \in \mathbb{R}^{d_h \times (d_h + d_x)}$ and $W_y \in \mathbb{R}^{d_y \times d_h}$ are weight matrices and $\mathbf{b}_h \in \mathbb{R}^{d_h}$ and $\mathbf{b}_y \in \mathbb{R}^{d_y}$ are bias vectors. Note that bias vectors are often omitted in the definitions of RNN.

RNN could work theoretically, but actually, it would be challenging to train the parameters due to vanishing and exploding gradients. Usually, RNN is trained using backpropagation through time (BPTT) algorithm. BPTT unrolls all time steps of RNN and applies regular backpropagation for neural networks. Therefore, as shown in Fig. 1, unrolled RNN can be considered as a deep multilayer perceptron (MLP), and this is why the gradients vanish or explode as discussed in MLP literature.

To solve the problems about gradients, Hochreiter and Schmidhuber proposed a new type of RNN in 1997 [9]. The core module is constant error carousel (CEC), which can preserve the gradient by utilizing shortcut

Long Short-Term Memory, Fig. 1 Illustration of back-propagation through time (BPTT) algorithm to train RNN network, where \otimes is a concatenation of two vectors. It can be seen as a very deep MLP, which causes vanishing and exploding gradients problem. Note that the output length $T' = T$ here

connections. The idea of shortcuts has affected later neural networks such as highway networks and ResNet. This new RNN is referred to as long short-term memory (LSTM).

Theory

In LSTM, another memory c is utilized in addition to the hidden state h . This memory c is called memory cell and considered as long-term memory, while h is considered as short-term one.

LSTM has several versions, but let us start with the detail of LSTM with a forget gate. The calculations at the t -th step would seem to be complicated:

$$c_{t-1/2} = c_{t-1} \odot g_f, \quad (6)$$

$$g_f = \sigma \left(W_f \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} + b_f \right), \quad (7)$$

$$c_t = c_{t-1/2} + g_i \odot z, \quad (8)$$

$$g_i = \sigma \left(W_i \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} + b_i \right), \quad (9)$$

$$z = \tanh \left(W_z \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} + b_z \right), \quad (10)$$

$$h_t = g_o \odot \tanh(c_t), \quad (11)$$

$$g_o = \sigma \left(W_o \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} + b_o \right), \quad (12)$$

where \odot denotes the Hadamard product, namely, element-wise product of two vectors, and $W_{(\cdot)}$, $b_{(\cdot)}$ is a pair of a transformation matrix and a bias vector. The vectors $g_{(\cdot)}$ are gates to update memories in LSTM. The elements of gate vectors are normalized between 0 and 1. Thus, each element of gates represents the strength for which elements of memories are filtered using the current input and the last memory. Figure 2 illustrates Eqs. (6, 7, 8, 9, 10, 11, and 12).

What LSTM does is simpler than it looks. At the t -th step, the memories h and c are updated and then the output y_t is computed as follows:

$$y_t = \tanh(W_y h_t + b_y). \quad (13)$$

Updating the long-term memory

Equations (6, 7, 8, and 9) are updating the long-term memory c_{t-1} to c_t as shown in Fig. 3. The update is composed of two sub-steps. First, given the last short-term memory h_{t-1} and the current input x_t , LSTM forgets a part of cell c_{t-1} in Eq. (6) using a forget gate g_f calculated in Eq. (7). Second, a new memory is inserted to the latest cell $c_{t-1/2}$ in Eq. (8) using the current input, the last short-term memory, and the input gate g_i calculated in Eq. (9).

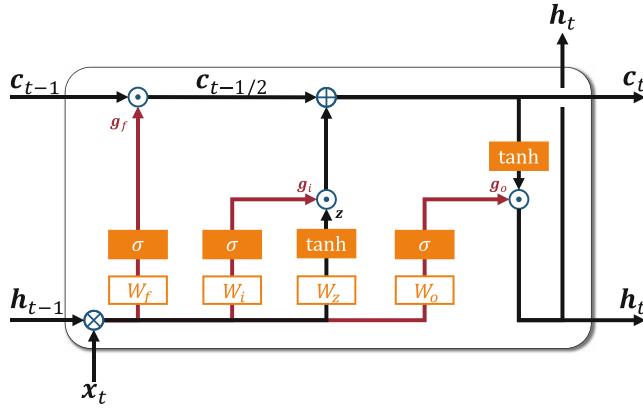

CEC, the main contribution of LSTM, is included in this part. As depicted in Fig. 1, the hidden memory in RNN is updated for several times through multiplications using the parameter matrix W_h and an activation function, namely, $\tanh(\cdot)$, for each element. Instead, the long-term memory is updated by simple summations and multiplications with a vector; therefore, LSTM can prevent the gradient from vanishing and exploding.

The forget gate is not proposed in the original LSTM paper. The first use of the gate for LSTM can be seen in [4].

Updating the short-term memory

Given the updated long-term memory, LSTM then updates the short-term memory, as shown in Fig. 4.

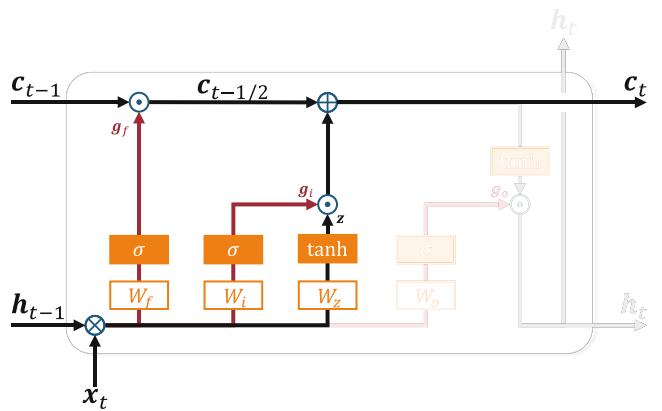

Output gate g_o is calculated from the previous short-term memory h_{t-1} and the current input

Long Short-Term Memory, Fig. 2 Illustration of LSTM, where \odot and \oplus are, respectively, the Hadamard product and summation of two vectors. The paths for the gate vectors are shown in dark red, while the others are

in black. Note that the outputs are updated \mathbf{h}_t and \mathbf{c}_t . The calculation of the output y_t given the short-term memory \mathbf{h}_t described in Eq. (13) and the bias vectors are omitted for simplicity

**Long Short-Term
Memory, Fig. 3** Updating
the long-term memory

x_t in Eq. (12). The short-term memory can be updated by passing the latest cell memory.

Estimating the output

The updated short-term memory is utilized to predict the posterior probability of the t -th element of the target sequence by Eq. (13).

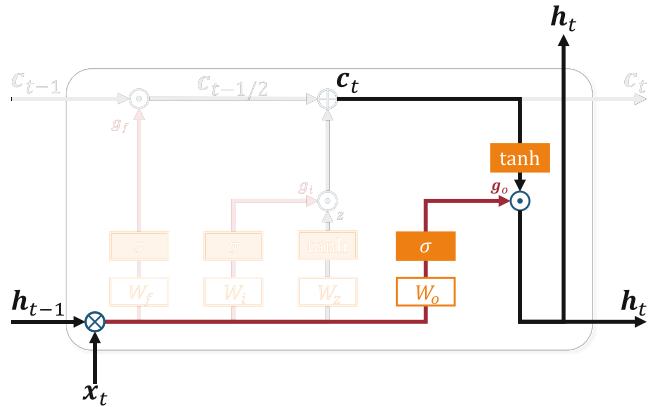

Strictly speaking, the gradient vanishing problem is relaxed in the original LSTM; however, the gradient explosion problem is not directly solved yet. Pascanu et al. enable a stable training procedure for LSTM [10]. Particularly, the authors find that clipping the norm of the gradient can simply avoid its explosion without any losses of its accuracy. In RNN, the chain rate shows that the gradient of the estimation error with respect to the parameter is significantly influenced by

the gradient of the memory with respect to the previous memory. Additionally, it is bounded by the product of the norm of the input vector and weight matrix for the recurrent part. The threshold of clipping each gradient can be defined using the averaged norm of weight matrices.

Additionally, Graves and Shmidhuber [6] implement bidirectional LSTM to present each training sequence forward and backward to two separate LSTMs. Both LSTMs are connected to the same output layer. By estimating the outputs using future inputs, bidirectional LSTM can utilize more contexts than a forward LSTM that uses only previous inputs.

Generally, LSTM is trained using BPTT. Graves and Shmidhuber [6] enable the explicit

Long Short-Term Memory, Fig. 4 Updating the short-term memory

use of BPTT for LSTM. The original algorithm for LSTM training [5] uses a combination of BPTT and real-time recurrent learning (RTRL), which can be regarded as a particular case of BPTT when the gradient is not backpropagated through different time steps.

The detailed description of the partial derivatives using BPTT for LSTM can be found in [7]. The LSTM used for explaining BPTT in [7] has peephole connections, which is explained later in Open Problems. Since peephole connections are often omitted to implement LSTM, in this entry, simpler descriptions about BPTT are shown below.

Although BPTT seems complicated because of the recurrent part, the basic idea is relatively simple. Let $g_{(\cdot)}^t$ and z_t be, respectively, defined as the gate vector $g_{(\cdot)}$ and the block input z at the t -th step, while t is omitted except here for simplicity. Let $W_{(\cdot)}$ be divided into $W_{(\cdot)}^h$ and $W_{(\cdot)}^x$ so that:

$$W_{(\cdot)}(h_{t-1}^\top x_t^\top)^\top = W_{(\cdot)}^h h_{t-1} + W_{(\cdot)}^x x_t. \quad (14)$$

The deltas of the memories are then as follows:

$$\begin{aligned} \delta h_t &= \delta y_t + W_z^h \delta z_{t+1} \\ &\quad + W_f^h \delta g_f^{t+1} + W_i^h \delta g_i^{t+1} + W_o^h \delta g_o^{t+1}, \end{aligned} \quad (15)$$

$$\delta c_t = \delta h_t \odot g_o^t \odot \tanh'(c_t) + \delta c_{t+1} \odot g_f^{t+1}. \quad (16)$$

Let \bar{z}_t be the input for the activation function for calculating z_t in Eq. (10), i.e.,

$$\bar{z}_t = W_z \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} + b_z. \quad (17)$$

Similarly, let $\bar{g}_{(\cdot)}$ be the input for the activation function for calculating gate vectors:

$$\bar{g}_{(\cdot)} = W_{(\cdot)} \begin{bmatrix} h_{t-1} \\ x_t \end{bmatrix} + b_{(\cdot)}. \quad (18)$$

The deltas for these variables are calculated as:

$$\delta \bar{z}_t = \delta c_t \odot g_i^t \odot \tanh'(\bar{z}_t), \quad (19)$$

$$\delta \bar{g}_f^t = \delta c_t \odot c_{t-1} \odot \sigma'(\bar{g}_f^t), \quad (20)$$

$$\delta \bar{g}_i^t = \delta c_t \odot z_t \odot \sigma'(\bar{g}_i^t), \quad (21)$$

$$\delta \bar{g}_o^t = \delta h_t \odot \tanh(\bar{c}_t) \odot \sigma'(\bar{g}_o^t). \quad (22)$$

Finally, the gradients for the parameters of z are derived as:

$$\begin{aligned} \delta W_z^x &= \sum_{t=1}^T \delta z_t x_t^\top, \\ \delta W_z^h &= \sum_{t=1}^{T-1} \delta z_{t+1} h_t^\top, \quad \delta b_z = \sum_{t=1}^T \delta z_t. \end{aligned} \quad (23)$$

Similarly, the gradients for the parameters of each gate vector are derived as:

$$\begin{aligned}\delta W_{(\cdot)}^x &= \sum_{t=1}^T \delta \mathbf{g}_{(\cdot)}^t \mathbf{x}_t^\top, \\ \delta W_{(\cdot)}^h &= \sum_{t=1}^{T-1} \delta \mathbf{g}_{(\cdot)}^{t+1} \mathbf{h}_t^\top, \quad \delta \mathbf{b}_{(\cdot)} = \sum_{t=1}^T \delta \mathbf{g}_{(\cdot)}^t.\end{aligned}\quad (24)$$

It is worth noting that the deltas about the long-term memory are the summation of future long-term memories as described in Eq. (16), while the deltas about the memory in RNN depend on the multiplication of the weight matrix and the future memories. This difference provides LSTM with tolerance against the gradient vanishing and exploding that frequently occur in RNN.

Application

In [6] bidirectional LSTM is implemented for speech recognition. In [1], RNN encoder-decoder model is proposed for machine translation. The model learns to *encode* a variable-length sequence into a fixed-length vector and to *decode* a given fixed-length vector into a variable-length sequence. This idea is modified by Sutskever et al. with a multilayered LSTM [13]. Four-layer LSTM achieves comparable performance to the state of the art for English to French translation at that time. For the NLP community, LSTM also contributes to a grammar model; embeddings from language models (ELMo) is a well-known word representation utilizing bidirectional LSTM.

The success in machine translation has opened up the use of LSTM for multiple types of sequence modeling. A straightforward use of LSTM decoder for natural language is to generate captions from images. Some researchers in Google combined their convolutional neural network for image recognition [14] with LSTM for machine translation [13] to generate a caption for an input image [18]. For video caption generation [17], the encoder is also based on LSTM to treat sequential frames in videos.

Open Problems

One of the biggest unsolved problems is that there is still no conclusion on which is the best machine learning method that models long sequences. Even RNN has several versions and modifications.

There is a modification of LSTM by applying peephole connections [3]. The gate vectors are calculated using the short-term memory \mathbf{h} , but it is not guaranteed that the long-term memory \mathbf{c} also contributes to the gates. Therefore, in [3], there are three connections: one from \mathbf{c}_{t-1} to the forget gate \mathbf{g}_f , another from \mathbf{c}_{t-1} to the input gate \mathbf{g}_i , and the other from \mathbf{c}_t to the output gate \mathbf{g}_o . It is worthy to note that, however, the peephole connections are not mandatory to obtain the best performance.

There is another variant of LSTM; gated recurrent unit (GRU) [1] is focusing only on gate functions rather than the long-term memory. GRU can reduce the number of parameters in comparison to LSTM since there are two gates in GRU: reset gate and update gate. The objective of the authors to keep the ability of LSTM to reserve long-term information while the whole network is made as simple as possible. We would like to know whether GRU can outperform LSTM, but the extensive comparison [2] could not find the significant difference between them.

Modeling of sequential data is not an exclusive feature of recurrent neural networks. Convolutional neural networks also show their capability to model sequences for several tasks, e.g., machine translation and speech synthesis [15].

A remarkable change in natural language processing is that the language model is no longer based on LSTM; the transformer model [16] and its variants generate surprisingly fluent sentences and translate different languages much more correctly than those based on LSTM. Transformer utilizes self-attention mechanism and omits recurrent parts, which enables highly parallel computation for training with a large number of parameters and a large-scale corpus.

However, LSTM still performs its powerful ability to model several types of sequences. For example, current reinforcement learning [19]

utilizes LSTM to learn temporal actions. Consequently, we should start by investigating whether LSTM is an appropriate approach, taking into account the length and amount of sequential data we would like to model.

► [Image-Based Rendering](#)

Definition

A Lumigraph (also known as light field [1]; see <http://graphics.stanford.edu/papers/light/> for a good explanation of the history, similarities, and differences between a light field and a Lumigraph.) is a four-dimensional representation of all the light rays passing through an empty volume of space [2]. It can be used to synthesize a novel image from any viewpoint within that space. The Lumigraph often refers to a light field augmented with a partial 3D model of the scene, which is used during the rendering process.

Background

If one considers a volume of empty space, the radiance of all the rays passing through this space can be organized in five dimensions, the three dimensions of space plus two dimensions for direction. This is known as the 5D *plenoptic function* of Adelson and Bergen [3, 4]. However, since radiance is constant along a ray in empty space, the space of all unique rays drops to four dimensions. This four-dimensional set of rays has come to be known as a light field or Lumigraph. An idealized image consists of a two-dimensional array of pixels, each of which represents the radiance along single ray passing through a single point in space or pinhole. Thus,

since a Lumigraph contains all the rays in a given space, this information can depict any image from any vantage point in the space represented by the Lumigraph. More generally, the image created by any lens and aperture embedded in the Lumigraph space can also be reconstructed. Finally, images not realizable by traditional lenses, such as multiperspective panoramas [5], can also be rendered.

These observations led to the development of the Lumigraph. Capturing a Lumigraph and then, after-the-fact, being able to reconstruct any image from any vantage point enable applications for depicting the appearance of a scene or object. Often, the empty space captured in a Lumigraph is all or a portion of the space surrounding the convex hull of an object. This allows the examination of the object from any vantage point. Alternatively, the Lumigraph may capture the space of views through a finite window. This provides the ability to move the viewpoint back and forth to depict any parallax due to varying depths in the scene, or to treat the window as a finite aperture with which to vary the plane of focus or the depth of field.

The interesting technical problems for Lumigraphs include how to:

- Capture the desired subset of rays
- Organize and store the Lumigraph
- Interpolate missing rays from discretely sampled rays
- Efficiently retrieve the visual information to enable real-time image reconstruction from any viewpoint

In the following sections, techniques developed in the original Lumigraph paper [2] are discussed and then generalized to work in the unstructured Lumigraphs of Buehler et al. [6].

Application

Lumigraph Capture

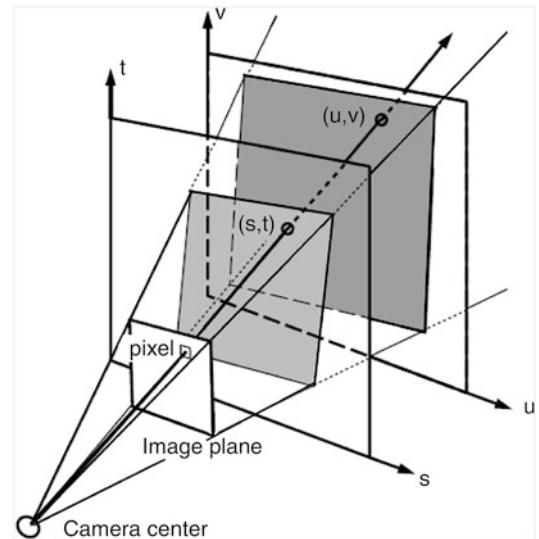

Unfortunately, it is impossible to instantaneously capture a dense 4D continuous field of rays in

some volume (See the discussion at the end of this entry on lenslet arrays as one alternative for capturing discrete subsets of the 4D field.). Instead, the space of rays is sampled with a camera or cameras. Each camera image (assuming a pinhole model) captures a discretized 2D slice of the 4D space. Each pixel represents some ray. In the original Lumigraph paper, an object was placed on a special stage with fiduciary marks. A handheld camera attached to a computer was pointed at the object and moved around it to capture a set of images from various vantage points. The fiduciary points allowed the camera's pose to be calculated in real time to provide feedback to the user about what regions of the surrounding sphere had been well sampled. In the concurrent light field paper, the camera was placed on a gantry from which the camera could be carefully maneuvered and the pose could be read off mechanically.

Lumigraph Organization

Each captured image contains an array of pixels representing the radiance values for a subset of rays passing through the aperture of the camera. The set of all rays from all captured images form the discrete information from which to generate any other novel view. Likewise, constructing the novel view involves finding, for each pixel (ray) in the novel view, one or more nearby rays from the captured set from which to reconstruct the desired pixel. To make the reconstruction efficient, the input set of rays may be reorganized to aid the ray lookup process. The original Lumigraph and light field papers used two-plane reparameterizations. The subsequent unstructured Lumigraph [6] work skipped this step, instead rendering directly from the original images. The two-plane parameterization used in the original papers is discussed next.

Consider two parallel planes. It is easiest to start with aligned rectangular sections of each plane, as shown in Fig. 1. The first plane is parameterized using s and t and the other using u and v . Each ray that intersects the two rectangles is associated with a 4D coordinate (s, t, u, v) . Since the rays are directional, the rays are assumed to carry light through the (u, v) plane before passing

Lumigraph, Fig. 1 The Lumigraph: a ray is represented by its 4D two-plane parameters (s, t) and (u, v) . (From [1], The Lumigraph, SIGGRAPH'96, (c) ACM)

through the (s, t) plane. Consider a single point (s_0, t_0) on the (s, t) plane and all the rays passing through that point. These rays represent an image one could get by placing the camera's center at (s_0, t_0) oriented toward the (u, v) plane. The (u, v) parameterization characterizes the image *rectified* to the (u, v) plane.

By placing the camera successively at all points on the (s, t) rectangle, a 4D Lumigraph is captured. Of course, any image with rays that pass through the two planes, such as from a camera placed behind the (s, t) plane, can contribute to filling in the Lumigraph. In Fig. 1, a pixel's 4D coordinate (s, t, u, v) is given by its intersection with the two planes. The original Lumigraph and light field papers resampled the rays from such more general input images into the two-plane parameterization.

Completing (Resampling) the Lumigraph

In any practical system, the Lumigraph is a collection of only a finite number of 4D samples. For example, given N^2 images with R^2 resolution, there are at most $N^2 R^2$ pixels representing unique rays in the Lumigraph. One could, for example, carefully place a camera at each $N \times N$

grid point on the (s, t) plane oriented precisely to cover the extent of the (u, v) plane. Unfortunately, even this simple configuration is very difficult to achieve. Instead, one can gather a much less organized set of images and *resample* the pixels into the 4D (s, t, u, v) coordinate system. Typically, the (s, t) plane is more coarsely discretized than the (u, v) plane, as the object being imaged is near the (u, v) plane. The assumption is that the object texture changes more rapidly across its surface than the directional changes in radiance of a single point on the surface.

Each pixel in an input image represents some ray (s, t, u, v) such as the ray shown in Fig. 2a. The question then becomes finding the *closest* discrete grid point to assign the color of this pixel to in the discretized Lumigraph (Fig. 2d–f). The simplest method to determine closest is to choose the closest discrete (s, t) and (u, v) grid points to ray's continuous coordinates. The original Lumigraph paper modifies this simple scheme to leverage depth information in the scene. A

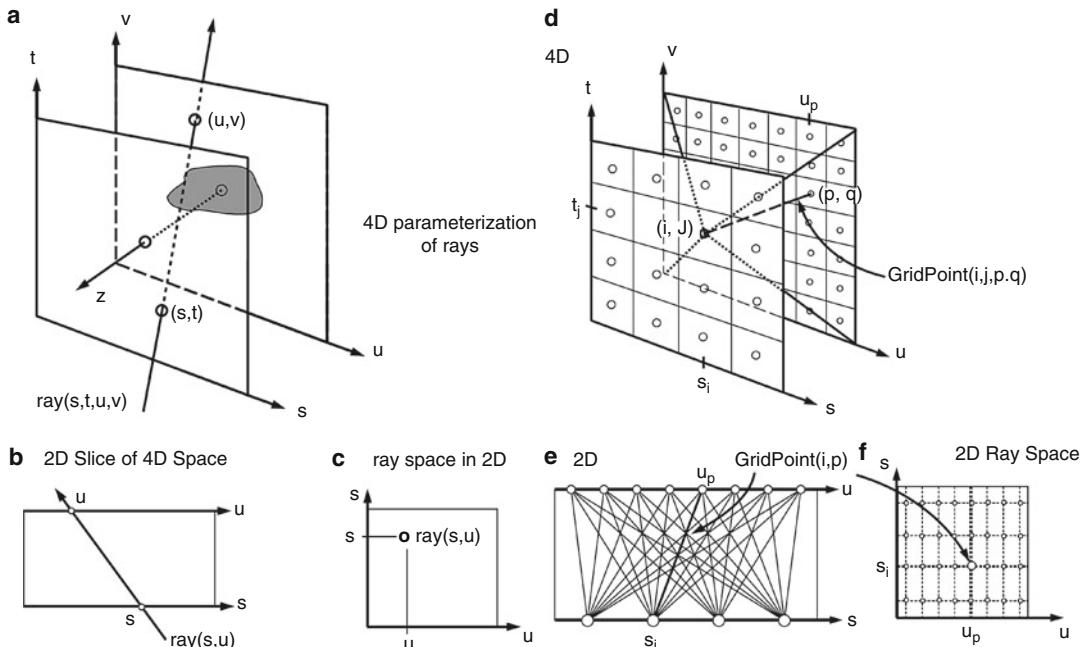

rough estimate of depth is obtained from the visual hull of the object being imaged, which is computed from the silhouettes of the object pulled from the blue background stage.

Consider the ray (s, u) in a two-dimensional Lumigraph (Fig. 3). The closest grid point to this ray is (s_{i+1}, u_p) . However, gridpoints (s_{i+1}, u_{p-1}) and (s_i, u_{p+1}) are likely to contain colors closer to the true color of the input ray since these grid points represent rays that intersect the object near the intersection with the ray. Suppose one knows the depth value z at which the ray first intersects the object. For nearby discrete s_i and s_{i+1} values, the corresponding u' and u'' values are computed for rays that intersect the same geometric location,

$$u' = u + (s - s_i)z/(1 - z) \quad (1)$$

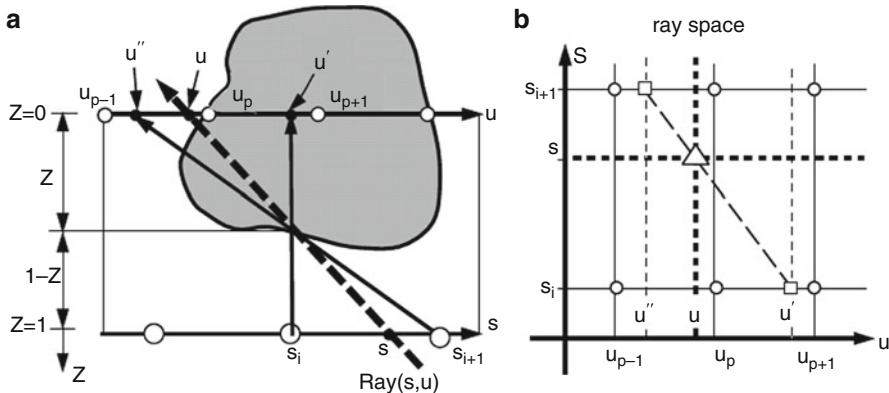

$$u'' = u + (s - s_{i+1})z/(1 - z). \quad (2)$$

As you can see, neither u' nor u'' is closest to the discrete point u_p . This observation is used to

Lumigraph, Fig. 2 Parameterization and discretization of the Lumigraph: (a) a ray is parameterized by its 4D two-plane parameters (s, t) and (u, v) . The object being imaged is near the (u, v) plane with the distance to any point on the object surface from the plane given as z ; (b)

a 2D slice of the 4D space for illustration purposes; (c) a 2D representation of the “ray space”; (d–f) discretizing the Lumigraph. (From [1], The Lumigraph, SIGGRAPH’96, (c) ACM)

Lumigraph, Fig. 3 Determining the closest grid point. (From [1], The Lumigraph, SIGGRAPH'96, (c) ACM)

Lumigraph, Fig. 4 Results of a 2D analog to the 4D push-pull algorithm. *Left figure* shows lines sampled in 2D (analogous to images in 4D). *Right* shows result of push-

pull fill-in. (From [1], The Lumigraph, SIGGRAPH'96, (c) ACM)

define a depth-corrected quadrilinear interpolant for *splatting* input rays into the Lumigraph. The details can be found in Gortler et al. [2].

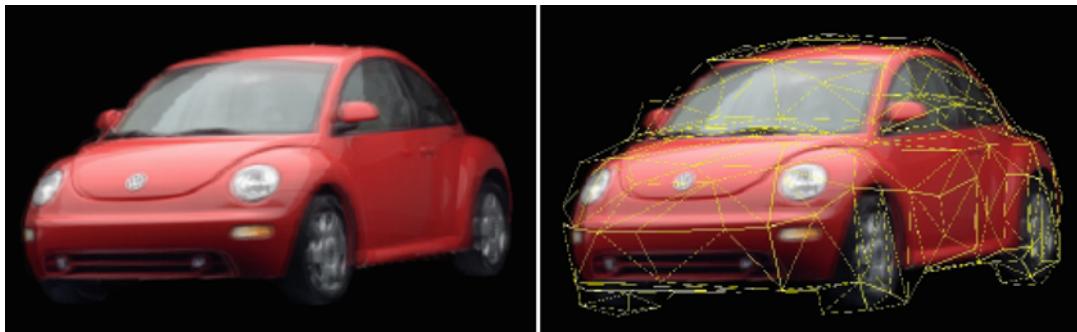

Finally, even given a large number of input cameras, there are bound to be many discrete samples in the Lumigraph left unfilled. Gortler et al. describe a *push-pull* multiresolution method to fill out the Lumigraph by averaging up the pyramid (pulling) and then pushing values down the pyramid while never overwriting values filled during the *pull*. Figure 4 shows a 2D analog of this process.

Reconstruction and Display

Rendering a novel view from a Lumigraph operates essentially in reverse of resampling. Each pixel in a desired image corresponds to a 4D ray. If this ray intersects the (s, t) and (u, v) planes, its 4D coordinate is determined by these intersections. The color values stored at the *closest* 4D gridpoints of the Lumigraph are retrieved and interpolated. Again, the depth correction discussed in the creation of the Lumigraph can be used in the definition of *closeness* and thus the interpolation coefficients.

Lumigraph, Fig. 5 A stereo pair of reconstructed images of a Lumigraph of a stuffed lion (Cross-eyed arrangement). (From [1], The Lumigraph, SIGGRAPH'96, (c) ACM)

Lumigraph, Fig. 6 An unstructured Lumigraph reconstruction of a VW bug and its proxy geometry. (From [6], Unstructured Lumigraph Rendering, SIGGRAPH 2001 (c) ACM)

Gortler et al. [2] relate this interpolation to the definition of skewed 4D basis functions for reconstruction and show differing artifacts resulting from different basis function choices. Figure 5 shows reconstructions of two nearby views (a stereo pair) of a fuzzy lion captured with a handheld camera.

Unstructured Lumigraphs

Five years after the original Lumigraph paper, Buehler et al. [6] developed a means to render directly from the original input images without first resampling the pixels/rays into a regular 4D structure. This *unstructured Lumigraph* relies on

an approximate 3D tessellated proxy as a means to measure the distance between an input ray and a desired output ray in the image being generated. The distance measure combines epipole consistency (does the desired ray pass near the center of a source camera?), angular deviation (do two rays that meet at the same point on the proxy differ in angle?), continuity (do two rays intersect the proxy at nearby points?), and resolution (do the two rays integrate similar sized areas on the proxy?).

Their paper describes a real-time rendering algorithm that uses graphics hardware to compute barycentric weight contributions from each input

camera. The weights are computed for the union of each tessellated triangle in the proxy with each triangle in a tessellated output image plane. Figure 6 shows a reconstructed image and the tessellated proxy used in weight calculations.

Open Problems

In recent years, new cameras have been developed that contain an array of lenslets that can capture a small light field on a single chip [7]. Such devices support after-capture refocusing, as well as limited viewpoint motions [8]. Applications to microscopy also show great promise [9]. Large arrays of cameras have also been used to enhance both spatial and temporal resolution and to refocus with large virtual apertures to see through occluders [10, 11]. It remains an open problem to find ways to effectively capture large Lumigraphs. Finally, adding a temporal dimension presents significant new issues to overcome.

Definition

Machine recognition of objects is the task of locating and recognizing a given object in an image and consists of the following steps: object detection, feature extraction, and recognition.

Background

Early computer vision recognition schemes focused primarily on the recognition of rigid three-dimensional (3D) objects, such as machine parts, tools, and cars. This is a challenging

problem because the same object can have markedly different appearances when viewed from different directions. It proved possible to deal successfully with this difficulty by using detailed 3D models of the viewed objects, which were compared with the projected 2D image (e.g., [14, 18, 33]). Over the last decade or so, computational models have made significant progress in the task of recognizing natural object categories under realistic, relatively unconstrained viewing conditions. Within object recognition, it is common to distinguish two main tasks: identification, for instance, recognizing a specific face among other faces, and categorization, for example, recognizing a car among other object classes. We will discuss both of these tasks below and use “recognition” to include both.

The qualitative improvement in the performance of recognition models can be attributed to three main components. The first is the use of extensive learning in constructing recognition models. In this framework, rather than specifying a particular model, the scheme starts with a large family of possible models and uses observed examples to guide the construction of a specific model which is best suited to the observed data. The second component was the development of new forms of object representation for the purpose of categorization, based on both computational considerations and guidelines from known properties of the visual cortex. These two components, representation and learning, are interrelated: initially, the class representation

provides a family of plausible models, and effective learning methods are then used to construct a particular model for a novel class such as “dog” or “airplane” based on observed examples. The third component was the use of new statistical learning techniques, such as regularization classifiers (SVM and others) and Bayesian inference (such as graphical models). We next discuss each of these advances in more detail.

Learning instead of design. A conceptual advance that facilitated recent progress in object recognition was the idea of learning the solution to a specific classification problem from examples, rather than focusing on the classifier design. This was a marked departure from the dominant practices at the time: instead of an expert program with a predetermined set of logical rules, the appropriate model was learned and selected from a possibly infinite set of models, based on a set of examples. The techniques used in the 1990s originated in the area of supervised learning, where image examples are provided together with the appropriate class labels (e.g., “face” or “non-face”). A comprehensive theory of the foundations of supervised learning has been developed, with roots in functional analysis and probability theory [6, 26, 27, 36]. The formal analysis of learning continues to evolve and to contribute to our understanding of the role of learning in visual recognition.

New image representations. A recognition scheme typically extracts during learning a set of measurements or “features” and uses them to construct new object representations. Objects are then classified and recognized based on their feature representation. Feature selection and object representation are crucial, because they facilitate the identification of elements that are shared by objects in the same class and support discrimination between similar objects and categories. Different types of visual features have been used in computational models in the past, ranging from simple local-image patterns such as wavelets, edges, blobs, or local-edge

combinations to abstract three-dimensional shape primitives, such as cylinders [21], spheres, cubes, and the like [4].

A common aspect of most past recognition schemes is that they use a fixed small generic set of feature types to represent all objects and classes. In contrast, recent recognition schemes use pictorial features extracted from examples, such as object fragments or patches, together with their spatial arrangement [1, 3, 19, 30]. Unlike generic parts, these schemes use a large set of features, extracted from different classes of objects. The use of large feature sets is also connected to an interesting new trend in signal processing, related to “over-complete” representations. Instead of representing a signal in terms of a traditional complete representation, such as Fourier components, one uses a redundant basis (such as the combination of several complete bases).

Representations using such features have been used successfully in recent computer vision recognition systems for two reasons. First, these representations can be learned and used efficiently; second, they proved to capture effectively the broad range of variability in appearance within a visual class.

An additional comment is appropriate. The representations described above are view based, as opposed to object-centered models. A representation based on image appearance can include not only 2D image properties but also 3D aspects such as local depth variations or 3D curvature.

New statistical learning methods. Over the last few years, the mathematics of learning has become the “lingua franca” of large areas of computer science and, in particular, of computer vision. As we discussed, the use of a learning framework enabled a qualitative jump in object recognition. Whereas the initial techniques used to construct useful classification models from data were quite simple, there are now more efficient algorithms originally introduced in the area of learning in the 1990s such as regularization algorithms (also called kernel machines), which include SVM [35, 36] and boosting [12]. By now, the area of learning has

grown to include, in addition to discriminative algorithms, probabilistic approaches with the goal of providing full probability distributions as solutions to object recognition tasks. These techniques are mostly Bayesian and range from graphical models [13, 15] to hierarchical Bayesian models [16, 17]. At the same time, the focus of research is shifting from supervised to unsupervised and semisupervised learning problems, using techniques such as manifold learning [2]. Semisupervised problems, in which the training set consists of a large number of unlabeled examples and a small number of labeled ones, are gaining attention.

Application

A number of early schemes, mainly focusing on the class of human faces, obtained significant improvement over previous methods [5, 29, 31, 32, 38]. The techniques have evolved to reach practical applications, as evidenced by their use in current digital cameras. The more recent versions of these computational schemes have started to deal successfully with an increasing range of complex object categories such as pedestrians, cars, motorcycles, airplanes, horses, and the like, in unconstrained natural scenes, to deal with a broad range of objects within each class (e.g., [1, 8, 19, 22–24, 30, 34, 39]). The algorithms that were refined over the last few years can deal successfully with a large number of different object classes, in complex and highly cluttered scenes. They are being applied to databases of hundreds [9] and even thousands of object classes [7]. Yearly competitions in computer-based recognition, such as the Pascal challenge [25, 28], witness continuous improvement in the range of classes and in scene complexity successfully handled by automatic object categorization algorithms [10, 11, 37].

Definition

Manifold learning or nonlinear dimensionality reduction refers to a class of methods that aim to preserve geometric and topological properties of a finite set of samples drawn from a high-dimensional non-Euclidean space.

Background

Manifold learning methods shed light on the geometric nature of the dataset at hand, before task-specific modeling requirements kick in. If one has an understanding of the “shape” of the data, one can potentially develop specific algorithms that effectively use that structure. Manifold learning as a dimensionality reduction tool can be seen as a generalization of classic linear tools like principal component analysis (PCA). Early versions of manifold learning, such as multidimensional scaling (MDS) [1] and Sammon mapping [2], have been available in statistics literature since the 1970s.

These methods produced a two-dimensional embedding, given a pairwise distance matrix of points. A series of breakthroughs occurred in the early 2000s, due to the invention of locally linear embedding (LLE) [3], Isomap [4], Laplacian eigenmaps [5], etc. which allowed generating embeddings of manifolds embedded in very high-dimensional spaces (e.g., images) while allowing one to preserve different properties such as local neighborhood connectivity, etc. All of these methods work under the assumption that samples in these high-dimensional spaces actually lie on a much lower-dimensional manifold, which has since come to be known as the *manifold hypothesis*. In the case of images, this is easily understood with the following example: consider an $n \times n$ image that captures a single object under fixed lighting and a moving camera. While the observed image lives in \mathbb{R}^{n^2} , the intrinsic dimensionality of this specific set of images should be related to the degrees of freedom in the camera's positioning and environmental lighting variables [5]. Uncovering such hidden structure from data samples forms the core of the field of manifold learning [6].

Theory

We provide a working description of a manifold; for a mathematically precise introduction to the theory of manifolds, we refer the reader to the classic texts by Boothby [7] and Spivak [8]. A topological space is called a differentiable manifold if, amongst other properties, it is *locally Euclidean*. This means that for each $p \in M$, there exists an open neighborhood U of p and a mapping $\phi : U \rightarrow \mathbb{R}^n$ such that $\phi(U)$ is open in \mathbb{R}^n and $\phi : U \rightarrow \phi(U)$ is a diffeomorphism. The pair (U, ϕ) is called a *coordinate chart* for the points that fall in U ; for any point $y \in U$, one can view the Euclidean coordinates $\phi(y) = (\phi_1(y), \phi_2(y), \dots, \phi_n(y))$ as the coordinates of y . The dimension of the manifold M is n . This is a way of flattening the manifold locally. Using ϕ and ϕ^{-1} , one can move between the sets U and $\phi(U)$ and perform calculations in the more convenient Euclidean space. If there exist multiple

such charts, then they are compatible, i.e., their compositions are smooth. Some of the key mathematical ideas needed to fully describe manifolds are curvature, tangent spaces, Riemannian metric, geodesics, and parallel transports.

In manifold learning, one is given a discrete set of samples from an unknown manifold. The samples can be given directly as points embedded in a high-dimensional Euclidean space, or provided indirectly as a pairwise distance matrix induced by a metric structure, or pairwise similarity relationships encoded by domain knowledge. Given this information, the methods aim to derive computational approximations of coordinate charts, tangent structures, geodesic distances, etc. For instance, once a coordinate chart is constructed, one can use the low-dimensional vectorial representation thus obtained for further use in machine learning or other applications.

M

Examples

Examples of manifold learning techniques include Isomap [4], locally linear embedding (LLE) [3], Laplacian eigenmaps [5], diffusion maps [9], etc. Each method aims to preserve different aspects of the geometry of the manifold. For example, Isomap aims to preserve pairwise distance relationships, whereas LLE aims to preserve local neighborhood structures. However all these methods require that neighborhoods and associated operations in high-dimensional space are not ambiguous. In some cases, there may be issues such as the “short-circuit” problem, where points that should be far away come close together in the Euclidean sense, either due to noise or due to the intrinsic curvature of the manifold. A different class of methods has been developed to provide robustness to such issues including diffusion maps [9] and Stochastic Neighborhood Embedding (SNE) [10]. In diffusion maps, instead of considering the shortest paths between points as measured on the data graph, which is susceptible to short circuits, one looks instead at diffusion distances. In SNE, one tries to ensure the distribution of data in the lower-dimensional space is close

to the original distribution, as measured by the KL divergence between certain conditional probability distributions. An improved version of this algorithm known as t-SNE [11] enabled significantly better optimization, with the use of a better loss function and a Student's t-distribution in the lower-dimensional space. Today, t-SNE is one of the most popular tools used for visualization of high-dimensional data because of its ability to identify local structure better than most other techniques. A more recent technique known as Uniform Manifold Approximation and Projection (UMAP) [12] provides embeddings comparable to t-SNE while being significantly faster to compute.

Applications

In its early days, the primary applications of manifold learning were to reduce the representation dimension, to beat the curse of dimensionality in machine learning applications such as face recognition (cf. [13]). Another parallel stream of work has been to leverage these methods for understanding structure of data by embedding into 2D or 3D maps. Techniques such as t-SNE have become standard tools in contemporary deep learning workflows [14], where a 2D embedding can be used to visualize how a deep neural network has learned to represent data. Another successful application of manifold learning is in obtaining a more meaningful metric between samples, as the “right” metric between high-dimensional samples is rarely known in practice. As a result, a widely adopted strategy is to compute distances using the Euclidean metric in the lower-dimensional space. For example, Johnson et al. [15] used a Euclidean distance metric in the hidden representations of a pre-trained neural network to approximate a “perceptual” similarity in the application of image style transfer.

Open Problems and Recent Trends

Deep neural networks have been revolutionary in modeling high-dimensional data, leading to

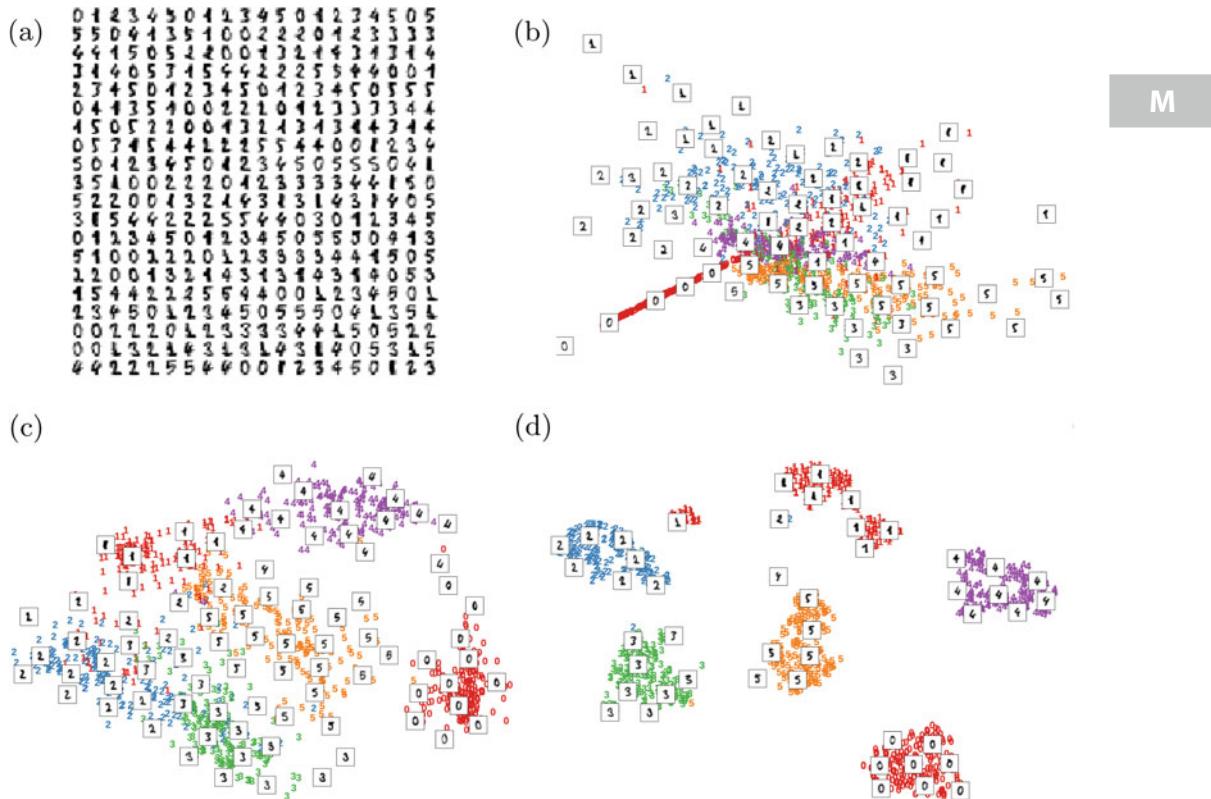

breakthroughs in several challenging tasks such as image/language classification, image reconstruction, language translation, etc. A big part of their success is due to being able to automatically learn intermediate representations of high-dimensional data that are best suited for a particular task. In this section, we outline some of the recent successes in modeling high-dimensional data using neural networks and present other open problems.

Understanding manifolds generated by deep neural networks An autoencoder is a special type of a neural network where the task is to reconstruct the original input, by forcing an intermediate representation to be of much lower dimensionality. This acts as a compression technique, which allows us to represent an image $X \in \mathbb{R}^m$ by a *latent* vector $z \in \mathbb{R}^d$ where $d \ll m$. The space of all possible latent vectors is referred to as a latent space, $\mathbb{Z} \subset \mathbb{R}^d$, which is an approximation of the low-dimensional manifold of the original data. While classical manifold learning techniques were primarily used to reduce the dimensionality of the data for improved visualization and modeling, sampling from the low-dimensional manifold, to create new types of high-dimensional data, is not easy. Recent breakthroughs in generative modeling have allowed us to sample from the manifold effectively, enabling a wide variety of new applications. Variational Auto-Encoders (VAEs) [16] allow us to learn a latent space where each high-dimensional sample is embedding into a distribution instead of a single low-dimensional point, typically parameterized as a multivariate Gaussian. A Generative Adversarial Net (GAN) [17] is another technique that provides an efficient way to sample from the low-dimensional data manifold, without explicitly determining its form. A GAN learns to map samples belonging to a low-dimensional prior distribution, to the dataset of high-dimensional samples. It achieves this by using two networks that compete against each other, which can be studied as a two-player game, which is complete when the system attains Nash equilibrium. Samples from a GAN are known to be highly *realistic*, i.e., to have very likely come from the true data manifold.

Differential geometry and machine learning
Several machine learning applications involving perceptual tasks in computer vision, speech analysis, etc. need to formally account for invariances to factors of a physical nature. For instance, invariance to illumination, pose, shape deformation, etc. are core problems in machine learning, which are usually tackled with clever choices of invariant features, or by increasing the diversity of the training set to include the required variability. However, the formal study of invariant structures leads to geometrically constrained sets in many cases, which are being increasingly exploited to learn invariant representations. Typical non-Euclidean domains considered in this endeavor have included the Stiefel and Grassmann manifolds, submanifolds in Hilbert spaces, special orthogonal group, tensors, etc., in areas as diverse as face recognition, robotic

manipulation, and activity analysis. A recent compilation of differential geometric techniques and its applications in machine learning can be found in [18].

These methods differ from classical manifold learning in that the structure of the underlying manifold is known *a priori*, whereas it needs to be estimated from data in the former case. There are several examples where data that are known to be lying on Riemannian manifolds can be further reduced to a lower-dimensional space. This has led to the development of techniques such as PCA to operate on such geometric spaces. For example, Fletcher et al. [19] proposed principal geodesic analysis (PGA) that generalizes PCA to manifolds. Harandi et al. [20] proposed a dimensionality reduction technique that can map higher-dimensional SPD matrices to lower-dimensional SPD matrices. There has also

Manifold Learning, Fig. 1 A qualitative comparison of a few popular manifold learning methods on a subset of the MNIST digits data. (a) Samples from the 8×8 digit data.

(b) Locally linear embedding of the data. (c) ISOMAP embedding of the data. (d) t-SNE embedding of data

been work to generalize PGA to manifold-valued trajectories in [21], which enables visualization and exploration of the entire manifold-valued sequences in low-dimensional, vector-valued spaces. In most of the examples in manifold learning, the embedded space is assumed to be Euclidean; however if the final goal is not visualization, this assumption can also be relaxed. This naturally leads to the idea of estimating the geometric properties of the lower-dimensional space, such as the Riemannian metric and the exponential and inverse exponential maps from data [22, 23]. These ideas have recently been extended to latent spaces inferred by neural networks recently [24, 25].

Experimental Results

In this section, we present a small-scale qualitative comparison of a few popular dimensionality reduction approaches. The dataset chosen is a subset of the MNIST digit dataset with digits from 0 to 5. Three methods – LLE, ISOMAP, and t-SNE – are compared. These visualizations are generated from the code adapted from SciKit [26, 27]. As shown in Fig. 1, different methods preserve different aspects about the data. LLE aims to preserve local neighborhood relations, and ISOMAPS aims to preserve global distance relationships, whereas t-SNE aims to preserve distributional properties, resulting in different visualizations. t-SNE has increased in popularity in recent years, due to its apparent ability to separate classes as well as preserve neighborhood relationships.

Definition

When objects exhibit large within-class variation and/or when image features are under- or over-segmented, the image features extracted from two exemplars belonging to the same category may no longer be in one-to-one correspondence but, in general, many-to-many correspondence. If the features are structured, i.e., captured in a graph, then computing the correct correspondence can be formulated as a many-to-many graph matching problem.

Background

The matching of image features to object models is typically formulated as a one-to-one assignment problem, based on the assumption that for every salient image feature belonging to the object to be matched, e.g., SIFT feature, image patch, contour fragment, there exists a single corresponding feature on the model (and vice versa). While the one-to-one correspondence assumption has been prevalent in the object recognition community throughout its entire evolution, including the paradigms of graph matching [9], alignment [13], geometric invariants [11], local appearance [14], and a recent return to local contour-based features [8], one-to-one feature correspondence is a highly restrictive assumption that breaks down as within-class variation increases and as the segmentation and extraction of more abstract image features suffer from over- or under-segmentation [7]. In the more general case, feature correspondence is not one-to-one, but rather *many-to-many*. If a feature set is described by a graph, with nodes representing features and edges capturing pairwise relations between features, computing the correct many-to-many feature correspondence can be formulated as *many-to-many graph matching*.

Consider two simple examples, shown in Fig. 1. In Fig. 1a, a set of multiscale blobs and ridges have been extracted from two exemplars (humans) belonging to the same

Many-to-Many Graph Matching, Fig. 1 Two graph matching problems in computer vision for which assuming a one-to-one feature correspondence will lead to incorrect correspondences, and which can only be solved if formulated as a many-to-many graph-matching problem. In (a), a multiscale blob and ridges decomposition [18] of the two humans yields a single ridge for the extended arm (*top*) and two coterminating ridges for the bent arm (*bottom*). In this example, articulation has violated the one-to-one feature correspondence assumption; if a one-

to-one correspondence is enforced for the arm, e.g., the red highlighted features, it will be incorrect. In this case, the correspondence should be two-to-one (or more generally, many-to-many). In (b), two different cup exemplars (*bottom row*) have been region segmented (*top row*), yielding regions that are rarely in one-to-one correspondence (due to within-class variation or region over- and/or under-segmentation). Once again, the correct correspondence is not one-to-one, but rather many-to-many

category. In the top image, the straight arm yields a single elongated ridge, while in the bottom image, the bent arm yields two smaller and coterminating elongated ridges. In this case, simple object articulation (a form of within-class variation) has led to a violation of the one-to-one correspondence assumption. Instead, the correspondence is clearly two-to-one; enforcing one-to-one correspondence will lead to an incorrect matching of the entire arm to either the upper or lower arm, e.g., the red highlighted features. In Fig. 1b, two region segmentations of two exemplars belonging to the same class yield a set of region correspondences that are rarely one-to-one, but more typically many-to-many. Once again, enforcing a one-to-one feature correspondence will ensure an

incorrect matching, and will miss the correct correspondence.

The problem of computing a one-to-one correspondence between a model feature graph and a cluttered image graph can be formulated as a largest isomorphic subgraph problem, whose complexity is NP-hard. The complexity of the many-to-many matching problem is even more prohibitive, for the space of possible correspondences is greater (any subset of features in the image may match any subset of features on the model). The intractable complexity of the many-to-many matching problem can only be reduced by exploiting the types of regularities suggested by the perceptual grouping community, such as proximity, continuity, conservation of mass, etc. In what follows, a formal statement of the prob-

lem is introduced, and a number of approaches to its solution is reviewed.

Theory

The main objective of the many-to-many graph matching problem is to establish a minimum cost mapping between the vertices of two attributed, edge-weighted graphs. In an attribute-weighted graph $G = (V, E)$, let $\mathbb{L}(v)$ denote the set of attributes associated with $v \in V$. Given a subset $U \subset V$, let $\mathbb{L}(U) = \cup_{u \in U} \mathbb{L}(u)$. For a set $U \subset V$, let $G|_U$ denote the subgraph of G induced on the vertices in U , and let $w(u, v)$ denote the weight of an edge $(u, v) \in E$. Finally, let $\mathbb{P}(G)$ denote the power-set 2^V for the vertex set of G . A *many-to-many mapping* between two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ is a mapping among power-sets $\mathbb{P}(G_1)$ and $\mathbb{P}(G_2)$ and can be characterized as a function:

$$\mathcal{M} : (\mathbb{P}(G_1) \times \mathbb{P}(G_2)) \rightarrow \{0, 1\}. \quad (1)$$

For two sets, $U \in \mathbb{P}(G_1)$ and $V \in \mathbb{P}(G_2)$, there will be a cost $C(\mathbb{L}(U), \mathbb{L}(V))$ associated with mapping the labels in set $\mathbb{L}(U)$ to those in $\mathbb{L}(V)$. An example of a common cost function is the edit-distance between the labels in sets $\mathbb{L}(U)$ and $\mathbb{L}(V)$. Let $S(G_1|_U, G_2|_V)$ denote the structural distance between induced subgraphs $G_1|_U$ and $G_2|_V$. Observe that every mapping \mathcal{M} has a natural representation as a matrix, with $\mathcal{M}_{U,V} = 1$ if the sets $U \in \mathbb{P}(G_1)$ and $V \in \mathbb{P}(G_2)$ are mapped to each other under \mathcal{M} , and $\mathcal{M}_{U,V} = 0$ otherwise. Combining these two cost functions will result in the cost function $C(\mathcal{M})$ associated with the mapping \mathcal{M} :

$$\begin{aligned} C(\mathcal{M}) &= \sum_{U \in \mathbb{P}(G_1), V \in \mathbb{P}(G_2)} \mathcal{M}_{U,V} \\ &\times C(\mathbb{L}(U), \mathbb{L}(V)) \times S(G_1|_U, G_2|_V). \end{aligned} \quad (2)$$

In defining an optimal many-to-many matching between two attributed graphs, G_1 and G_2 , a many-to-many mapping \mathcal{M}^* of minimum cost $C(\mathcal{M}^*)$ subject to specific requirements

on the structure or cardinality of \mathcal{M}^* will be obtained. For example, to prevent a trivial solution that sets $\mathcal{M}_{U,V} = 0$, for all U and V , one can require a matching such that its cardinality, i.e., $\sum_{U,V} \mathcal{M}_{U,V}$, exceeds a threshold while minimizing $C(\mathcal{M})$. Other functions, such as maximizing the number of vertices from V_1 and V_2 that participate in \mathcal{M} , can be used to evaluate the quality of the mapping. Note that cost functions $C(\mathbb{L}(U), \mathbb{L}(V))$ and $S(G_1|_U, G_2|_V)$ may be used to enforce constraints such as consistency of mapped labels, limits of feasible label mappings, or allowed structural mapping of induced graphs $G_1|_U$ and $G_2|_V$ by imposing arbitrary large values or by being ill-defined.

The above description of the many-to-many matching results in an intractable computational problem. First, due to the exponential size of power-sets $\mathbb{P}(V_1)$ and $\mathbb{P}(V_2)$ in terms of number of vertices in G_1 and G_2 , the size of the search space for the many-to-many matching problem is exponential. Even simplifying the problem to one-to-one mappings, by replacing the power-sets $\mathbb{P}(V_1)$ and $\mathbb{P}(V_2)$ with sets V_1 and V_2 , respectively, will result in the multidimensional matching problem that is known to be NP-complete for arbitrary labeled graphs.

M

Related Work

Many-to-many graph matching has been studied extensively in a variety of contexts, including graph edit distance [2, 16], spectral methods [4, 17], optimization problems [20], metric embedding [5], abstract models [10], and grammars [1, 21]. The classical formulation of graph edit distance introduces a set of graph edit operations, such as insertion, deletion, merging, splitting, and substitution of nodes and edges. Given a set of graph edit operations and a cost function, the objective is to find the lowest cost sequence of graph edit operations that transform one graph into the other. The edit distance between two graphs critically depends on the costs of the underlying edit operations; typically, lower costs are assigned to the most frequent edit operations. A number

of approaches have addressed the problem of defining an appropriate cost, e.g., [3].

Many-to-many graph matching has also been studied in the context of spectral methods by examining the spectral properties of graph adjacency matrices. In [4], the authors present an approach based on renormalization projections of vertices into a common eigensubspace of two graphs. Instead of finding the overall similarity of two graphs from the positions of vertex projections, this approach uses an agglomerative hierarchical clustering technique to produce many-to-many vertex correspondences.

Another spectral method is due to [17, 19], which constructs a low-dimensional “signature” of a directed graph’s “shape” from the magnitudes of the eigenvalues of the graph’s adjacency matrix. The eigenvalues are invariant to the reordering of a graph’s branches and are shown to be robust under minor structural perturbation of the graph. This vector can be used for both structural indexing and for matching in the presence of noise and occlusion. If two signatures (vectors) are close, their corresponding (sub)graphs, possibly having different cardinalities, are in many-to-many correspondence.

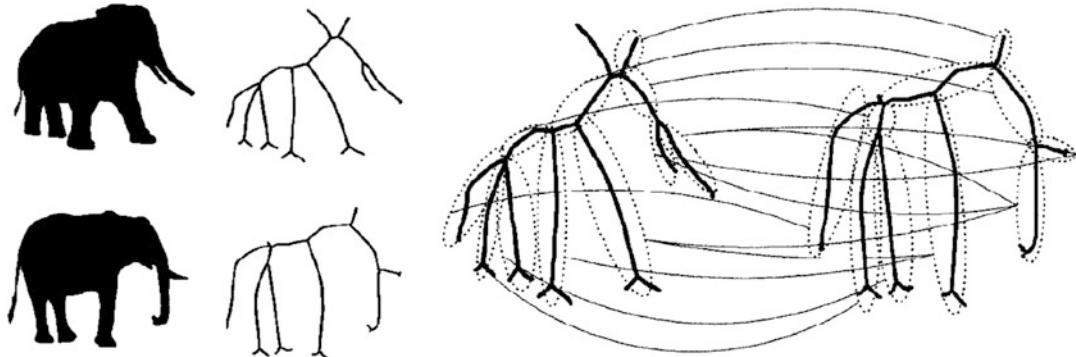

Recently, the approach presented in [20] formulates the many-to-many graph matching problem as a discrete optimization problem. The algorithm starts by extending the optimization problem for one-to-one matching to the case of many-to-one matching. The algorithm then obtains many-to-many vertex correspondences through two many-to-one mappings. Since this formulation of the many-to-many matching requires the solution of a hard optimization problem, the authors propose an approximate algorithm based on a continuous relaxation of the combinatorial problem.

The concept of a low-distortion graph embedding has been used to obtain many-to-many vertex correspondences [5]. Specifically, low-distortion graph embedding is employed to transform the problem of many-to-many graph matching to a many-to-many point matching problem in a geometric space. This transformation maps nodes to points and edge weights to interpoint distances, not only

simplifying the original graph representation (by removing the edges), but also retaining important local and global graph structure; moreover, the transformation is robust under perturbation. Representing two graphs as sets of points reduces the many-to-many graph matching problem to that of many-to-many point matching in the geometric space, for which a number of efficient distribution-based similarity measures are available. The authors use the Earth Mover’s Distance [15] algorithm to find such correspondences and show that the resulting many-to-many point matching realizes the desired many-to-many matching between the vertices of the input graphs.

A number of researchers, e.g., [10, 12] and [6], have explored many-to-many graph matching in the context of model-based abstraction from images. The work presented in [10] starts by forming a region adjacency graph from each image. The approach then searches the space of pairwise region groupings in each graph, forming a lattice. Each input image yields a lattice such that its bottom node represents the original region adjacency graph and its top node represents the silhouette of the object. The framework defines a common abstraction as a set of nodes, one per lattice, such that for a pair of nodes, their corresponding graphs are isomorphic. The lowest common abstraction (LCA) is defined as the common abstraction whose underlying graph has the maximum number of nodes. Thus, the resulting LCA carries the most informative abstraction common to each image. Although effective, this technique does not find a match between two graphs whose common abstraction does not exist.

The two algorithms presented in [12] and [6] use the many-to-many graph matching technique of [5] for automatically constructing an abstract model from examples. The work in [12] computes the multi-scale ridge/blob decomposition (AND-OR) graph for each input image and obtains the many-to-many node correspondences between each pair of graphs, yielding a matching matrix. By exploring this matrix, the algorithm first finds features that match one-to-one across many pairs of input images. The many-to-

Many-to-Many Graph Matching, Fig. 2 Example many-to-many correspondences computed by [5]. After representing two silhouettes as skeleton graphs, the graphs are embedded into geometric spaces of the same dimensionality. The embedded points are then

many matchings between these features are then analyzed to obtain the decompositional relations among them. The extracted features and their relations are used to construct the final abstract model.

After obtaining many-to-many node correspondences based on [5], the algorithm in [6] computes the abstracted medial axis graph by first computing the averages of the corresponding pairs of subgraphs to yield the nodes in the abstracted graph, and then defining the overall topology of the resulting abstract parts to yield the relations. Each matching pair of subgraphs corresponds to a single node in the abstracted graph, and two abstracted nodes are connected by an edge if the corresponding subgraphs are adjacent in the original graphs. This procedure forms the basis of an iterative framework in which pairs of similar medial axis graphs are clustered and abstracted, yielding a set of abstract medial axis graph class prototypes.

In the domain of grammars, objects are represented as variable hierarchical structures. Each part in this representation can be defined in terms of other parts, allowing an object to be modeled by its coarse-to-fine appearance. Overall, grammar-based models including AND-OR graphs support structural variability. To represent intra-category variation and to account for many-to-many correspondence, the grammar creates a large number of configurations from

matched using the Earth Mover's Distance algorithm. The right part illustrates the many-to-many correspondences between the vertices of the input graphs. Each dashed ellipsoid represents a set of vertices from the original graph

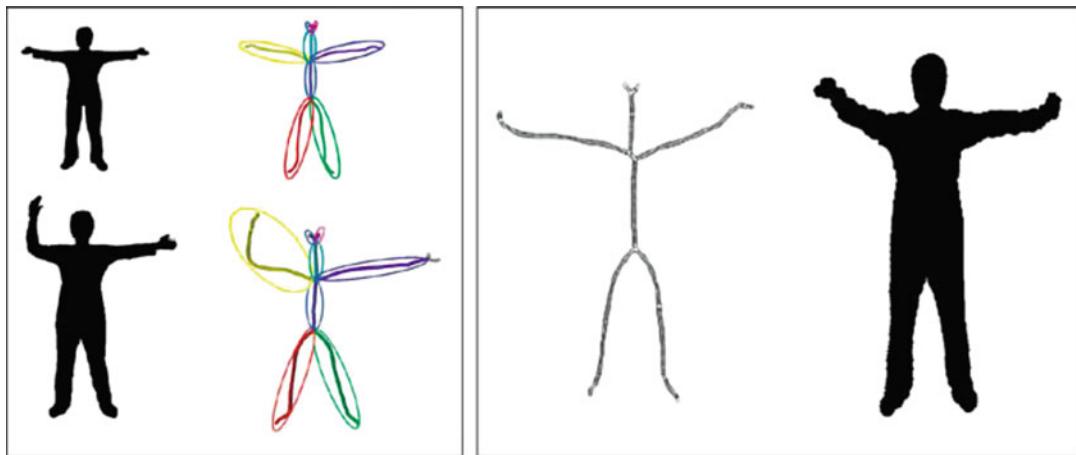

a small vocabulary set. To scale to a large number of object categories, the AND-OR graph, learning, and inference algorithms are defined recursively. Some examples of this type of approach include [1, 21].

M

Experimental Results

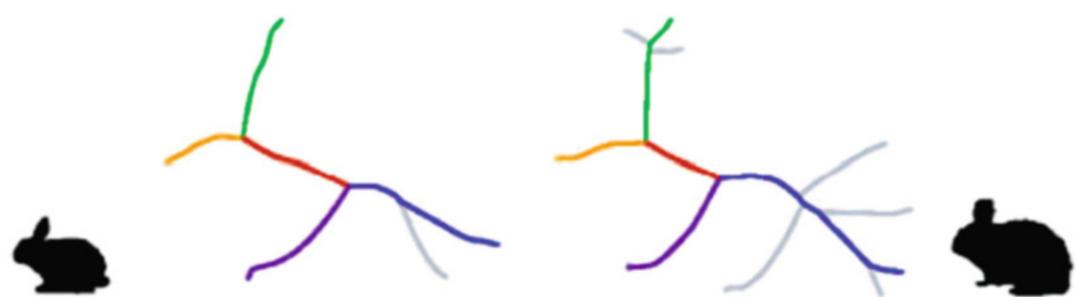

In this section, some example results from some of the many-to-many matching approaches described in the Related Work section are illustrated. After representing silhouettes as skeleton graphs in Fig. 2, the algorithm proposed in [5] obtains many-to-many node correspondences through metric embedding, as discussed earlier. Based on the many-to-many correspondences of this algorithm, Fig. 3 demonstrates an example for the abstract shape created by the approach presented in [6]. The left part presents input silhouettes, their skeleton graphs, and many-to-many correspondences. The right part presents the abstract skeleton graph and its shape reconstructed from this graph.

Graph edit distance is another important class of many-to-many graph matching algorithms. Figure 4 shows the result of matching the skeleton graphs for two input shapes using the graph edit distance algorithm described in [16]. Same colors indicate the matching skeleton parts while gray colors show spliced or

Many-to-Many Graph Matching, Fig. 3 A shape abstraction example of [6] based on many-to-many correspondences obtained by [5]. The *left image* shows input silhouettes and their skeleton graphs in which the same

color is used to show the corresponding parts. Using these correspondences, the abstract skeleton graph and its silhouette are created as shown on the *right*

Many-to-Many Graph Matching, Fig. 4 Graph edit distance algorithms compute many-to-many correspondences of a pair of graphs by finding the lowest cost sequence of graph edit operations needed to transform

one graph into another. In the example, same colors indicate the matching skeleton parts, while gray colors show spliced or contracted edges. (The example is taken from Ref. [16])

contracted edges. Observe that the many-to-many correspondences are intuitive in these figures.

Matte Extraction

Jiaya Jia
 Department of Computer Science and
 Engineering, The Chinese University of Hong
 Kong, Shatin, Hong Kong, China

Synonyms

Digital matting; Pulling a matte

Definition

An alpha matte has the same size as the input image. It contains respective weights to linearly blend latent foreground and background colors for each pixel to form the observed color. Estimating the alpha matte together with the foreground color image is generally referred to as matte extraction or digital matting.

Background

Classifying each pixel in an input image to either foreground or background is called *binary segmentation*, which is a fundamental computer vision problem. Digital matting relaxes the hard separation assumption and takes ubiquitous foreground and background color blending in image formation, which happens along almost all object boundaries, into consideration. Results from matte extraction can be used to generate a new composite.

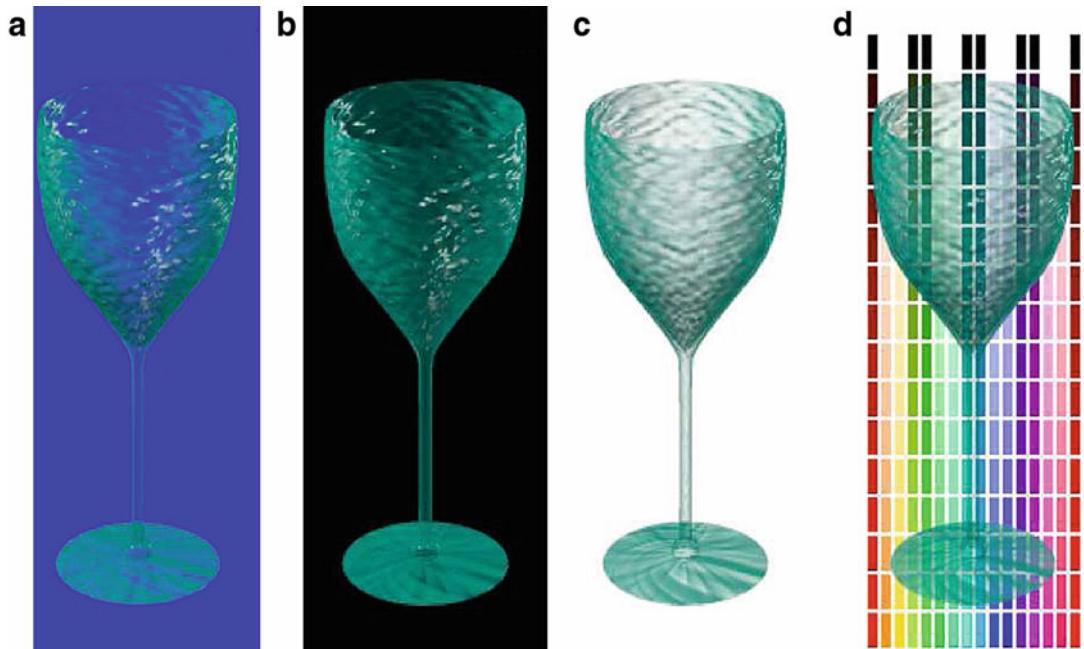

Color blending in natural images has a variety of causes, such as color interpolation during image production and light photons received by the camera sensor containing both background and foreground color for some pixels. Without additional information, digital matting is an ill-posed problem with many unknowns. So generally, either multiple frames are taken or a certain amount of user interaction is involved to sample foreground and background color in image and video matting.

Theory

In the digital matting framework, separating the background image B and foreground image F with respect to an alpha matte α from an input natural image I is expressed as

$$I = \alpha F + (1 - \alpha) B. \quad (1)$$

If $\alpha(x, y) = 1$, the pixel with coordinate (x, y) is definitely in the foreground. $\alpha(x, y)$ being 0 defines an absolutely background pixel. $\alpha(x, y)$

Matte Extraction, Fig. 1 Blue screen matting [1]. (a) Object against known constant *blue*. (b) Object against constant *black*. (c) Pulled foreground. (d) New composite

can also be in between 0 and 1, indicating a certain level of color mixing. Digital matting aims to estimate α and F (sometimes also B) from I . Existing methods follow one of the following lines.

Blue Screen Matting

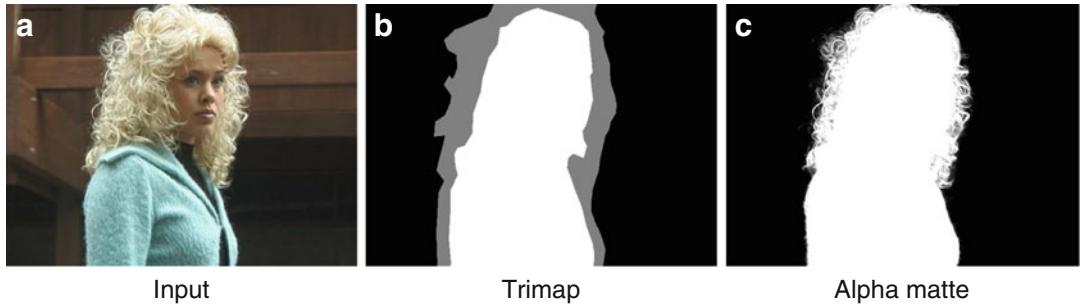

Blue screen matting [1], which is widely employed in movie and commercial production, needs to set up a controlled environment and uses a single or multiple constant-color backgrounds (as shown in Fig. 1). The blue screen matting problem is directly solvable. Its triangular matting technique, which captures images with two backgrounds containing different shades of the backing color, is particularly noteworthy because a closed-form solution exists. This technique can produce very accurate matting results usable as ground truth data. Blue screen matting can be applied in a frame-by-frame fashion to video foreground object extraction.

Natural Image Matting

In natural image matting, background B is generally unknown and possibly contains complex

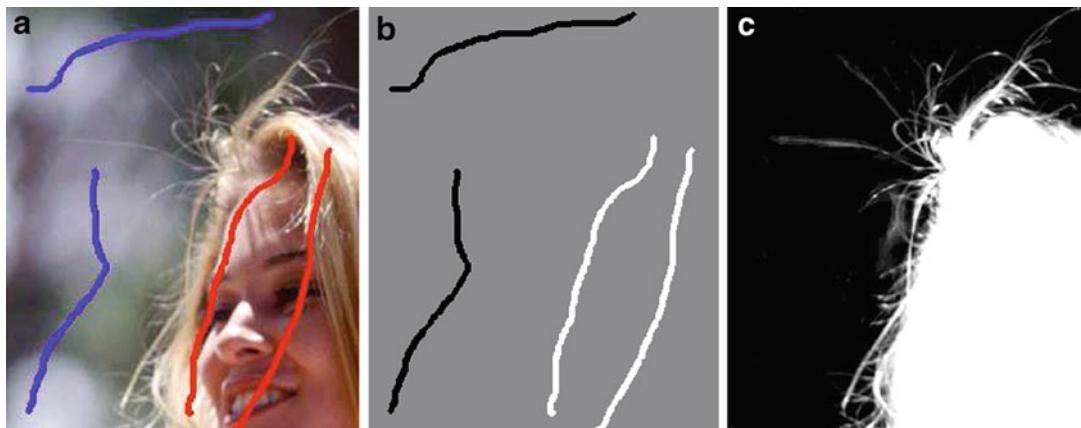

structures. In this case, simultaneously estimating α , F , and B becomes an ill-posed problem. Several methods [2–4] need user input of additional segmentation information to constrain it. *Trimap* is a popular format that partitions the image into three regions, i.e., “definitely foreground” (DF for short), “definitely background” (DB for short), and “unknown region”, as shown in Fig. 2b. In DF and DB, α is set to 1 and 0, respectively. Digital matting only estimates α , together with the foreground and background color, in the unknown region by gathering color information from DF and DB.

There have been several methods proposed to sample color from DF and DB. In knockout [5], F is computed as the weighted average of foreground color along the perimeter of the DF region. B is computed similarly but with a final refinement step. Ruzon and Tomasi [2] sample F and B from local windows and then parameterize them as a mixture of unoriented Gaussians. Alpha values are computed by maximizing a function that interpolates the mean and variance of the Gaussians. Bayesian matting [3] gathers color samples from DF and DB using sliding

windows and fits them with oriented Gaussian distributions. A *maximum a posteriori* (MAP) estimation of α , F , and B is applied. The final α values are chosen from the foreground and background color pairs that maximize the probability. Global Poisson matting [4] contributes a gradient-domain alpha matte estimation. When the condition of locally smooth color change in DF and DB is violated, user interaction is involved to improve the matting result with the supply of a group of filters.

The quality of results of these methods partly depends on how accurate the trimap is since color is sampled and the alpha matte is estimated within windows. Many later approaches instead require the user to only draw several foreground and background scribbles to coarsely indicate

DF and DB and leave all unspecified pixels in the unknown region. This scheme simplifies user interaction but provides looser constraints for digital matting, as shown in Fig. 3. Representative work that can robustly solve for alpha mattes based on it includes (1) the iterative-optimization method [6], which samples color from user-drawn scribbles, builds the Markov Random Field (MRF), and solves for segmentation and matte extraction using belief propagation, and (2) closed-form matting [7] that introduces a color line model and based on it derives a quadratic cost function only involving α and a matting Laplacian, enabling linear optimization. In addition, Rhemann et al. [8] extract high-resolution mattes by trimap segmentation and by employing gradient preserving alpha pri-

ors. The soft-scissor method of Wang et al. [9] can achieve real-time matting along with user painting the foreground boundary.

There are also automatic image matting methods. A soft color segmentation method was proposed in [10], where a global objective function is modeled by global and local parameters. These parameters are alternately optimized until convergence. It can be applied to matting without intensive user interaction. Spectral matting [11] is a single image approach. It shows that the smallest eigenvectors of the matting Laplacian span individual matting components, making their estimation equivalent to finding linear transformation of the eigenvectors. Flash matting [12] captures a pair of flash/no-flash images and assumes only the foreground region is lit by flash. This method can automatically extract foreground in a joint Bayesian matting framework.

Albeit some inevitable limitations as described in respective papers, all the above techniques advance image matting from different aspects. Other recommended readings also include [13–15].

Video Matting

Digital matting was extended to videos in various ways. Typical video matting methods deal with foreground regions with hair, trees, or smoke, where color blending exists for a large amount of pixels. To preserve temporal coherence among frames, with the input of a monocular video, Bayesian video matting [16] propagates manually specified trimaps from keyframes to other frames using optical flow and suggests completing background using mosaic construction. This method is improved in [17] by incorporating stronger prior terms. The geodesic matting method [18] introduces temporal neighbors for each pixel and infers foreground and background scribbles in the video based on user input in only sparse frames. With the setup of special devices or systems, defocus matting [19] and the camera-array method [20] make use of multiple cameras that take pictures with different focus settings and with the existence of parallax respectively to profit video matting.

The other set of methods [21, 22] adopt video matting in a refinement step to improve foreground boundary estimation after video cutout where unknown regions are generally narrowbands around the boundaries.

Application

Digital matting exploits pixel-wise color blending and is an indispensable technique for high-quality object extraction from images and videos. The matte estimate together with the computed foreground color can then be used to form a new composite with another background image. Simple composition applies linear color blending again based on (1), while several other approaches, include drag-and-drop pasting [23], context-sensitive blending [24], and compositional matting [25], explore the structure relationship between the source and target images and combine color blending with other schemes.

Matte extraction and the corresponding composite construction are fundamental tools for image/video editing and finds many applications in computer graphics and vision. Movie and commercial production relies on it to naturally insert objects into a virtual or real scene. Digital matting can possibly be combined with other decomposition, recognition, and tracking techniques to further improve the performance and expand the usability.

Experimental Results

Rhemann et al. [26] established a digital matting evaluation website containing data classified into high, strong, medium, and little transparency groups. Training data are also provided. This website contains updated experimental results of many approaches.

Maximum Likelihood Estimation

Synonyms

[Maximum likelihood estimator](#)

Definition

Maximum likelihood estimation seeks to estimate model parameters that best explain some given, independent measurements according to a noise model.

Background

Many problems in computer vision can be formulated as finding the parameters of a predefined model given measurements or training examples.

For example in image segmentation one may want to describe a region by a simple region model, e.g., by a constant intensity value μ . There are many measurements, namely all the pixel intensities in the region. Assuming that these pixel intensities are independently generated from the constant intensity model according to a Gaussian distribution, the goal is to find the most likely parameter μ given these measurements. In this simple example, the optimal parameter μ is the mean of all intensities.

There are many more similar problems in computer vision, for instance, in the scope of optical flow estimation, camera calibration, image denoising, or pattern recognition. In the special case of a Gaussian noise model, maximum likelihood estimation comes down to a least squares approach.

Maximum likelihood estimation is often criticized because it ignores a-priori information, which can be interpreted as assuming a uniform prior density on the parameter space. This becomes especially problematic when the model is described by many parameters and there are relatively few measurements. In cases where good a-priori assumptions can be made, maximum likelihood estimation should be replaced by maximum a-posteriori estimation, which takes the prior density into account.

Theory

Given a probabilistic model that is described by a parameter vector $\mathbf{w} \in \mathbb{R}^D$ and given N independent measurements $\mathbf{x}_n \in \mathbb{R}^K$, $N \geq D$, one aims at maximizing the likelihood

$$p(\mathbf{x}_1, \dots, \mathbf{x}_N | \mathbf{w}) = \prod_{n=1}^N p(\mathbf{x}_n | \mathbf{w}). \quad (1)$$

For numerical reasons, rather than maximizing this probability, it is common to maximize its

logarithm, the so-called log-likelihood:

$$\begin{aligned} \mathbf{w}^* &= \operatorname{argmax}_{\mathbf{w}} \log p(\mathbf{x}_1, \dots, \mathbf{x}_N | \mathbf{w}) \\ &= \operatorname{argmax}_{\mathbf{w}} \sum_{n=1}^N \log p(\mathbf{x}_n | \mathbf{w}). \end{aligned} \quad (2)$$

Application

Applying this to a simple regression problem, where a line is to be fitted to a couple of points, one has the constraints

$$w_1 x_{1,n} + w_2 = x_{2,n}, \quad n = 1, \dots, N. \quad (3)$$

Assuming a Gaussian distribution with constant covariance yields

$$\sum_{n=1}^N \log p(\mathbf{x}_n | \mathbf{w}) \propto \sum_{n=1}^N (w_1 x_{1,n} + w_2 - x_{2,n})^2. \quad (4)$$

The connection to least squares estimation can be seen immediately, but one could as well assume a Laplace distribution, which is more robust to outliers among the measurements and would lead to

$$\sum_{n=1}^N \log p(\mathbf{x}_n | \mathbf{w}) \propto \sum_{n=1}^N |w_1 x_{1,n} + w_2 - x_{2,n}|. \quad (5)$$

A necessary condition for a maximum of this expression is that the gradient with respect to the parameter vector must vanish:

$$\begin{aligned} \frac{\partial}{\partial w_1} \sum_{n=1}^N |w_1 x_{1,n} + w_2 - x_{2,n}| &= 0 \\ \frac{\partial}{\partial w_2} \sum_{n=1}^N |w_1 x_{1,n} + w_2 - x_{2,n}| &= 0 \end{aligned} \quad (6)$$

leading to the nonlinear system

$$\begin{aligned} \sum_{n=1}^N \frac{1}{2} \frac{(w_1 x_{1,n} + w_2 - x_{2,n}) x_{1,n}}{|w_1 x_{1,n} + w_2 - x_{2,n}|} &= 0 \\ \sum_{n=1}^N \frac{1}{2} \frac{(w_1 x_{1,n} + w_2 - x_{2,n})}{|w_1 x_{1,n} + w_2 - x_{2,n}|} &= 0, \end{aligned} \quad (7)$$

which can be solved by iteratively keeping the denominators fixed, solving the resulting linear system and updating the denominator. Gaussian distributions lead to linear systems that can be solved directly. More details and examples on maximum likelihood estimation can be found in [1, 2].

Definition

A mirror is an optical device used for beam-forming or imaging based on the directional reflection of electromagnetic radiation.

Background

Computer vision applications apply mirrors in a twofold manner: for optical imaging and for illumination purposes. Furthermore, mirrors themselves could be test objects in visual inspection systems. This leads, with regard to the 3D shape of the mirror, to the shape-from-specular-reflection problem and, in the context of visual inspection systems, to deflectometry.

Theory and Application

Mirrors consist of a smooth substrate with a metal coating (e.g., Au, Ag, Al) and/or dielectric layers.

In the case of a surface mirror, the reflection takes place at a metal coating on the front side that has to be protected against scratches. The main advantage of a surface mirror is the lack of beam displacement due to the glass substrate. Alternatively, the backside of a glass substrate can be coated with a metal layer and with an additional protection against humidity and mechanical damage. Backside mirrors are usually more robust than surface mirrors, but lack their optical characteristics mentioned above.

The physical effect leading to the reflection of electromagnetic waves on metal surfaces can be simply described as “short circuit” of the electrical field. The reflection depends on wavelength, incident angle, and polarization.

Dielectric mirrors are composed of multiple thin layers of dielectric materials. They exhibit very high reflectance values and very low intrinsic absorption. The reflectance depends also on wavelength, incident angle, and polarization. Advanced multilayer structure designs can be used to obtain certain functionality [1]:

- A broader reflection bandwidth
- A combination of desirable reflectivity values in different wavelength ranges
- Special polarization properties (for non-normal incidence, thin-film polarizers, polarizing beam splitters)
- Non-polarizing beam splitters
- Edge filters, e.g., long-pass filters, high-pass filters, band-pass filters
- Tailored chromatic dispersion properties

Such mirrors are especially used in laser applications.

Furthermore, thin metal layers allow semi-transparent mirrors to be realized for coaxial illumination.

The electromagnetic theory of light is fundamental for the physical understanding of specular reflections [2]. Thereby, the law of reflection describes the geometric aspects, and the Fresnel equations the reflection coefficients, i.e., the radiometric behavior.

The law of reflection states the relationship of the incident \vec{s}_i and reflected \vec{s}_r light rays with the

normal of the specular surface \vec{n} :

$$\vec{s}_i \times \vec{n} = \vec{s}_r \times \vec{n}, \quad (1)$$

with $\|\vec{s}_i\| = \|\vec{s}_r\| = \|\vec{n}\| = 1$.

Equation 1 leads, with $\|\vec{s}_i \times \vec{n}\| = \sin \theta_i = \sin \theta_r = \|\vec{s}_r \times \vec{n}\|$, directly to the following two conditions:

- The angle of the incident ray equals that of the reflected ray ($\theta_i = \theta_r$).
- The incident and reflected ray are coplanar with the surface normal.

In computer graphics and ray-tracing, the law of reflection is often used in the form of a Householder transformation:

$$\vec{s}_r = \mathbf{H} \vec{s}_i \quad \text{with} \quad \mathbf{H} := \mathbf{I} - 2\vec{n}\vec{n}^T, \quad (2)$$

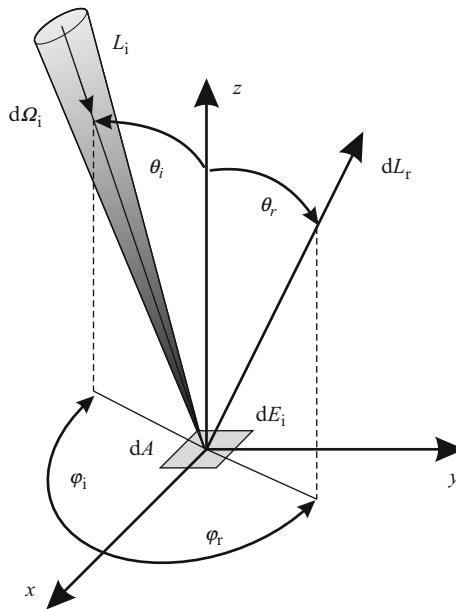

with the identity matrix \mathbf{I} .

The bidirectional reflectance distribution function (BRDF; $\rho(\theta_i, \varphi_i; \theta_r, \varphi_r)$) describes the reflectance characteristics of a surface, i.e., the ratio of incident and reflected radiance in dependency of incident and observation angles, Nicodemus et al. [3]. According to Horn and Sjoberg [4], the BRDF for an ideal mirror is (cf., Fig. 1):

$$\begin{aligned} \rho(\theta_i, \varphi_i; \theta_r, \varphi_r) &= \frac{dL_r}{L_i \cos \theta_i d\Omega_i} \\ &= 2 \delta(\sin^2 \theta_r - \sin^2 \theta_i) \delta(\varphi_r \\ &\quad - ((\varphi_i + \pi) \bmod 2\pi)). \end{aligned} \quad (3)$$

In general, the amount of reflected light intensity depends on the wavelength, incident angle, and polarization of the incident light and on the characteristics of the surface itself, e.g., refraction index, shape, and roughness.

The Fresnel equations describe the relationship between reflected intensity, incident angle, and polarization state of the incident electromagnetic wave of a smooth surface. These formulas are applicable in the two cases of dielectric and strongly absorbing materials (metals) and

Mirrors, Fig. 1 Geometry of reflection and the BRDF, thereby $d\Omega_i$ denotes an infinitesimal solid angle of the incident radiation, L_i, L_r the incident and reflected radiance, and dE_i the irradiance on the surface element dA

establish the theoretical basis for the creation of polarized light with mirrors.

In Fig. 2, the reflectance of some metals is plotted against the wavelength. Most metals have a strong reflectance in the infrared spectrum. For laser applications, mirrors with gold coatings are often sufficient for low-power operation, whereas high-power lasers require advanced dielectric multilayer structures.

With dielectric films even higher reflectance values can be achieved.

Furthermore, the reflectance depends on the surface quality. The dependency on surface roughness σ (root-mean-squared roughness), wavelength λ , and the reflectances R_σ for rough and R for ideal smooth surfaces can be stated as [6]:

$$R_\sigma = R \exp \left[- \left(\frac{4\pi\sigma \cos \theta_i}{\lambda} \right)^2 \right]. \quad (4)$$

The surface roughness requirements in the far-infrared spectrum are lower than in the visible

range. With large incident angles θ_i and surfaces with very small roughness, mirrors applicable even for X-ray applications can be manufactured.

The most familiar type of mirror is the plane mirror, which has a flat surface. This mirror is mostly used for beam deflection purposes. In Fig. 3a, the geometry of reflection on a plane mirror is shown.

Thereby the image of an object is virtual with magnification equal to one, upright, right-left inverted, without aberrations, and symmetric to the mirror plane.

Figure 3b shows two plane mirrors in an angular mirror setup, whereby $\gamma = 2\delta$. A special case is a triple mirror with three pairwise orthogonal planes ($\delta = 90^\circ$), which is used as a retroreflecting element.

Curved mirrors are also used, such as spherical, ellipsoid, paraboloid, or conical mirrors. Figure 4 shows convex and concave mirrors for optical imaging. The focal distance of a spherical mirror with radius r is given by:

$$f = \frac{r}{2}. \quad (5)$$

The mirror equation:

$$\frac{2}{r} = \frac{1}{s} + \frac{1}{s'} \quad (6)$$

describes the relationship between object and image distances (s, s') with the mirror radius r .

A big advantage of mirrors above lenses is the lack of chromatic aberrations, but with the disadvantage of higher centering and adjustment requirements.

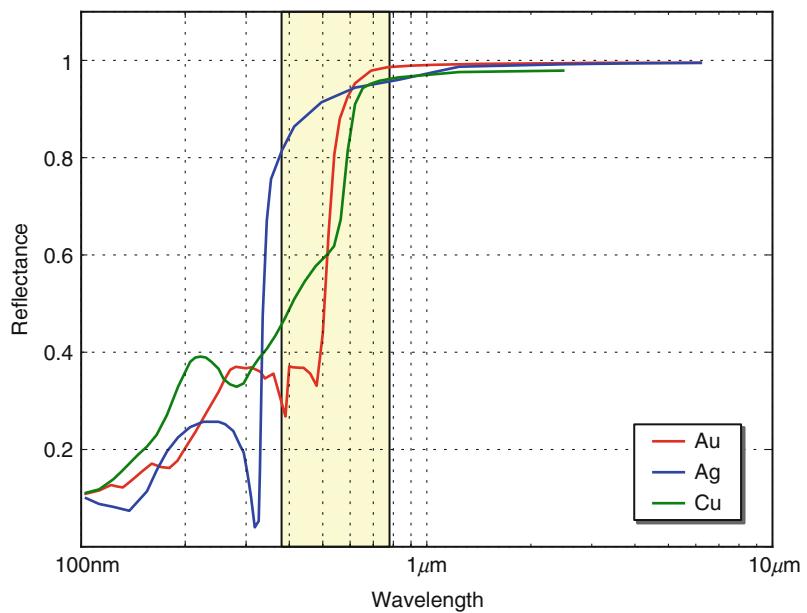

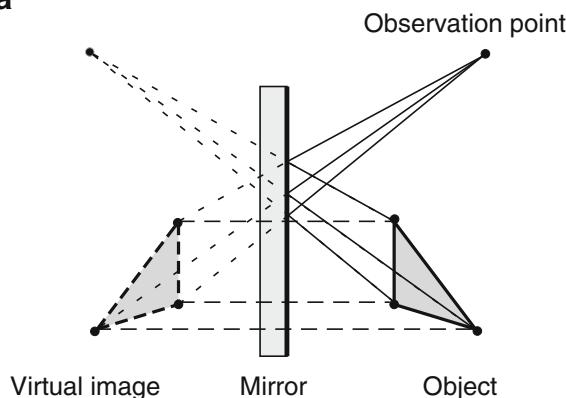

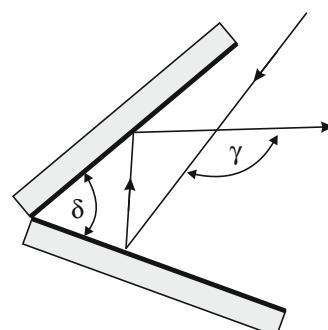

Torrance and Sparrow [7] and Phong [8] have, among many others, introduced surface models which can be used to describe specular reflections. Modeling of mirrors or partially reflecting surfaces is of ongoing interest for computer graphics applications.

Open Problems

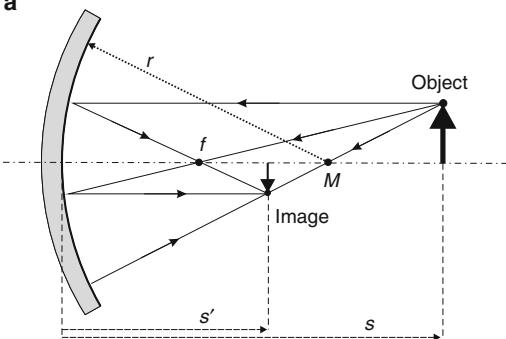

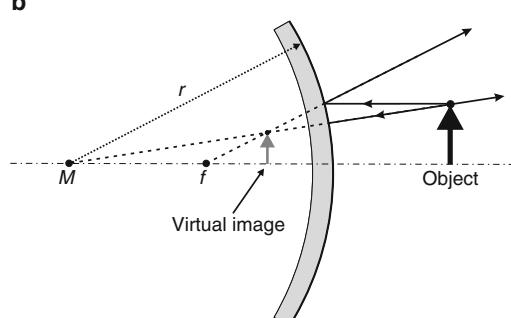

The main principle for the visual inspection of mirrors is to use a highly controllable

Mirrors, Fig. 2

Reflectance vs. wavelength curves for gold (Au), silver (Ag), and copper (Cu) at normal incidence [5]

environment, where a screen presenting a well-designed pattern is observed via the specular reflecting surface. Knowing that pattern, it is possible to inspect the surface qualitatively and – at least with certain additional knowledge – to reconstruct the surface quantitatively. This reconstruction problem is ill-posed in a mathematical sense, and several regularization approaches have been proposed. The reconstruction of large and complex formed mirrors is still a challenge in the field of computer vision [9–13].

Although the reconstruction problem is ill-posed, humans can usually estimate the shape of mirrors quite well, c.f., Fleming et al. [14]. The visual perception of mirror-like objects is an ongoing research effort.

Another area of ongoing research is the development of mirrors for the extreme ultraviolet (EUV) spectral range, used in EUV lithography tools. These mirrors can be standard Mo/Si mirrors or multilayer setups [15].

Mobile Observers

Jan-Olof Eklundh

School of Computer Science and
Communication, KTH – Royal Institute of
Technology, Stockholm, Sweden

M

Definition

A mobile (visual) observer is an agent or a system that perceives its environment using vision. In computer vision this typically is a mobile device such as a robot carrying one or more cameras.

Background

Gibson [1] claimed that a mobile observer is a prerequisite for natural vision. He discriminated between *ambient* or *ambulatory vision*, when the observer can move its head or body, and *snapshot* or *aperture vision* in cases when one or several images are recorded momentarily at certain fixation points. All those aspects are treated in computer vision, although current

trends are on processing static images in the spirit of *snapshot* or *aperture vision*. Computer vision researchers began to study *visual motion* in the 1970s, when it became possible to connect video cameras to computers. This work did not really concern mobile observers, but such existed even earlier, when cameras were used as input devices to robots, e.g., in the work on “Shakey” [2]. Nowadays, mobile observers most often occur in the context of mobile robots, but recent developments on *wearable vision* have widened the interest in the topic. *Ambient vision* is what you have for instance in the case of *pan-tilt heads*, which are used in a large range of applications.

Theory

There have been attempts to find the notions of active and mobile observers theoretically. In biological vision Gibson’s work is of a landmark nature, but there are many other proposals as well, e.g., relating to functionalism [3]. In computer vision the problem has been considered from the point of view of active vs. passive vision [4–6]. In [7–9] the theoretical aspects are more directly addressed. However, even with these attempts, one can hardly say that there exists any complete theory for a mobile observer.

Problems and Applications

The mobile observer obtains a stream or sequence of images as input rather than single images. This provides rich information about the environment as well as of the movements of the observer. However, observer motion also implies that there is image motion in almost every point in the sequence. In a static world, observer motion creates essentially all the variations over time in the images, i.e., those that are due to change of viewpoint and not, e.g., in illumination. If there are things in the environment that also move, the two types of motion are confounded in the images.

A mobile observer can derive (static) scene geometry through *structure-from-motion* algorithms. Moreover, *ego-motion*, i.e., the motion of the observer, can be estimated. Generally such methods assume a static background that is prominent in the field of view. Independently moving objects can then also be detected, and under certain conditions their motion can be estimated. *Ego-motion estimation* obviously plays an important role here. There are many types of algorithms for this, e.g., based on *optical flow*, monocular or binocular *feature tracking*, or *image stabilization*. There also exist algorithms for using *omnidirectional* or *composite cameras*, which highlights the fact that effects of ego-motion are manifested in a wide field of view. For instance, small rotations of an observer moving straight ahead can be estimated from peripheral flow, something that is useful in driving and in guiding of autonomous robots.

A mobile observer can be active or passive. In the first case, it purposively guides its motion and/or the way it directs its gaze on the basis of tasks it is involved in and as a reaction to what it observes. *Gaze control* and *fixation* in dynamic situations have been studied extensively in the field of *active vision*. In some cases these mechanisms have been used to control observer motion, e.g., for exploring a scene or an object and to facilitate recognition. Then *viewpoint planning* becomes an issue. However, a more general case is when the observer motion is only loosely dependent of what is seen, except for possible control of gaze. For instance, a mobile observer can induce depth cues through parallax by (small) camera motions that are not pure rotations. Another example is given by a robot moving from one point to another while observing an object along its path, analogously to a person riding in a car. Many applications contain elements of both active and passive observations, for instance in robot navigation including *obstacle avoidance* and *mapping* (as in *SLAM*), *hand-eye control* in grasping and manipulation, and in general for an ambulant observer, such as those studied in the context of *wearable* or *egocentric vision*.

Open Problems

The study of mobile observers from a computational perspective involves a broad range of problems traditionally addressed in computer vision. However, there are certain issues that become central. For instance, the *correspondence problem* is ubiquitous. In applications such as those described above, the tight connection between *perception and action* is apparent. Visual sensing involving motor control raises problems on time criticality and real-time computations [9]. Other problems arise because the mobile observer continuously samples the visual world. Meaningful behavior based on the huge amounts of information requires methods for *attention* and *visual search*. In all, although some of the problems encountered in the study of mobile observers largely overlap those generally treated in computer vision, there are others that are specific to this area.

Definition

Model-based object recognition addresses the problem of recognizing objects from images by means of a suitable mathematical model that is used to describe the object.

Background

In model-based object recognition, an object model is typically defined so as to capture object's geometrical and appearance properties at the appropriate level of specificity. For instance, an object model can be designed to recognize a generic "face" as opposed to "someone's face" or vice versa. In the former case, which is often referred to as the object categorization problem, the main challenge is to design models that are capable of retaining key visual properties for representing an object category, such as a "face," at the appropriate level of abstraction. Such

models can be then used to recognize novel object instances from a query image. Moreover, a model must be able to generalize across variations in the object's visual characteristics due to viewpoint and illumination changes as well as due to occlusions or deformations. Meeting all of these desiderata can be extremely challenging. This makes object recognition an open, yet key, problem in computer vision.

Object Models for Recognition

The design of an object model must reflect its ability to (i) capture geometrical and appearance characteristics of the object at the appropriate level of specificity and (ii) generalize across variations in viewpoint, illumination, occlusions, and deformations. The complexity of the representation can be reduced by making assumptions on the type of object specificity or the degree of viewpoint, occlusions, and deformation variability. Ultimately, the strategy in designing an object model will depend on the relevant application scenario.

Object models that are designed to recognize objects at the highest level of specificity – e.g., “my face” as opposed to “a face” – are often referred to as single-instance object models. These models are capable of recognizing a specific object instance while guaranteeing the ability to handle occlusions and a large degree of viewpoint variability. Research on 3D object recognition, from early contributions [1–9] to the most recent ones [10–13], follows these assumptions. Since single-instance object models do not need to accommodate any intra-class variations, they often consist of a rigid collection of visual features associated to a number of 2D or 3D templates. In recognition, by matching features of the query image with those associated to the models, it is possible to identify the object of interest and determine its 3D pose with respect to a common reference system. This matching process is usually subject to a geometrical validation phase that helps verify that the appearance, and geometric properties of the query object are consistent

with the estimated pose transformation between observation and object model. While critical for ensuring sufficient discrimination power for recognizing single-instance objects as well as for enabling large viewpoint variability, tight geometrical constraints become inadequate when shape and appearance intra-class variability must be accounted for.

Object models that are designed to recognize objects at a lower level of specificity – e.g., “a face” as opposed to “my face” – are often referred to as categorical object models. The ability to generalize across instances in the same category is critical and is typically achieved by characterizing the object as a collection of features whose appearance and geometrical properties tend to systematically occur in the category of interest. For instance, if the goal is to recognize a car, appearance properties such as the “color of the body” are not adequate to help obtain the right level of generalization (abstraction), whereas the orientation of edges associated to a wheel can capture more general appearance cues across instances. Appearance properties are typically captured by image descriptors such as [10, 14] associated to interest points that are detected at different locations and scales of the image. A popular design choice is to describe the object appearance by histograms of vector-quantized descriptors [15–17]. The ability of image descriptors such as [10] to be invariant to affine illumination transformations makes the appearance models robust to variability in illumination conditions. Geometrical properties are captured by retaining the spatial organization of features in the image and include simple characterizations based on the 2D location of either feature points or aggregation of features (e.g., edges, parts, fragments) with respect to a given object reference point [18–22]. Object models constructed upon constellation of parts such as [18–20] are suitable to accommodate object variations due to occlusions and simple 2D planar geometrical deformations (isometries or affinities). Suitable machine learning and probabilistic inference techniques such as expectation maximization (EM) [23], latent SVM (LSVM) [24], Markov random field (MRF) [25, 26], con-

ditional random field (CRF) [27], generalized Hough voting [28], and RANdom SAmple Consensus (RANSAC) [29] are used to automatically select appearance and geometrical properties so as to reach the appropriate level of generalization and discrimination power.

Most of the object models for object categorization mitigate the complexity of the representation by assuming that objects are viewed from a limited number of poses and learn an object model that is specialized to identify the object from a specific viewpoint. These are often referred to as view-dependent object models. If similar views in the training set are available, the recognition problem is reduced to match the new query object to one, or a mixture, of the learnt view-dependent object models [30, 31]. The drawback of view-dependent object models is that (i) they can accommodate very limited viewpoint variability – mostly changes in scale or 2D rotation transformations – and (ii) different poses of the same object category result in completely independent models, where neither features or parts are shared across views. Because each single-view models are independent, these methods are often costly to train and prone to false alarms, if several views need to be encoded.

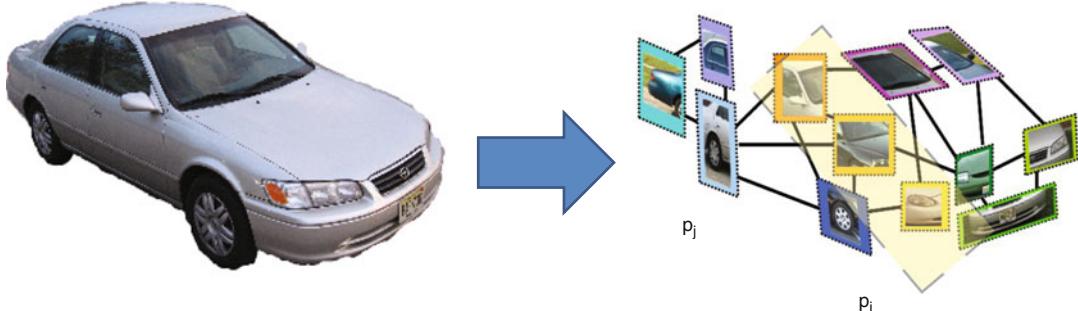

Object models that can accommodate both large viewpoint changes and large intra-class variability (low degree of specificity) overcome the above limitations by introducing a representation that seeks to effectively captures the intrinsic three-dimensional nature of the object category. These models are typically divided into two types: 2-1/2D layout models and 3D layout models [34]. In the 2-1/2D layout models [32, 33, 35], object diagnostic elements (features, parts, contours) are connected across views to form an unique and coherent 2-1/2D model for the object category (Fig. 1). Relationships between features or parts capture the way that such elements are transformed as the viewpoint changes. These methods share some key ideas with pioneering works in 3D object recognition [1–6, 8, 9] as well as with the theory of aspect graphs [7, 36]. In the 3D layout models [37–42], object elements are organized in a common 3D reference frame and form a compact

3D representation of the object category. Such 3D structures of features (parts, edges) can give rise, for instance, to either a 3D generalization of 2D pictorial structures or constellation models or to hybrid models where features (parts or edges) lie on top of 3D object reconstructions or CAD volumes.

Open Problems

Although object recognition has been a core problem in computer vision for more than four decades and several powerful models have been proposed, state-of-the-art methods are still far from the level of accuracy, efficiency, and robustness that the human visual system achieves in recognizing, detecting, and categorizing objects from images. Recently, several new paradigms have been explored to address the above limitations. One major effort involves large-scale object recognition. With the introduction of ultra-large-scale datasets such as the ImageNet [43] – a collection of millions of images organized into a hierarchical ontology of thousands of categories – it is now possible to evaluate methods for object categorization that seek to (i) efficiently process these many images and categories and (ii) understand objects at different level of specificity; this is also referred to as to the fine-grain categorization problem [44–46]. Another major effort is related to the introduction of a recent paradigm whereby objects are modeled and recognized by means of their attributes. As pioneered by [47–49], visual attributes such as “it is metallic”; “it has wheels” can be used to obtain more effective and descriptive characterizations of object categories (i.e., a car or a truck). This has the benefit of (i) making the “boundaries” between different categories more fluid than in traditional parameterizations, (ii) enabling more powerful methods for fine-grained categorization [45], and (iii) providing critical building blocks for transferring visual properties across categories (transfer learning, one shot learning) [47, 49].

Other important problems for future work include the ability to (i) overcome the traditional

Model-Based Object Recognition: Traditional Approach, Fig. 1 Example of 2-1/2D layout models as introduced in [32] and generalized in [33]. *Left panel:* An image of an object category of interest. *Right panel:* In the 2-1/2D layout model, object parts are connected to form a graph structure. Each node P_i captures diagnostic

paradigm whereby objects are identified as just bounding boxes in images but rather provide a richer characterization in terms of their accurate outlines or segments, 3D properties (pose or 3D shape) [37, 42], as well as attributes; (ii) find a common ground between bottom-up representations (from pixels to features), akin to recent developments on convolutional neural networks [50, 51], and top-down models as recently advocated in [52] and (iii) describe the interplay between objects and their components at different levels of semantic resolution [53, 54].

Definition

People tracking is the process of estimating and recording the locations of target people in 2D image sequences (monocular computer vision) or 3D spaces over time (binocular computer vision). It may also refer to the process of estimating and recording the pose (or joint locations) of target people.

Background

Visual object tracking is a fundamental problem in computer vision. As a person is the most important type of object, people tracking has received tremendous interest from both academia and industry. While generic object tracking methods can be directly applied to people tracking,

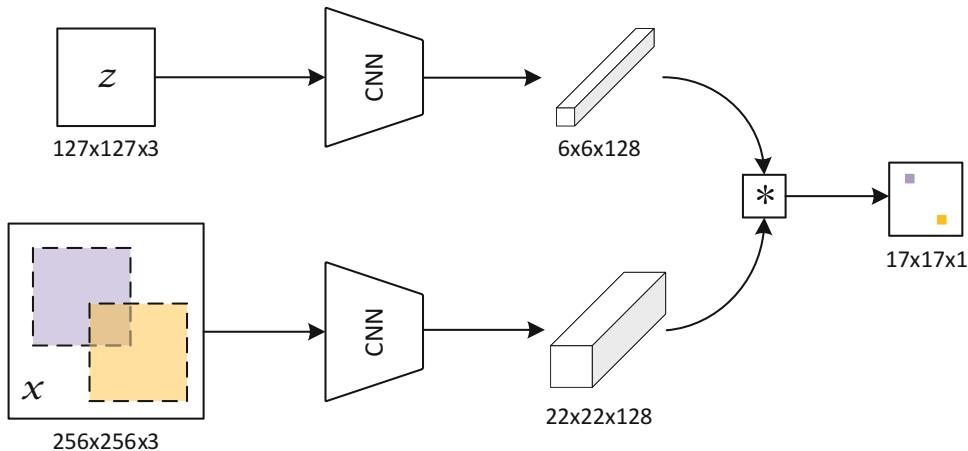

there are also many algorithms and schemes that are tailored for people tracking.

Monocular People Tracking

Monocular people tracking finds applications in surveillance, video indexing, and many other video analytic applications. When a specific person is considered, people tracking can be treated as a generic visual object tracking problem. The most well-known tracking algorithm is the Kanade-Lucas-Tomasi (KLT) feature tracking algorithm [1]. The basic idea is to find a bunch of good features to track and then estimate the object changes based on the points movement. It was the dominant tracking algorithm before the MOSSE tracker [2] was proposed. MOSSE tracker is a correlation filter (CF)-based tracker designed for fast object tracking. There have been several modifications to this method, including kernelization [3] and scale adaptation [4]. In recent years, the Siamese fully convolutional network (SiamFC)-based trackers have attracted much attention [5, 6]. These trackers also perform fairly well on human objects. Figure 1 shows the architecture of the original SiamFC tracker.

When multi-person tracking is considered, it can be similarly treated as a generic multiple object tracking (MOT) problem. In MOT research, it is often assumed that object detection results are given in each frame as input, and the tracking task is to associate the detections to find object trajectories. Existing works solve the data association problem based on the Hungarian algorithm, Markov decision process (MDP) [7], or more complex graph models [8]. There are a handful of efforts that treat object detection and tracking as a coupled optimization problem [9].

For the human object, there is a stronger demand to jointly optimize detection and tracking. It is observed that people detectors are able to locate pedestrians even in complex street scenes, but false positives have remained frequent. Tracking methods are able to find a particular individual in image sequences but are severely challenged by real-world scenarios

Monocular and Binocular People Tracking, Fig. 1

Fully convolutional Siamese network for visual object tracking [5], where z is the target object and x is the search image. CNN denotes the convolutional neural network

for feature extraction, and $*$ denotes the cross-correlation operation. The output is a scalar-valued score map, where the location of the maximal value indicates the location of the object in the search image

such as crowded street scenes. Therefore, the advantages of detection and tracking should be combined in a single framework [10]. Breitenstein et al. [11] propose a tracking-by-detection algorithm which uses the continuous confidence of pedestrian detectors and online trained, instance-specific classifiers as a graded observation model. Tang et al. [12] propose training people detectors explicitly on failure cases of the overall tracker.

In addition to the tracking algorithms which treat a human in its entirety, there are approaches which utilize the body parts or articulations. Rather than simply determining the position and scale of a person, Andriluka et al. also extract the 2D articulation [10] or 3D pose [13] for the tracking task. Shu et al. [14] extend part-based human detection methods to the tracking task. Henschel et al. [15] use body parts, such as the head and/or shoulder, to facilitate person tracking in very crowded scenes.

Note that, although person reidentification has been a separate research topic, it is a highly related concept. Traditionally, person re-ID addresses the association of people across nonoverlapping cameras, but it can be used for linking the detected persons across the whole video after long-term occlusion in multi-person

tracking [16]. Some of the results achieved by this work are shown in Fig. 2.

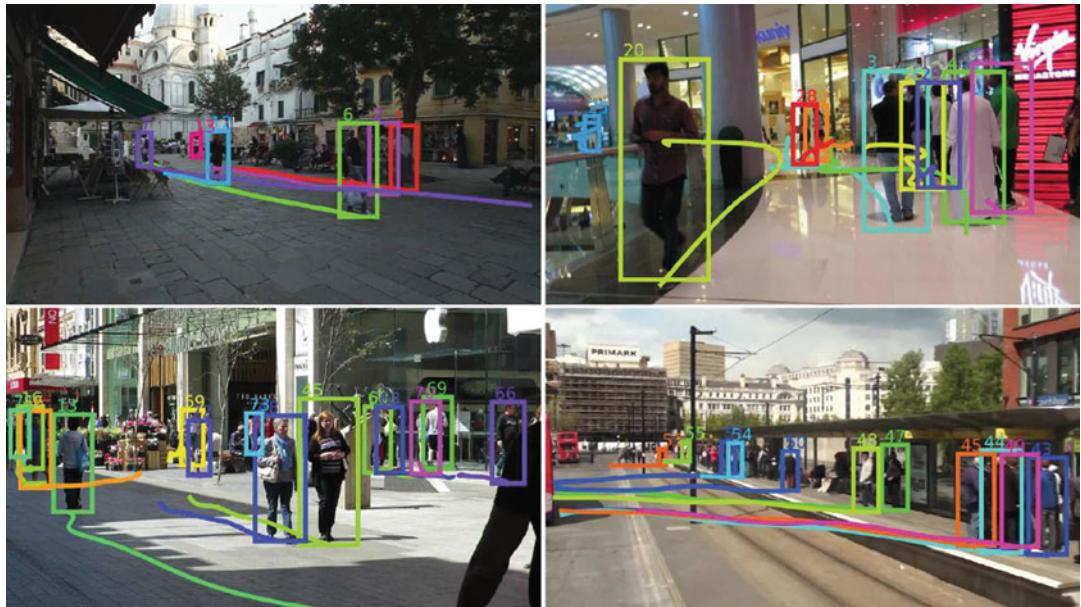

M

Binocular People Tracking

People detection and tracking are key capabilities for a mobile robot acting in populated environments. It is often addressed in the context of binocular vision because a robot can be equipped with two cameras. Conversely, robot control and human-robot interaction are the most important applications of binocular people tracking.

Around a decade ago, when the mainstream tracking algorithms were feature-based tracking, Chen et al. [17] proposed a binocular person following algorithm which uses Lucas-Kanade feature detection and matching to determine the location of the person in the image and thereby control the robot. Matching was performed between two images of a stereo pair, as well as between successive video frames. It is one of the earliest works that do not rely on clothing colors for tracking.

Usually, depth information can be estimated from a pair of stereo images. The depth information complements the appearance model and allows tracking algorithms to achieve good

Monocular and Binocular People Tracking, Fig. 2 Some tracking results achieved by [16] on the MOT16 benchmark. The line under each bounding box indicates the lifetime of the track

results in challenging scenarios. The majority of binocular people tracking algorithms are directly based on RGB-D data, but the depth information can be used in different ways. For example, Ess et al. [18] consider multi-person tracking in busy pedestrian zones. The depth information is used to verify people candidates obtained by a people detector. Luber et al. [19] combine a multi-cue person detector for RGB-D data with an online detector that learns individual target models. In the 3D tracking method proposed by Cao et al. [20], depth information obtained from a moving binocular camera is used to detect and recover from occlusions.

Open Problems

People tracking faces challenges when there are appearance changes due to illumination, pose changes, or cluttered background. But the biggest challenge arises from the person interactions and long-term occlusions in crowded real-world scenes. These may cause identity switches between multiple tracked people. Incorporating long-range person re-ID into

the tracking algorithms could be a feasible solution. Besides, joint detection and tracking is a promising approach to improve the overall system performance.

Definition

Motion blur is due to motion of scene objects or the camera, while the camera shutter is open, thus causing scene points to be imaged over a large area of camera sensor or film. The motion blur is a projection of the motion path of the moving objects onto the image plane. The motion path of a point can be due to translation and rotation of the camera or scene objects in three dimensions. There can be different paths for different parts of the scene, and in light-limited situations, when using long exposures, these paths can be quite large, resulting in very large blurs.

Background

Image blur can be described by a point spread function (PSF). A PSF models how an imaging system captures a single point in the world – it literally describes how a point spreads across an image. An entire image is then made up of a sum of the individual images of every scene point, where each point’s image is affected by the PSF associated with that point. For an image to be “sharp” means that one ideally does not want any image blur. Thus the PSF should be minimal, i.e., a delta function, where each scene point should correspond only to one image point. In practice, PSFs can take on a range of shapes and sizes depending on the properties of an imaging system. When this PSF is large relative due to camera or scene motion and relative to the image resolution and pixel size, an image with motion blur is captured.

The fundamental cause of motion blur is that a camera does not sample light from a single moment in time, but instead captures images by integrating the light over an exposure window. The relative motion between camera and scene objects is the primary factor in motion blur, as illustrated in Fig. 1. The path of motion during exposure affects the PSF and thus the blur shape and size. Properties such as exposure duration, lens focal length, and pixel size play an additional role.

Theory

Image blur is described by a point spread function (PSF). The PSF models how an imaging system captures a single point in the world.

The most commonly used model for blur is a linear model, where the blurred image b is represented as a convolution of a kernel k , plus noise:

$$b = i \otimes k + n, \quad (1)$$

where $n \sim \mathcal{N}(0, \sigma^2)$, which represents an additive Gaussian noise model. In this model, the blur is assumed to be constant over the entire image, i.e., spatially invariant; however, that is often not

true in practice [1, 2]. If there is depth variation in the scene, the motion blur can change with that depth due to parallax. Similarly, if there is scene motion, the blur can change as a function of this motion. In these cases, one can think of the blur kernel, k , as being a function of image position, i.e., $k(x, y)$.

To model spatially varying blur, the spatially invariant kernel and convolution in Eq. 1 can be replaced by a sparse re-sampling matrix that models the spatially variant blur, and the convolution process is now a matrix-vector product:

$$\mathbf{b} = \mathbf{A}\mathbf{i} + \mathbf{n}. \quad (2)$$

Each column of \mathbf{A} is the un-raveled kernel for the pixel represented by that column. Thus the blurred response at a pixel in the observed image is computed as a weighted sum, as governed by \mathbf{A} , of the latent sharp image \mathbf{i} formed into a column-vector.

Representation To model motion blur, first, let us consider the image a camera captures during its exposure window. The intensity of light from a scene point (X_t, Y_t, Z_t) at an instantaneous time t is captured on the image plane at a location (u_t, v_t) , which is a function of the camera projection matrix P_t . In homogenous coordinates, this can be written as:

$$(u_t, v_t, 1)^T = P_t(X_t, Y_t, Z_t, 1)^T. \quad (3)$$

If there is camera motion, P_t varies with time as a function of camera rotation and translation causing points in the scene to project to different locations at each time. If there is scene motion, (X_t, Y_t, Z_t) also varies with time, which also affects where the points project on the image plane. The integration of these projected observations creates a blurred image, and the projected trajectory of each point on the image plane is that point’s “point-spread function” (PSF). The camera projection matrix can be decomposed as:

$$P_t = K\pi E_t, \quad (4)$$

Motion Blur, Fig. 1 With motion blur, the amount of blur depends on the relative motion between the camera and the scene objects; it depends on the focal length and of the lens, the scene depth, and the motion trajectories of objects

where K is the intrinsics matrix, Π is the canonical perspective projection matrix, and E_t is the time dependent extrinsics matrix that is composed of the camera rotation R_t and translation T_t . In the case of image blur, it is not necessary to consider the absolute motion of the camera, only the relative motion and its effect on the image. This can be modeled by considering the planar homography that maps the initial projection of points at $t = 0$ to any other time t [3], i.e., the reference coordinate frame is coincident with the frame at time $t = 0$:

$$H_t(d) = [K(R_t + \frac{1}{d}T_t N^T)K^{-1}] \quad (5)$$

$$(u_t, v_t, 1)^T = H_t(d)(u_0, v_0, 1)^T, \quad (6)$$

for a particular depth d , where N is the unit vector that is orthogonal to the image plane.

If the scene is not moving, given an image I at time $t = 0$, the pixel value of any subsequent image is:

$$I_t(u_t, v_t) = I(H_t(d)(u_0, v_0, 1)^T). \quad (7)$$

This image warp can be re-written in matrix form as:

$$\mathbf{I}_t = A_t(d)\mathbf{I}, \quad (8)$$

where \mathbf{I}_t and \mathbf{I} are column-vectorized images and $A_t(d)$ is a sparse re-sampling matrix that implements the image warping and resampling due to the homography. Each row of $A_t(d)$ contains the weights to compute the value at pixel (u_t, v_t) as the interpolation of the point $(u_0, v_0, 1)^T =$

in the scene. An example of camera motion blur is shown in the middle, where the blur kernel is drawn for each corner of the image. (From Joshi et al. [3]). An example of object motion blur is shown on the right. (From Jia [11])

$H_t(d)^{-1}(u_t, v_t, 1)^T$. Thus an alternative formulation for image blur is the integration of applying these homographies over time [3]:

$$\mathbf{B} = \int_0^s [A_t(d)\mathbf{I} dt]. \quad (9)$$

The leads to the spatially variant blur matrix in Eq. 2:

$$A(d) = \int_0^s A_t(d)dt. \quad (10)$$

For camera motion blur, A is a function of depth. If there is scene motion, the full model can be extended to handle the time-varying mapping of scene points, (X_t, Y_t, Z_t) , to the image plane.

M

Application

Estimation of camera motion blur [1, 3–9] and object motion blur [10–13] are extensively researched areas. Estimated blur kernels are typically used for improving image quality by reducing blur using image deblurring and deconvolution methods [1, 10, 14, 15]. There are also methods that reduce motion blur or make the blur more easily removable but changing how images are captured [13, 16]. Recently, machine learning approaches have been used to estimate, characterize, and remove motion blur [17–21].

Definition

Motion capture is the process of recording the motion of a subject, processing it on a computer, and mapping it onto a virtual character.

Background

Parameterizing human motion is not just of academic interest, e.g., for studying the

musculoskeletal system of humans, but has many applications in the industry. Historically, the first motion capture systems have been developed in the 1970s and 1980s to perform gait analysis in clinical settings. Today, however, sports sciences and the entertainment industry make heavy use of the technology as well. The setups are also not constrained to human gait analysis any longer. Instead, full-body motion of several humans, animals, stage props, and virtual cameras can be processed in real time.

When capturing motion, it is commonly assumed that the body or object can be decomposed into rigidly moving parts connected by joints. That way, the pose of a human, animal, or mechanical stage prop can be parameterized by a small set of joint angles organized in a hierarchical tree, the skeleton. This hierarchy can be inferred given trajectories of markers attached to the body. Yet, since this step is computationally expensive, the skeleton is normally supplied and scaled to the size of the actor beforehand.

Classification

Motion capture systems can be categorized by their use of sensors. Optical systems use cameras operating in the visible or infrared spectrum, whereas nonoptical systems are based on various other modalities.

Nonoptical Systems

Various nonoptical motion capture systems have been proposed using different sensors. They are grouped here because compared to optical motion capture, they occupy a marginal position. Yet, all approaches discussed here, have in common that they solve the main disadvantage of optical systems, the sensitivity to occlusion.

Mechanical tracking systems measure the angles of the joints mechanically, i.e., by attaching goniometers to the joints of the subject. Estimating the pose given the joint angles is straightforward, but several problems exist with the approach. The mechanical alignment of the goniometers with the body joints can be difficult, especially for joints with more than one degree of freedom, e.g., the shoulder, the devices are cumbersome, and limb lengths have to be

measured very accurately for every subject to prevent drift.

Magnetic fields can be used to estimate the orientation of a magnetic sensor relative to the source of the field. By modulating magnetic coils in the vicinity of the capture volume and measuring the field at different points in time, position and orientation of the sensor can be inferred. The approach has the advantage that it does not suffer from occlusion because the human body is transparent to magnetic fields. However, magnetic fields attenuate rapidly over distance and are sensitive to interference with electrical equipment. The latter is a severe shortcoming as motion capture systems are frequently used in conjunction with other equipment such as motion picture cameras, computers, or stage lights.

Inertial sensors measure acceleration and angular velocity of the limbs they are attached to. Aside from the acceleration of the body, accelerometers measure the gravitational acceleration. After compensating for gravitation, integrating measurements over time yields the pose of the subject. This approach is, like the previous methods, invariant to occlusion, but the numerical integration of measurements leads to drift in position and orientation. It can, however, be used effectively in conjunction with a drift-free method to compensate for drift and bridge occlusions with the acceleration data.

Optical Systems

The most common systems today are optical, i.e., they use one or more calibrated camera(s) to estimate the pose of the subject. Most commercial systems today require the actor to wear markers to simplify the tracking. One of the first marker-based systems used pieces of paper that glow under ultraviolet illumination. Nowadays, either small retroreflective balls or light-emitting diodes (LEDs) operating in the visible or infrared spectrum are used.

Passive systems are normally equipped with infrared lights located in rings around the cameras. This setup evokes a distinct dot for each retroreflective marker in the captured video frames. To further improve image quality, infrared filters in front of the cameras help

to reduce spurious highlights in the visible spectrum. There are two main drawbacks of passive marker-based systems. Since all markers look alike, their trajectories can easily be confused, and all optical systems have in common that they suffer from occlusions.

Active markers, e.g., pulsed LEDs, have the advantage that markers can be identified by the blinking pattern. That way, confusing marker trajectories becomes impossible. Additionally, active marker systems are not restricted to studio environments because the blinking patterns can be distinguished effectively from interference introduced by sunlight. One disadvantage of active markers is that they have to be powered. Carrying a battery pack is not a big burden for an actor, but some stage props such as arrows cannot easily be fitted with batteries.

Markerless systems are subject of intense scientific research. However, first commercial systems are available as well. Yet, it is still unclear, which of the proposed approaches will prove to be the most effective in the long run. Most vision-based approaches today use a combination of edge features, silhouette constraints, texture analysis, and feature tracking or optical flow. Pose optimization is performed using gradient descent, particle filters, simulated annealing, belief propagation, or a combination of these methods. The main advantage of markerless systems is that the amount of preparation of the subject is minimal. Common drawbacks of current systems are that they lack robustness or restrict the setting in other ways than by adding markers, e.g., it is assumed that the background is static. Markerless systems also tend to be computationally expensive. The most advanced systems today are able to capture a single actor in real time, compared to five actors with a marker-based system.

Theory

Generally, the different motion capture systems require different workflows to set up the system and then to fit a skeleton to the captured data.

Since optical systems are the most common, in the following, the procedure for this particular pipeline is outlined.

As a first step, all camera-based systems today need to be calibrated. That is, the relative positions of the cameras, their orientations, and their internal parameters (distortion) have to be estimated. This is commonly achieved by either placing a three-dimensional calibration object with known dimensions inside the capture volume or by covering the volume with a calibration wand, a typically one-dimensional object with known dimensions and marker positions. The advantage of wand-based calibration is that it is easier to cover the entire capture volume using only a small object. Covering the capture volume as exhaustively as possible is important to ensure accuracy of the calibration. Calibration objects, in contrast, tend to be as large as possible for a similar reason. In either case, the parameters of the cameras are extracted using a variation of Structure from Motion.

When using marker-based systems, the next step is to extract marker positions in the video frames. Normally, centroids and extents of the markers are extracted. The extents can be used as a measure of quality of the marker. For example, distant markers tend to be smaller and should be considered less reliable. For large systems, with dozens of cameras running at high framerates ($>[100]\text{Hz}$) and high resolution ($>[4]\text{Megapixel}$), doing this processing close to the cameras is essential because the required bandwidth for transmitting the entire frames to a central processing unit would be prohibitively expensive.

Subsequently, the 2D dots can be combined into 3D markers using the calibration matrices of the cameras. For passive markers, this step is ambiguous. So additional heuristics have to be taken into account. For example, dots can be tracked in 2D or 3D to propagate the identity of a marker, established in a previous frame to the current frame. 3D markers should also be consistent with as many of the 2D dots as possible. Finally, skeleton fitting can be posed as a nonlinear minimization problem

$$\arg \min_{\xi} \sum_{i=1}^M (m_i - s_i(\xi))^2, \quad (1)$$

where m_i is an estimated 3D marker position and $s_i(\xi)$ is the corresponding marker attached to the skeleton, as a function of the pose parameters ξ . This problem can be solved in many different ways. Commonly, gradient descent, Gauss-Newton, or Levenberg-Marquardt optimization is used. These approaches make use of the tracking assumption, i.e., the solution of the previous frame is used as a starting point for the current frame. Other methods, like particle filters or simulated annealing, are less likely to lose track by getting stuck in a local minimum but are computationally more expensive.

Alternatively, the 3D marker reconstruction step can be skipped. Instead, the nonlinear optimization is performed in image space of the cameras. That is, the distances between the projections of the skeleton's markers and the 2D markers are minimized rather than their distance in world space.

Markerless systems have to solve a very similar optimization problem. Only their method of acquiring correspondences between 2D image features and the tracked object is more sophisticated. Frequently, different characteristics are combined. Common features include edges, silhouettes, texture statistics, and corners.

Application

Historically, the first applications of motion analysis can be found in biomedicine. Gait analysis is used to assess pathological conditions of patients and to plan treatment such as orthopedic surgery and for follow-up monitoring. Similarly the methodology is applied in sports science, where the motion of athletes is optimized or monitored and automatically evaluated during endurance exercises.

More recently, motion analysis and motion capture have been applied in the entertainment industry. In its earliest form this involved a pro-

cess called rotoscoping, i.e., an artist traced the outline of an actor in every frame of a reference video to create 2D animations of a subject. Nowadays, marker-based systems are frequently used to capture motions for use in both computer games and motion picture productions because creating animations by hand with the fidelity required in this industry is a very time-consuming task. Most commercial marker-based systems are still limited to controlled studio environments. Although recently, systems using active markers have been proposed that can be used outdoors or in onset conditions.

Open Problems

Although the main challenges of marker-based motion capture are generally considered solved, there is still room for improvement. Directors ask for ever more actors to be tracked simultaneously in real time; systems that work in outdoor settings are still only available using active markers or do not support real-time feedback. Retroreflective markers cannot be used outdoors because interference with other light sources prevents detecting markers reliably. Vision-oriented systems may be able to solve these issues and in most cases make less assumptions about the scene. Many approaches use no markers and significantly fewer cameras. In some cases, even moving backgrounds can be handled, or cameras are not assumed to be static. However, vision-based systems tend to be computationally expensive and less robust. Overall, combining the general capabilities of vision systems with the speed and robustness of marker-based approaches would significantly advance the state-of-the-art.

Multi-baseline Stereo

David Gallup
Google Inc., Seattle, WA, USA

Definition

Multi-baseline stereo is any number of techniques for computing depth maps from several, typically many, photographs of a scene with known camera parameters.

Background

The goal of any stereo algorithm is to reconstruct the 3D surface geometry of a scene from multiple

photographs. Multi-baseline stereo can be seen as a generalization of binocular stereo, and it is one instance of a broader class of multi-view stereo algorithms. The classic binocular stereo problem focuses on using two views of a scene (the minimal case), whereas multi-baseline stereo uses more than two and typically many more views of the scene. More views not only provide a better signal to noise ratio but also eliminate most repetitive structure errors and offer new ways to handle occlusions.

Another type of multi-view stereo is volumetric stereo, which explicitly models the scene's surface in a volume, and is sometimes called object-based. Multi-baseline stereo on the other hand is image-based, and seeks to reconstruct the scene by assigning depth values to the pixels of one or more of the input images. Often this leads to better sampling of the input data and greater memory efficiency. The disadvantage is that special care must be taken at depth discontinuities.

Theory

Multi-baseline stereo shares the same theoretical concepts as other stereo problems. The inputs consist of a set of n input images with camera parameters. Camera parameters define a projection function which projects a 3D point into a pixel in the image. The goal is to compute a depth map for one or more of the input images. For simplicity we will focus on computing a depth map for a single view called the reference view.

Computing a depth map from images can be viewed as a maximum a posteriori estimation problem. Given images I_1, \dots, I_n , compute the depth map Z that maximizes $P(Z|I_1, \dots, I_n) = P(I_1, \dots, I_n|Z)P(Z)$. The likelihood $P(I_1, \dots, I_n|Z)$ describes how well the depth map fits the input data, and the prior $P(Z)$ describes desired properties of the depth map such as smoothness. This formulation can be expressed as an energy function:

$$\begin{aligned} E(Z) = & \sum_{p \in Z} E_{\text{data}}(Z(p)) \\ & + \sum_{(p,q) \in N} E_{\text{smooth}}(Z(p), Z(q)). \end{aligned} \quad (1)$$

The data term E_{data} measures how well the depth value $Z(p)$ matches the input images. These *matching scores* can be computed by comparing the intensity value in the reference view $I_{\text{ref}}(p)$ to the intensity values of the projections of $Z(p)$ in the matching views, $I_k(\text{proj}_k(Z(p)))$. Some views may be occluded, meaning that $Z(p)$ may not be visible from that view and $I_k(\text{proj}_k(Z(p)))$ will not match $I_{\text{ref}}(p)$. Occlusion handling aims to remove the influence of these occluded views and is a critical part of stereo. The smoothness term E_{smooth} penalizes variations between neighboring depth values (given by the set N).

Matching Scores

Consider a known 3D point X on the surface of the scene as shown in Fig. 1. Let x_0, \dots, x_k be the projections of X into each image. The image intensities at these points should be *photo-consistent* (have the same appearance) since they are all images of the same point on the surface. This will not necessarily be true for 3D points off the surface of the scene. Brightness constancy is the assumption that the intensity of light does not change from viewpoint to viewpoint, a property of Lambertian surfaces. This can be measured by taking the absolute difference or squared difference between the intensity value in the reference view and the intensity value in matching view. Typically a single pixel does not carry enough information to make an informative matching score, and so often the differences between patches of nearby pixels are also incorporated into the matching score. This yields the sum of absolute differences (SAD) and sum of squared differences (SSD) scores.

The brightness constancy assumption can be violated for many reasons, for example, different

exposure settings between images and specular surfaces that reflect light at different intensities depending on the angle. To account for some of these changes, patches can be normalized by removing the mean intensity of the patch and scaling the values so that variance is 1. This yields the normalized cross-correlation score (NCC). Let M and N be two rectangular image patches of size $w \times h$. These patches can be flattened to form vectors \mathbf{m} and \mathbf{n} of size $w \cdot h$. The NCC score is then

$$NCC(M, N) = \frac{(\mathbf{m} - \bar{\mathbf{m}}) \cdot (\mathbf{n} - \bar{\mathbf{n}})}{\text{var}(\mathbf{m}) \text{var}(\mathbf{n})}, \quad (2)$$

where $\bar{\mathbf{m}}$ is the mean of \mathbf{m} and $\text{var}(\mathbf{m})$ is its variance.

When patches originate from highly slanted surfaces, they may need to be corrected before being correlated. The surface's tangent plane can be defined given the point's surface normal, and images can be aligned by projecting them onto this plane. This transformation can be expressed as a homography. This adds two additional angle parameters per pixel to the problem. One method to account for the surface normal is to compute the matching score as the best score over all surface normals [1]. A much faster alternative is to consider only a small number of likely candidates [2]. Another is to iteratively estimate a depth map, using surface normals given by the depth map from the previous iteration.

Summing the SAD, SSD, or NCC scores from multiple views reduces the influence of noise as well as disambiguates mismatches due to repetitive structures since it is less likely that a mismatch will occur in all views simultaneously [3].

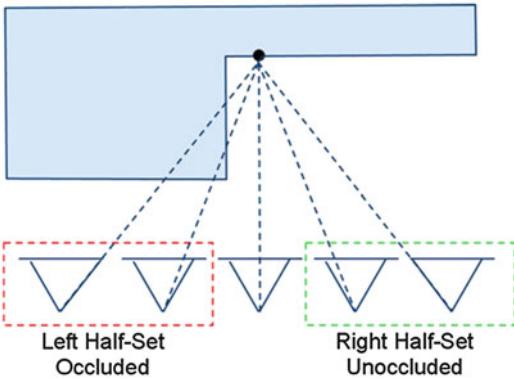

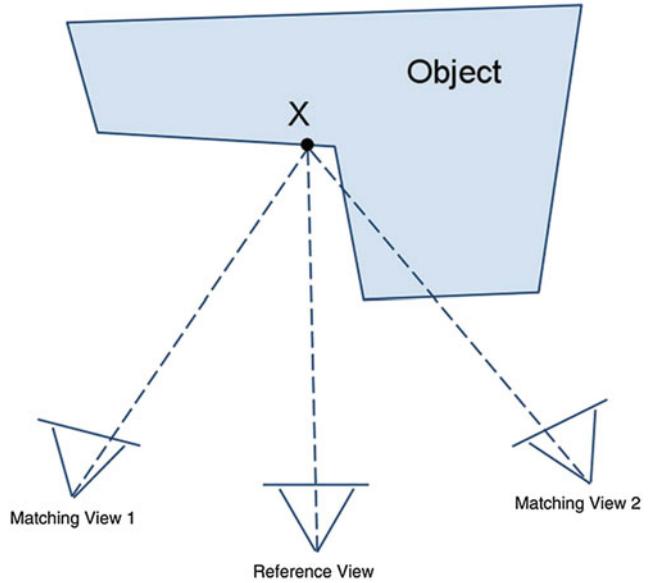

M

Occlusion Handling

Summing scores from multiple views treats all images equally. In fact some images may be occluded, meaning a different surface is seen from that viewpoint, and the matching score is arbitrarily bad. Handling these cases is important

Multi-baseline Stereo,

Fig. 1 A surface point X is projected into the images. Matching view 2 is occluded and should not contribute to the matching score

Multi-baseline Stereo, Fig. 2 Simple occlusion geometry. Typically, either the left half-set or the right half-set will be free of occlusion

for stereo, and multi-baseline stereo has advantages in this regard. One method based on robust statistics is to assume that at least k views are unoccluded and to discard the rest. The sum of the best k views can be obtained by sorting and summing. Another method is to assume an object will be occluded from one side and not another. Assuming cameras are arranged in a line, the unoccluded half-set will be either the left or right half-set of cameras [4]. See Fig. 2.

Other methods seek to detect occlusions explicitly by using the reconstruction itself to

identify occluded views. This is a chicken and egg problem: the occlusions must be known to reconstruct the scene, and the reconstruction of the scene must be known to detect the occlusions. Some methods model occlusions probabilistically [5], and others start with a safe configuration and update the reconstruction conservatively [6].

Optimization

Optimizing Eq. 1 is difficult due to the non-convex data and smoothness terms. Some methods ignore the smoothness term, and each pixel is optimized independently by exhaustive search. The Z function is discretized into points along viewing rays that project to individual pixels in the matching views. Testing all points for each pixel can be done efficiently using graphics hardware which is well suited for this type of *embarrassingly parallel* computation [12]. Methods that do use the smoothness term obtain better results, and if the benefits of normalization (NCC) are not needed, patches need not be used and single pixels can be used. The ambiguity of single pixel matching is resolved because the smoothness term regularizes the solution. The optimization problem is

NP-hard, but there are effective approximation algorithms based on graph cuts [8] and belief propagation [9].

Depth Resolution

The resolution of stereo as a depth sensor depends on the distance of the surface from the cameras. The depth resolution is the distance between pixels in a matching view projected onto a viewing ray in the reference view. In the binocular case, the resolution is

$$\Delta z = \frac{z^2}{bf}, \quad (3)$$

where Δz is the resolution, z is the distance to the reference view, b is the baseline or distance between camera centers, and f is the focal length of the cameras. Depth measurement uncertainty depends on the matching uncertainty which describes how precisely the two observed patterns can be registered and depends on factors like texture and image noise. Depth measurement uncertainty is proportional to depth resolution. With enough views, multi-baseline stereo has the advantage that the baseline can be treated as a variable rather than a constant. This gives greater control over the depth resolution and computation time of the stereo algorithm [10].

Application

Multi-baseline stereo is applied to many 3D reconstruction problems such as 3D city modeling [11], view synthesis [12], and digital archiving. Multi-baseline stereo is often used in real-time applications where high-quality depth can be computed from a large number of views without the need for computationally intensive optimization techniques. This is especially true for video applications, where the camera moves in a fairly linear manner, and so more general multi-view stereo techniques are unnecessary.

Definition

Multi-camera human action recognition deals with using multiple cameras to capture several views of humans engaged in various activities and then combining the information gleaned from the cameras for the classification of those activities.

Background

Research on human activity recognition gathered momentum in the mid- to late 1990s; much early work is summarized in a review by Aggarwal and Cai [1]. There emerged two dominant approaches during this period: (1) state-space modeling of human actions [2, 3] and (2) template matching [4, 5]. The focus during that early phase of this research was primarily on recognizing human activities on the basis of the images collected by a single camera. While this is still an active research area in computer vision (see Aggarwal

and Ryoo [6] for a survey), it unfortunately suffers from several serious shortcomings, many of them owing to the limitations inherent to images that are recorded from just one viewpoint. Human activities, in general, are much too complex in 3D to be described by cues extracted from single-viewpoint 2D projections. While it is true that the human eye (even just a single eye) can do a wonderful job of categorizing human activities, trying to replicate that in a computer would be far too ambitious a research project for a long time to come. It is not yet fully understood how the human brain fills in the information that it cannot see directly in order to recognize objects and movements despite severe occlusion and noise. While it is a proper exercise in humility to be awed by the capabilities of the human brain, it is nonetheless good to keep in mind that even a human can be fooled in its perception of an activity when the perception is limited to a single viewpoint. Magicians frequently take advantage of such limitations of human perception in order to produce their magical effects.

In addition to the problems caused by the fact that a single camera provides only single-viewpoint 2D projections of the scene, other reasons for the more recent interest in multi-camera approaches to activity recognition stem from the current global interest in wide-area surveillance, on the one hand, and in the design of intelligent environments for the living spaces of the future on the other. In both of these applications, the goal is to characterize a human activity as it is evolving with time and as it is occupying space that may not be limited to the coverage provided by a single camera. Consider a habitat of the future for the aged and the infirm where you may wish to use a network of cameras that silently watch for any undesirable human behavior, such as someone suddenly collapsing on the floor or tripping over a piece of furniture. To recognize such human activities, the camera system would need to analyze the sensed data over a period of time and, even more particularly, over some a span of physical space. Multi-camera imagery would obviously lend itself much better to the sort of data analysis

that would need to be carried out for the required inferences.

With a view to gaining insight into the various aspects of multi-camera human action recognition, in the remainder of this chapter, section “[Theory](#)” describes the theoretical details of the different types of approaches that have been proposed by researchers to accomplish multi-camera action recognition. Owing to this chapter’s intent of providing accessibility to the general readers, significant details about the algorithms are not discussed; rather, only the distinguishing highlights of the different approaches are presented. Section “[Application](#)” presents a discussion on some of the application areas that will benefit from multi-camera action recognition as compared to the single-camera modality. Since human action recognition is a complex and challenging problem, there are quite a few open problems that need to be addressed before this research becomes useful for mainstream society. Section “[Open Problems](#)” enumerates some of these open problems related to human action recognition in general and also those that are specific to the area of multi-camera action recognition. Finally, in section “[Experimental Results](#),” this chapter is concluded with a performance comparison between the different multi-camera approaches on a common benchmark dataset.

Theory

The first step in human action recognition involves creating a library of models for different human actions to be recognized. An action model characterizes the unique motion patterns associated with an action. These models can be created from a temporal sequence of either 2D images or 3D reconstructions obtained by combining multiple-camera images of a human actor. Researchers have proposed different approaches to creating the action models. For example, an action model may comprise of a set of local motion features extracted from the spatiotemporal volume of the action image sequence. Another example of an action model

is a set of exemplar human poses represented either as 2D silhouettes or 3D reconstructions. Yet another example is a set of spatiotemporal trajectories of different human body parts. Once the action models are created, new instances of human actions can be recognized. Given a test image sequence that contains an unknown human action, the same technique used for creating the action models is applied to the test sequence to generate its action representation. This action representation is then compared against each action model in the library. Finally, the test sequence is assigned the label of the most similar action model. In terms of the underlying operating principle, there is no difference between human action recognition and any other type of object recognition: a test object whose category label is to be ascertained is assigned the label of the closest matching model whose category is known.

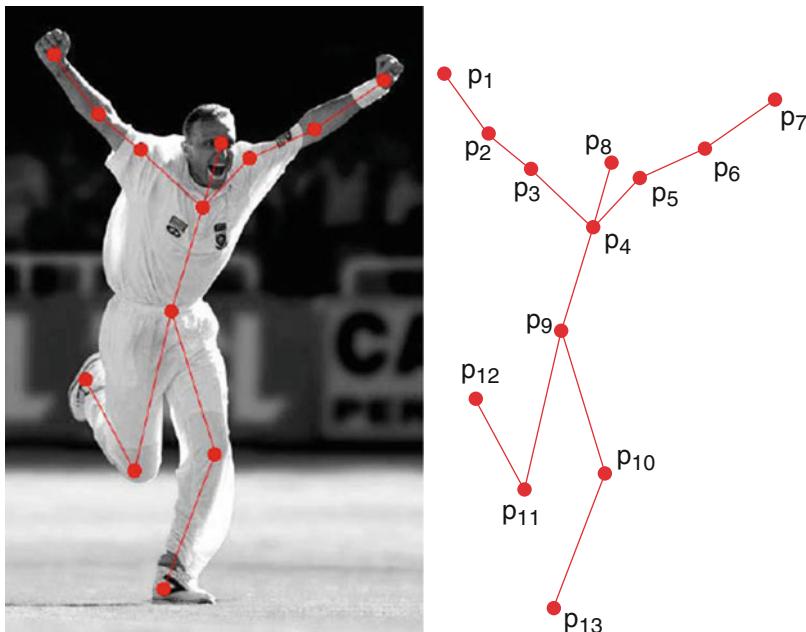

A common assumption in single-camera action recognition is that the test action and the model actions have been captured from identical or very similar camera viewpoints. The quality of match between the test action and the model actions is a function of the conformity between their camera views. As Souvenir and Babbs [7] point out, it would be impractical for any human motion analysis system to impose the constraint that humans engaged in an activity are facing the same direction relative to the camera view at all times. In order to alleviate this problem, several methods have been developed which use multiple cameras in the training and/or testing phases of action recognition. These methods provide viewpoint invariance, i.e., the ability to perform matching between a pair of action observations even if they have been acquired from different camera views. A good overview of multiple-camera action recognition approaches can be found in [8]. Based on the distinct fundamental ideas of these methods, they have been categorized into the following three classes:

1. Multi-view geometry-based methods
2. View-invariant representation-based methods
3. Exhaustive search methods

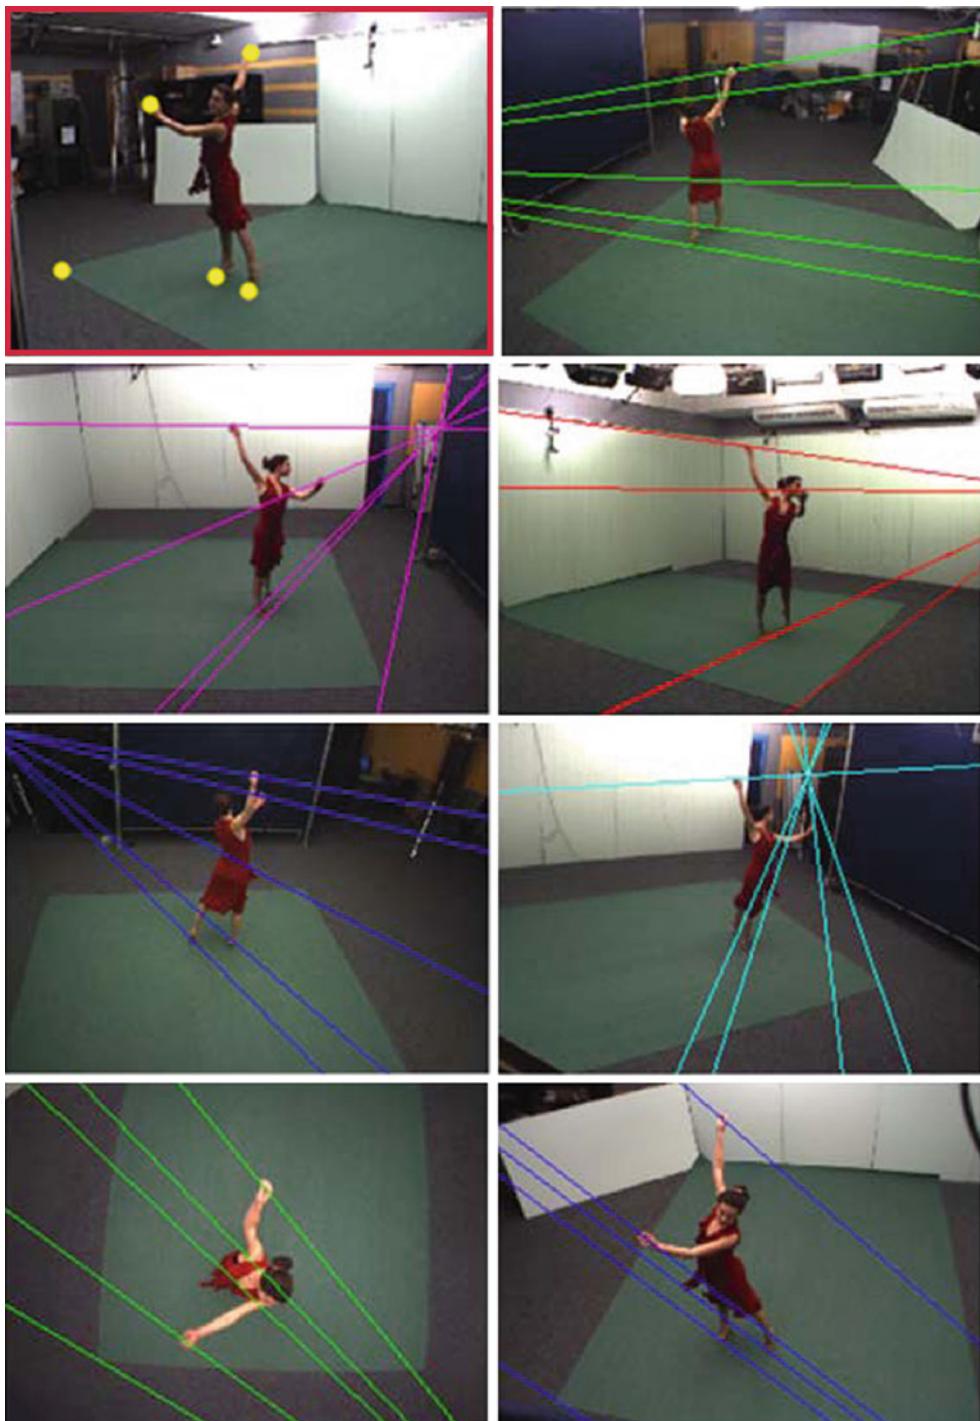

Multi-view Geometry-Based Methods

The multi-view geometry-based approaches utilize the epipolar geometric constraints between multiple cameras for human action recognition. The intuition is that if two actors perform the same action, then assuming the same temporal rate of action execution and their postures at all corresponding time instants is related by epipolar geometric relationships. Such relationships between the two views are applied to point correspondences where the points are generally chosen as the anatomical landmarks on the human body, e.g., head, shoulders, hands, and feet (see Fig. 1). Action recognition is performed by measuring the similarity between the postures of a test action sequence and a model action sequence at every time instant. The similarity measure can be expressed in terms of the point correspondences and a matrix F known as the fundamental matrix that is computed using epipolar geometry (Fig. 2). Given at least eight pairs of point correspondences (x_i, x'_i) ,

the fundamental matrix F satisfies the relation $x_i^T F x'_i = 0$, $i = 1, \dots, n \geq 8$. In practical settings, the point correspondences between the action representations in two different views will generally not be precise, and hence, the quantity $x_i^T F x'_i$ will not be exactly zero. Nevertheless, the residual $\sum_i |x_i^T F x'_i|^2$ can be used as the matching cost or the similarity measure. If the matching cost is below a certain threshold, then the point correspondences come from the same action represented in the different views. Generally, the test action postures and the action models are derived from different persons with different body sizes and proportions; therefore, certain anthropometric constraints may also need to be imposed to normalize the landmark points to a common coordinate frame before the epipolar geometric constraints can be applied. Such and other similar constraints on the point correspondences have been used for matching of different action instances in [9, 11–13].

View-Invariant Representation-Based Methods

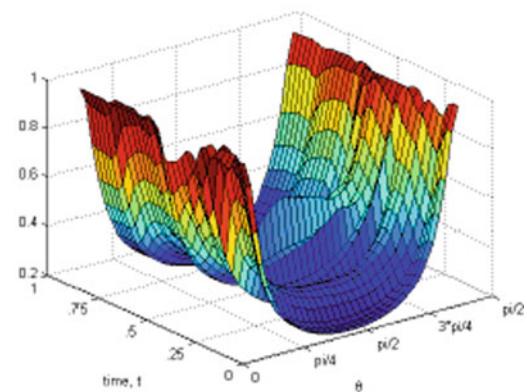

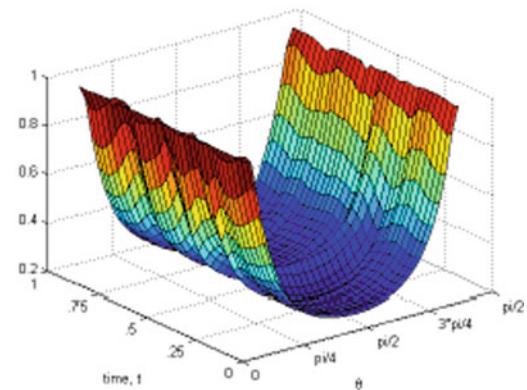

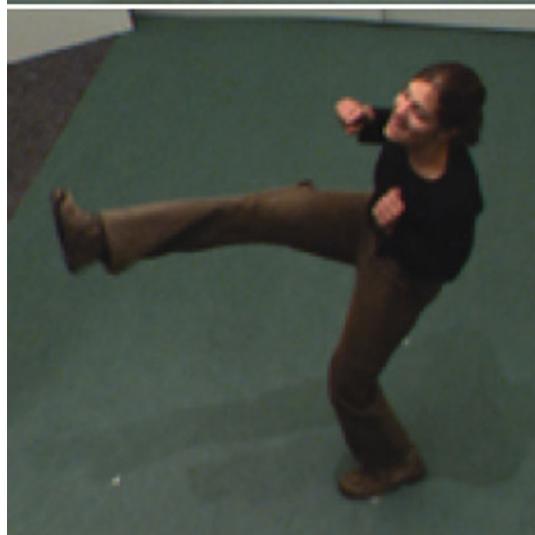

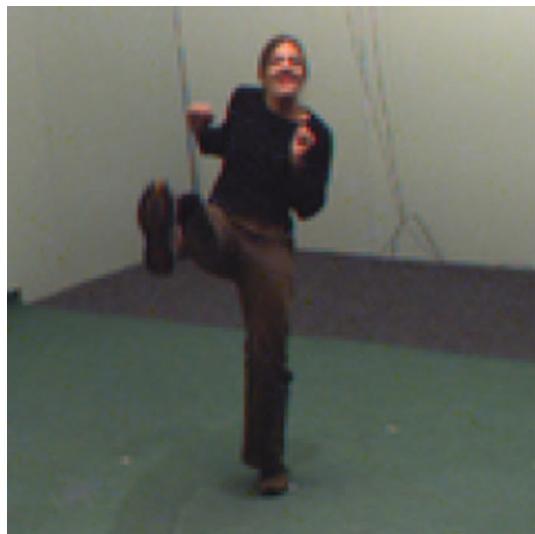

In addition to the multi-view geometry-based approaches, there are other interesting methods that accomplish viewpoint invariant action recognition based on machine learning techniques. It is a conceivable scenario that a discriminative model of an action is available for one camera viewpoint (source view) and the action recognition needs to be performed in another view (target view) for which such a model is not available. This issue has been addressed in [14], where a transfer learning approach is used along with examples of corresponding observations of actions from both views in order to learn how the appearance of an action changes with the change of viewpoint. It is worth noting that such learning can be performed with one set of actions and then applied to a new unknown action for which the transfer model is not explicitly built. Transfer learning is applied by splitting the source domain feature space using the action descriptors and the action labels to produce certain split-based features. These split-based features are considered transferable between the source view and the target view and therefore are used to construct an action-discriminative split of the target domain feature space. For a test action sequence in the target view, its action descriptors are extracted, and action recognition is performed by a nearest neighbor matching with the action descriptors of the model actions which were transferred from the source view.

In [7], the variation in the appearance of an action with viewpoint changes is estimated by learning low-dimensional representations of the actions using manifold learning. The action descriptor used is the \mathcal{R} transform surface which is a temporal extension of the well-known Radon transform (Fig. 3). In the figure, the horizontal axes correspond to time t and the polar angle θ used in Radon transform computations. The \mathcal{R} transform surface is a high-dimensional data that lies on a nonlinear manifold, and hence it can be embedded into a lower dimensional space. In this low-dimensional space, learning how the data varies as a function of the viewpoint provides a representation which allows to avoid storing

action examples from all possible viewpoints. Action recognition is performed by obtaining a similarity measure between two \mathcal{R} transform surfaces S_1 and S_2 , such as the L^2 distance $\|S_1 - S_2\|$. Another interesting approach has been described in [15], where the temporal self-similarity between the frames of an action sequence was shown to be highly stable with a changing viewpoint (Fig. 4). Specifically, for the same action sequence recorded from very different views, the so-called temporal self-similarity matrices (SSMs) corresponding to the different views were shown to be very similar. This observation was consistent even when different image features were used for computing the self-similarity matrix. By constructing histogram-based descriptors from the elements of the SSM (as described in [15], Sect. IV), action recognition can be performed by applying classifiers like nearest neighbor or support vector machine on these descriptors. Recently, Kusakunniran et al. [16] proposed a view transformation model based on support vector regression for solving the multi-view gait recognition problem. This view transformation model uses local regions of interest (ROIs) in one view to predict the motion information of the corresponding regions in a different view. In order to perform gait recognition, the gait features from the different actors' gait sequences and possibly different view angles are first normalized to a common viewing angle using the view transformation model followed by a similarity measure calculation between the normalized gait features using the Euclidean metric.

Exhaustive Search Methods

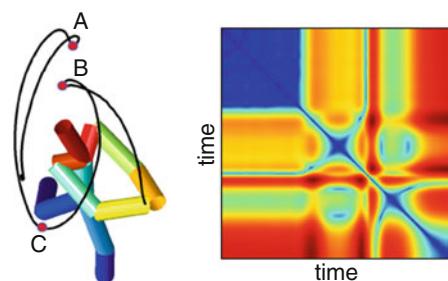

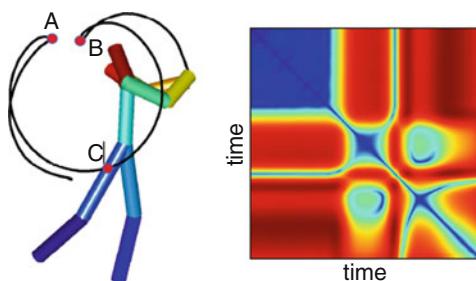

The third popular approach in the multi-camera human action recognition is to perform an exhaustive search in the space of multi-view action poses to find the best match for the test action poses. Such an exhaustive search can be performed in 2D or 3D. During the training time, a set of multiple fixed cameras installed around the actor is used to record the multi-view sequences of his or her actions (Fig. 5). In the 2D exhaustive search approach, an observation

Multi-camera Human Action Recognition: Traditional Approaches, Fig. 5 Acquiring simultaneous multi-view action sequences for training. (Ahmad and Lee [17], ©2006 IEEE)

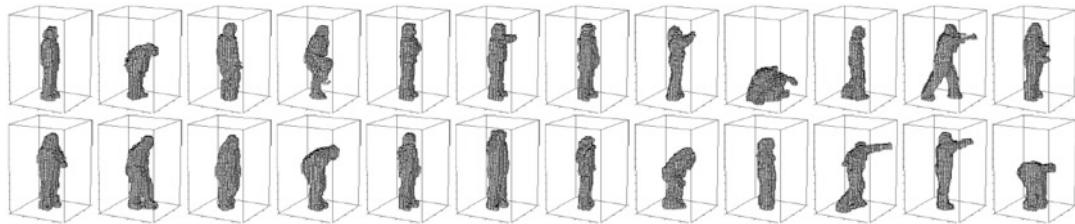

is recorded for the unknown action and matched against each recorded view from the training session. The matching can be performed using the shape features derived from the 2D silhouettes, the motion features obtained from the optical flow, or histograms of local spatiotemporal cuboid features. In order to accomplish action recognition, this 2D search is performed at every time instant of the action sequence, and the model action resulting in the smallest feature distance over all the time instants is used to label the unknown action. A limitation of the 2D approach is that the same spatial configuration of cameras has to be used during the training and testing sessions. Generally, during the test time, the observations are recorded from a single view, but more than one view can also be used with the appropriate changes in the matching algorithm. The 2D approach has been used by several research groups [17–19].

The 3D exhaustive search approach provides more flexibility with regard to the placement of the cameras in the monitoring environment. Different spatial configurations of cameras can

be used during the training and testing sessions. Here, instead of storing all the discrete views of the action during the training time, they are combined to produce an action model based on 3D reconstruction (Fig. 6). The key advantage of such a strategy is that there is no restriction on what camera view(s) can be used to record the test action sequence. If the camera parameters of the arbitrary camera view used during the testing session are known, then the model 3D action representations can be projected into that 2D view for matching with the observation. Some examples of such an approach are [20, 21].

Application

Vision-based human activity recognition has diverse applications. Generally, any practical application related to monitoring human activities requires that the monitoring can be done over an extended physical space beyond the viewing area of a single camera. It may also be required to monitor an event from

Multi-camera Human Action Recognition: Traditional Approaches, Fig. 6 An action model consisting of 3D exemplars that were selected based on 11 types of actions by 10 human actors [20]. Given a test sequence of

several viewpoints simultaneously so as to obtain richer descriptions of complex human activities. Such requirements necessitate the use of multiple cameras for capturing the events. In this section, some of the application areas are briefly discussed where multi-camera human activity recognition or multi-camera event detection is currently being used or has strong potential for use in the near future.

1. *Wide-area surveillance* – Facilities like government buildings, military installations, airports, subways, power plants, dams, and so on require round-the-clock surveillance. Some examples of the general human-related activities that need to be monitored are wide-area perimeter breaches by intruders, a person approaching the doors after hours, leaving of a suspicious unattended object by a person, extended loitering around the facility perimeter, and persons tampering with the facility security systems. In such scenarios, it is necessary to study not only the isolated activities of the persons but also the patterns of their interactions with their surroundings, such as who are other persons they interact with, are they carrying any objects, how long have they been present, or are they loitering around the security systems.
2. *Monitoring the elderly and children* – Assisted living homes and day care centers require constant monitoring of the activities of the elderly and children to avoid incidents such as an elderly person tripping over a furniture and falling down or a child playing too close to hazardous areas like a swimming pool or an

2D action silhouettes, action recognition involves finding the best matching exemplar sequence and the best matching 2D projections. (©2007 IEEE)

electrical appliance. Commercial applications are available for day care centers that allow the installation of multiple wireless surveillance cameras in play areas, resting areas, or dining areas, where the video and audio feed from the cameras can be transmitted to a central computer connected to the Internet. Parents can thus check on the safety of their children at any time by viewing over the Internet.

3. *Three-dimensional human motion analysis for sports and medicine* – A 3D motion-based system can be used to perform a marker-based or markerless capture of the human motion while performing ordinary activities like walking or bending or sports activities like a golf swing, swimming strokes, tennis serves, gymnastics, and so on. In the field of medicine, such human motion data is used to characterize the dynamics of activities, discover the fundamental principles that govern movement, and understand the causes of movement disorders. In the area of sports, the motion data of the athlete can be analyzed by the coach for recommending changes in the dynamics to achieve more energy-efficient and agile performance, or it may be compared with the 3D reference motion of another expert athlete.
4. *Enhanced sports viewing experience* – Multiple cameras are routinely used in sports like football, cricket, and soccer to capture many views of a dynamic event for providing an enriched fly through experience of the scene to the viewers or for use by the referees when it is difficult to make judgments based on a single-camera view.

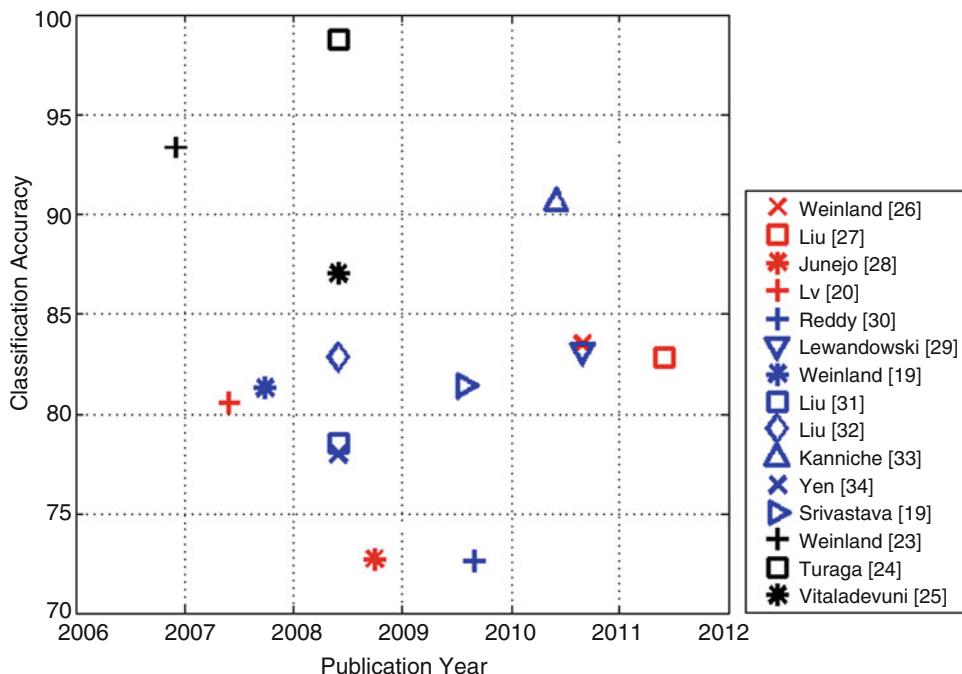

Open Problems

In the last 15 years, substantial progress has been made in the field of human action recognition. The accomplishments have primarily been in the area of single-person action recognition in an uncluttered background and recognizing a set of simple activities like walking, jumping, waving hands, punching, and so on. This is evidenced by the popularity of datasets like KTH, Weizmann, and IXMAS for benchmarking the action recognition algorithms (please see [8], Sect. 6 for description of these datasets). These datasets capture simple actions performed by a single human, with a clean background, and negligible variations in spatial scale of the person or temporal speed of execution. The challenge for the research community, in most simple words, is to extend the current recognition algorithms to work on datasets comprising of video sequences captured in unconstrained settings such as the Hollywood movie dataset [22] or the YouTube video dataset [23].

Specifically in the area of multi-camera action recognition, an open problem is to obtain non-rigid point correspondences on the human body that are needed for applying the geometric constraints. The main underlying difficulty is the reliable detection and tracking of human body parts in an unconstrained visual setting. Similarly, a limitation on the view-invariant representations like self-similarity matrices [15] and \mathcal{R} transform surface [7] is that they are constructed from the temporal variation of the features; hence, they need the full video sequences to be available offline. Real-time applications like video surveillance and human-computer interaction will benefit from the development of view-invariant features that can be computed online.

Experimental Results

This chapter is concluded with a chronological summarization of the different algorithms' action recognition performances on a benchmark

Multi-camera Human Action Recognition: Traditional Approaches, Fig. 7 Action recognition performance of different algorithms on IXMAS dataset

dataset named the INRIA Xmas Motion Acquisition Sequences (IXMAS) [24].

The IXMAS dataset is the most commonly used dataset for evaluating the multi-camera action recognition algorithms. It contains 13 daily-life actions, such as *check watch*, *cross arms*, and *scratch head*. Each action is performed 3 times by 11 actors. The actions are captured using five calibrated and synchronized cameras. The actors are free to perform the actions in any orientation, making this a fairly challenging dataset.

Figure 7 presents the reported average recognition accuracies of several recent works on multi-camera action recognition. It is important to note that not all the approaches use the same evaluation methodologies, and, hence, it is difficult to compare them merely based on these values.

For easier comparison, these works are categorized into three groups based on their evaluation methodologies: (1) the methods, which use 3D representations in the recognition stage [24–26]; (2) the methods, which report camera-specific recognition accuracies [21, 27–29]; and (3) the methods, which incorporate results from multiple cameras (e.g., using simple voting) [19, 20, 30–35]. These groups are distinguished by black, red, and blue markers in Fig. 7, respectively.

Definition

Multidimensional scaling (MDS) refers to a family of techniques in data analysis that aim to realize a given matrix of *dissimilarities* $\mathbf{D}^{n \times n}$ (i.e., a distance matrix), as n points in a k -dimensional Euclidean space:

Find $\mathbf{X} \in \mathbb{R}^{n \times k}$ such that $\|\mathbf{x}_i - \mathbf{x}_j\|$ is as close as possible to $d_{ij} \forall i, j$.

Background

The various multidimensional scaling models can be broadly classified into *metric* vs. *nonmetric* and *strain* (classical scaling) vs. *stress* (distance scaling)-based MDS models. In metric MDS, the goal is to maintain the distances in the embedding space as close as possible to the given dissimilarities, while in nonmetric MDS, only the order relations between the dissimilarities are important (i.e., $d_{ij} > d_{kl}$). *Strain*-based MDS is an algebraic version of the problem that can be solved by eigenvalue decomposition. *Stress*-based MDS uses a geometric distortion criterion which results in a nonlinear and non-convex optimization problem. Each of these models has its own merits and drawbacks, both numerically and application-wise. On top of these basic models, there exist numerous generalizations, including embedding into non-Euclidean domains, working with different stress models, working in different subspaces, and incorporating machine learning approaches to obtain faster, more accurate, and more robust embeddings. The following sections will review these models, with emphasis on their role in computer vision applications.

Historically, MDS first appeared (informally) in the works of Dutch cartographer Jacob van Langren in the seventeenth century who was the first to show a table of distances alongside the map corresponding to these distances in a single figure [1]. The first modern version of MDS, called classical scaling, is due to Torgerson who used it within the field of Psychophysics [2]. Later works by [3–5] formulated the problem

as a minimization over a *stress* function and introduced the first nonmetric MDS model. A complete historical review can be found in [6]. A short review of the role of MDS in computer vision is given in section of “[Applications](#).”

Theory

Metric Multidimensional Scaling

Strain-Based Scaling (Classical Scaling)

The Euclidean case. Let $\mathbf{D}^{n \times n}$ be a (symmetric) matrix of pairwise Euclidean distances between n points $\{\mathbf{y}_i\}_{i=1}^n$ in \mathbb{R}^m and denote by \mathbf{E} the matrix whose entries are the squares of these distances, i.e., $e_{ij} = d_{ij}^2 \equiv \|\mathbf{y}_i - \mathbf{y}_j\|^2$. We have

$$\mathbf{E} = \mathbf{1}\mathbf{c}^\top + \mathbf{c}\mathbf{1}^\top - 2\mathbf{Y}\mathbf{Y}^\top \quad (1)$$

where \mathbf{c} is a vector containing the diagonal elements of $\mathbf{Y}\mathbf{Y}^\top$. Assuming $n > m + 2$, from (1) we have that the rank of \mathbf{E} is $m + 2$ [7]. Our goal is to find a set of points $\{\mathbf{x}_i\}_{i=1}^n$ in \mathbb{R}^k such that $\|\mathbf{x}_i - \mathbf{x}_j\|^2 \approx e_{ij}$. Let $\mathbf{H} \equiv \mathbf{I} - \frac{1}{n}\mathbf{1}\mathbf{1}^\top$ denote a *centering matrix*, i.e., multiplying a vector by this matrix results in a vector with zero mean. Applying \mathbf{H} on both sides of a matrix is called a *double centering transform* and results in a matrix whose mean along both columns and rows is zero. Since $\mathbf{H}\mathbf{1} = (\mathbf{1}^\top \mathbf{H})^\top = \mathbf{0}$, we get that

$$\mathbf{K} \equiv -\frac{1}{2}\mathbf{H}\mathbf{E}\mathbf{H} = \mathbf{H}\mathbf{Y}\mathbf{Y}^\top\mathbf{H} \quad (2)$$

is a positive semi-definite Gram matrix of rank m . Classical (multidimensional) scaling aims at minimizing the following distortion criterion called *strain*

$$\min_{\mathbf{X} \in \mathbb{R}^{n \times k}} \text{Strain}(\mathbf{X}) \equiv \min_{\mathbf{X} \in \mathbb{R}^{n \times k}} \left\| \mathbf{X}\mathbf{X}^\top - \mathbf{K} \right\|_F^2, \quad (3)$$

which amounts to finding the closest symmetric positive semi-definite matrix of rank $k \leq m$ to the matrix \mathbf{K} . Let $\mathbf{K} = \mathbf{V}\Lambda\mathbf{V}^\top$ be the spectral decomposition of \mathbf{K} . The solution of (3) is given

by

$$\mathbf{X}^* = \mathbf{V}_k \mathbf{\Lambda}_k^{\frac{1}{2}} \quad (4)$$

where \mathbf{V}_k denotes the first k columns of \mathbf{V} , and $\mathbf{\Lambda}_k^{\frac{1}{2}}$ denotes a $k \times k$ diagonal matrix whose diagonal elements are the largest k eigenvalues of \mathbf{K} . The distortion can be quantified by summing over the smallest $m - k$ eigenvalues:

$$\text{Strain}(\mathbf{X}^*) = \sum_{i=k+1}^m \lambda_i^2. \quad (5)$$

Note that

$$\mathbf{H}\mathbf{E}\mathbf{H} = \mathbf{E} - \frac{1}{n}\mathbf{E}\mathbf{1}\mathbf{1}^\top - \frac{1}{n}\mathbf{1}\mathbf{1}^\top\mathbf{E} + \frac{1}{n^2}\mathbf{1}^\top\mathbf{E}\mathbf{1} \quad (6)$$

i.e., performing a double centering transform does not require multiplication by a centering matrix on both sides but rather can be done efficiently by subtracting the mean from each row and column and then adding back the mean of the entire matrix.

The non-Euclidean case. The above derivation assumed that the matrix \mathbf{D} is a matrix of Euclidean distances. In real applications, this matrix represents a set of dissimilarities which might not be Euclidean distances or not even distances at all. A classical example is that of the perceptual distances between the RGB color channels in a digital image, as conceived by the human eye. A small change in the green channel is more noticeable than a similar change in the blue channel due to the eye's higher sensitivity to green. In these cases, there is no guarantee that the matrix \mathbf{K} defined in (2) will be PSD or even that it has k positive eigenvalues, as required by (4).

Numerical Considerations. Despite (3) being a non-convex optimization problem, it enjoys a global solution in the form of an eigendecomposition. Nevertheless, it suffers from a few drawbacks:

- Classical scaling may be impossible to obtain in case \mathbf{D} is not a Euclidean distance matrix.

- Eigendecomposition techniques are expensive to apply and require the availability of the complete matrix \mathbf{D} , which may be time-consuming to obtain in the best case or impossible to obtain in the worst case.
- Classical scaling is very sensitive to outliers due to the double centering transform (2), which spreads the effect of a single outlier to the rest of the points in the same row/column.
- The strain distortion criterion relies on algebraic manipulations and lacks a geometric interpretation. This sometimes results in inferior embeddings (see, e.g., [8]).

These drawbacks require the introduction of different MDS models and more delicate optimization methods. For example, iterative methods can be used for strain minimization, which allow the introduction of weights to handle missing entries in \mathbf{D} [9], at the expense of the global convergence guarantees. Some of these approaches will be outlined in section “Generalizations.”

Stress-Based Scaling (Distance Scaling)

As an alternative to strain minimization, consider the following nonlinear optimization problem:

$$\begin{aligned} & \min_{\mathbf{X} \in \mathbb{R}^{n \times k}} \sigma(\mathbf{X}) \\ & \equiv \min_{\mathbf{X} \in \mathbb{R}^{n \times k}} \sum_{i < j} w_{ij} (\|\mathbf{x}_i - \mathbf{x}_j\| - d_{ij})^2. \end{aligned} \quad (7)$$

Here d_{ij} is a (symmetric) measure of dissimilarity between two sample points i and j ; $w_{ij} \geq 0$ is a (symmetric) weight assigned to the pairwise term between those samples. The term $\sigma(\mathbf{X})$ is called Kruskal stress, LS-stress, ℓ_2 -stress, or simply stress.

One efficient way to solve (7) is via the SMA-COF algorithm [10]. First, note that

$$\begin{aligned} \sigma(\mathbf{X}) &= \text{Tr}(\mathbf{X}^\top \mathbf{V} \mathbf{X}) - 2 \text{Tr}(\mathbf{X}^\top \mathbf{B}(\mathbf{X}) \mathbf{X}) \\ &\quad + \sum_{i < j} w_{ij} d_{ij}^2, \end{aligned} \quad (8)$$

where \mathbf{V} and $\mathbf{B}(\mathbf{X})$ are symmetric row- and column-centered matrices given by

$$v_{ij} = \begin{cases} -w_{ij} & i \neq j \\ \sum_{k \neq i} w_{ik} & i = j \end{cases} \quad (9)$$

$$b_{ij} = \begin{cases} -w_{ij}d_{ij}\|\mathbf{x}_i - \mathbf{x}_j\|^{-1} & i \neq j, \mathbf{x}_i \neq \mathbf{x}_j \\ 0 & i \neq j, \mathbf{x}_i = \mathbf{x}_j \\ -\sum_{k \neq i} b_{ik} & i = j, \mathbf{x}_i \neq \mathbf{x}_j \end{cases} \quad (10)$$

and define

$$\begin{aligned} h(\mathbf{X}, \mathbf{Z}) &= \text{Tr}(\mathbf{X}^\top \mathbf{V} \mathbf{X}) - 2 \text{Tr}(\mathbf{Z}^\top \mathbf{B}(\mathbf{Z}) \mathbf{X}) \\ &\quad + \sum_{i < j} w_{ij} d_{ij}^2, \end{aligned} \quad (11)$$

which is a convex (quadratic) function in \mathbf{X} for a given \mathbf{Z} . By using the Cauchy-Schwarz inequality, it is possible to show that $h(\mathbf{X})$ is a *majorizing* function of $\sigma(\mathbf{X})$, i.e., satisfying (see [11])

$$h(\mathbf{X}, \mathbf{Z}) \geq \sigma(\mathbf{X}) \quad \forall \mathbf{X}, \mathbf{Z} \quad (12a)$$

$$h(\mathbf{X}, \mathbf{X}) = \sigma(\mathbf{X}). \quad (12b)$$

We now define the following iteration:

$$\mathbf{X}_{k+1} = \underset{\mathbf{X}}{\operatorname{argmin}} h(\mathbf{X}, \mathbf{X}_k) = \mathbf{V}^+ \mathbf{B}_k \mathbf{X}_k, \quad (13)$$

where $\mathbf{B}_k \equiv \mathbf{B}(\mathbf{X}_k)$, and \mathbf{V}^+ denotes the pseudo-inverse of the rank deficient matrix \mathbf{V} . By virtue of (12) and (13) it follows that

$$\sigma(\mathbf{X}_{k+1}) \leq h(\mathbf{X}_{k+1}, \mathbf{X}_k) \leq h(\mathbf{X}_k, \mathbf{X}_k) = \sigma(\mathbf{X}_k), \quad (14)$$

i.e., (13) is guaranteed to produce a sequence of monotonically decreasing stress values.

The multiplicative update (13) suggests that at each iteration, each coordinate in the current embedding is a weighted mean of the coordinates of the embedding from the previous iteration, starting with an initial embedding \mathbf{X}_0 , where the weights are given by the ratio of the pairwise distances, $d_{ij}\|\mathbf{x}_i - \mathbf{x}_j\|^{-1}$.

Numerical Considerations Each iteration (13) of SMACOF requires the computation of the pairwise Euclidean distances between all points in the current embedding, a task of complexity $\mathcal{O}(n^2)$,

and the solution of a linear system involving the matrix \mathbf{V} . Despite being rank deficient, \mathbf{V} is not necessarily sparse, and computing its pseudo-inverse is of order $\mathcal{O}(n^3)$, except when \mathbf{V} has a special form. For example, in case all the weights w_{ij} are equal to 1, we get

$$\mathbf{V}^+ = \frac{1}{n} \left(\mathbf{I} - \frac{1}{n} \mathbf{1} \mathbf{1}^\top \right), \quad (15)$$

and since $\mathbf{1}^\top \mathbf{B} = \mathbf{0}$, (13) reduces to

$$\mathbf{X}_{k+1} = \frac{1}{n} \mathbf{B}_k \mathbf{X}_k. \quad (16)$$

Nonmetric MDS

In nonmetric MDS (nMDS), also called ordinal MDS, the goal is to preserve (as best as possible) the *rank order* of the distances in the embedding space rather than their *value*. For example, for any four points i, j, q, l satisfying $d_{ij} > d_{ql}$, the goal is to find an embedding such that $\|\mathbf{x}_i - \mathbf{x}_j\| > \|\mathbf{x}_q - \mathbf{x}_l\|$. It is always possible to find an order preserving embedding of \mathbf{D} , using the following methodology [13]: due to (2), the following relation holds between the elements of \mathbf{K} and \mathbf{E} :

$$e_{ij} = k_{ii} + k_{jj} - 2k_{ij}. \quad (17)$$

The matrix

$$\mathbf{K}' = \mathbf{K} - \min(\lambda_{\min}(\mathbf{K}), 0) \mathbf{I} \quad (18)$$

is always positive semi-definite and can therefore be decomposed as $\mathbf{K}' = \mathbf{X} \mathbf{X}^\top$. We have:

$$\begin{aligned} \|\mathbf{x}_i - \mathbf{x}_j\|^2 &= k'_{ii} + k'_{jj} - 2k'_{ij} \\ &= k_{ii} - \min(\lambda_{\min}(\mathbf{K}), 0) + k_{jj} \\ &\quad - \min(\lambda_{\min}(\mathbf{K}), 0) - 2k_{ij} \\ &= e_{ij} - 2 \min(\lambda_{\min}(\mathbf{K}), 0). \end{aligned} \quad (19)$$

Thus, \mathbf{X} is a Euclidean embedding of \mathbf{E} with all entries shifted by a constant factor $2 \min(\lambda_{\min}(\mathbf{K}), 0)$, and thus all relative comparisons are preserved.

Despite this nice theoretical result, it may not serve as a practical algorithm since it usually results in high-dimensional embeddings. For a more practical approach, we model the nMDS problem with the following distortion function, the Shepard-Kruskal stress, also called *stress-1*

$$\sigma_1(X) = \min_{\theta} \frac{\sum_{i < j} (\|x_i - x_j\| - \theta(d_{ij}))^2}{\sum_{i < j} \|x_i - x_j\|}, \quad (20)$$

where $\theta(\cdot)$ denotes an arbitrary monotonic transformation. Other definitions of nonmetric stress functions exist. This model makes sense, for example, in Psychophysics, where the dissimilarities represent perceptual differences and their value is therefore rather arbitrary. The straightforward way for minimizing (20) is by alternate minimization:

1. Fix θ and solve for X , e.g., with gradient descent.
2. Minimize over θ using *isotonic regression*.

It is also possible to combine nonmetric MDS with a strain-based models, although it is quite unusual [9].

Numerical Considerations

- Since (20) is not convex in X , the first step may get caught in local minima.
- The above approach requires order relations between all pairs of points. These order relations might be contradictory, as they often come from human observations.

These problems can be addressed by a generalized nMDS scheme [13].

Acceleration Schemes

The algorithms discussed above scale poorly due to slow convergence rate and quantities that require long computation times and large memory requirements. For example, the complexity of eigenvalue decomposition, as required by the classical scaling algorithm, is in general $\mathcal{O}(n^3)$. Computing a Euclidean pairwise distance matrix between n points,

as required in (10), takes $\mathcal{O}(n^2)$. Moreover, the SMACOF algorithm (13), being a first-order optimization method, requires hundreds to thousands of iterations to converge. In order to accelerate MDS algorithms, one can resort to two different strategies: *numerical acceleration* and *approximation*. In the first, dedicated optimization techniques are used in order to obtain faster convergence rates, without compromising the accuracy of the embedding. In the latter, a small compromise is allowed in order to achieve drastic savings in computation time and memory. These two approaches are often used in conjunction, where an approximated solution is successively refined as part of a larger numerical scheme.

In [14], Newton's method was explored as an alternative to the SMACOF algorithm for the minimization of (7). While the number of iterations until convergence drops dramatically, the cost per iteration becomes prohibitive for even moderate values of n , making second-order methods impractical. Several works [15–17] propose to split the MDS problem into several subproblems (“resolutions” or “scales”) by embedding only a subset of carefully chosen points. The coarse embedding obtained from this sample set is then interpolated and refined. One can distinguish between *multiresolution* and *multigrid* approaches. The first solves each subproblem independently before advancing to the next, while the second takes into account the higher-resolution subproblem already when solving the lower resolution one. Such a multigrid algorithm for MDS was described in [16]. The setting requires the availability of an additional structure, namely, a discrete manifold that can be manipulated to obtain distances between points in different scales. Specially constructed decimation and interpolation operators allow moving between scales, but since these are ad hoc constructions, they are hard to generalize for different manifolds. A spectral approach was described in [17] which achieves better performance and generalizes easily across manifolds.

Another form of numerical acceleration relies on vector extrapolation techniques [18]. These

techniques try to extrapolate the next iteration based on a few previous iterations, often leading to substantial acceleration at a very modest cost of some extra computations per iteration. Rosman et al. [19] suggested to use the reduced rank extrapolation (RRE) variant in order to accelerate the SMACOF iteration for distance scaling. This technique indeed increases the convergence rate, but a few iterations of the full problem are still required in order to produce an expressible subspace of search directions. Being a meta-algorithm, it can be used together with other acceleration techniques. For more details, see [11].

Subspace Methods

Subspace methods restrict some of the quantities appearing in the MDS algorithms to a lower-dimensional linear subspace, thus achieving significant improvement in computation time. This reduced complexity is often traded for larger embedding distortion, but one has to keep in mind that the sought Euclidean embedding is usually just an intermediate step within some larger task which may overall benefit from this kind of implicit regularization. The different subspaces used vary between ad hoc and algebraic to geometric constructions. Indeed, the MDS algorithms described above rely only on the provided dissimilarity matrix and completely ignore the way these dissimilarities were obtained. For example, if these dissimilarities were obtained by measuring geodesic distances between points on a manifold \mathcal{M} , having access to this manifold opens up the possibility to refine the embedding by incorporating the local manifold structure into the optimization problem. A key tool in these techniques is the Laplace-Beltrami operator (LBO), an analogue of the Euclidean Laplacian for manifolds. In the discrete setting, this operator is given by $\mathbf{L} = \mathbf{A}^{-1}\mathbf{W}$, where \mathbf{A} is a diagonal matrix with positive entries called *mass matrix*, and \mathbf{W} is a symmetric positive semi-definite matrix whose rows and columns sum to zero, called *stiffness matrix*. These matrices are obtained from the discrete version of the manifold, for example – by the well-known cotangent scheme [20]. The spectrum of the Laplacian can

be obtained by solving the generalized eigenvalue problem $\mathbf{W}\phi = \lambda\mathbf{A}\phi$. The matrices containing the eigenvalues and eigenvectors of \mathbf{L} shall be henceforth denoted by Λ and Φ . These act as non-Euclidean counterparts of “frequencies” and “Fourier basis,” correspondingly.

Subspace approaches for classical scaling can be used to interpolate the dissimilarity matrix \mathbf{D} from only a few entries d_{ij} $i, j \in \mathcal{I}$, as a preliminary stage to the standard classical scaling algorithm. Aflalo and Kimmel [21] proposed to perform the interpolation by minimizing the Dirichlet energy

$$\begin{aligned} E_{\text{Dirichlet}}(\mathbf{D}) \equiv \langle \nabla \mathbf{D}, \nabla \mathbf{D} \rangle_{\mathcal{M}} &= \text{Tr} \left(\mathbf{D}^T \mathbf{W} \mathbf{D} \mathbf{A} \right) \\ &\quad + \text{Tr} \left(\mathbf{D} \mathbf{W} \mathbf{D}^T \mathbf{A} \right), \end{aligned} \quad (21)$$

where $\langle \cdot, \cdot \rangle_{\mathcal{M}}$ denotes an inner product computed on the manifold. This kind of energy function is frequently used in computer vision as a means of promoting “smoothness” of signals. Representing \mathbf{D} in the LBO eigenspace Φ ,

$$\mathbf{D} = \Phi \alpha \Phi^T \quad (22)$$

leads to the following optimization problem:

$$\begin{aligned} \min_{\alpha} \text{Tr} \left(\alpha^T \Lambda \alpha \right) + \text{Tr} \left(\alpha \Lambda \alpha^T \right) \\ \text{s.t. } (\Phi \alpha \Phi^T)_{ij} = d_{ij}, \quad \forall i, j \in \mathcal{I}. \end{aligned} \quad (23)$$

In practice, since \mathbf{D} is a smooth function on \mathcal{M} , the subspace Φ can be truncated, leading to drastic savings in computation time. The choice of this particular subspace is due to it being optimal for the interpolation of functions with bounded gradient norm on manifolds [22]. The combination of (21) together with (22) gives an additional benefit: the Hessian of (21) is diagonalized by Φ , leading to a simpler optimization problem. The hard constraints in (23) can also be replaced by a penalty, leading to an even simpler problem that can be solved in closed form. The use of (22) in the classical scaling algorithm from section “[Strain-Based Scaling \(Classical Scaling\)](#)” has been called *spectral MDS* [21]. A similar

work suggested to work in the spatial domain and use bi-Laplacian smoothing instead of the Dirichlet energy, leading to smoother and more accurate interpolations [23].

One prominent drawback of the spectral MDS framework is that the savings in time for distance computation due to the subspace representation do not translate to savings in computation time of the Euclidean embedding. Another drawback is that while the LBO eigenbasis is optimal for the interpolation of smooth functions, something better can be done when interpolating a *particular* function, for example – by using a basis extracted from the data itself. Shamai et al. [24] proposed to use $q \ll n$ linearly independent columns of the squared-Euclidean distance matrix \mathbf{E} , encoded as a matrix $\mathbf{F}^{n \times q}$, and find a matrix $\mathbf{M}^{q \times n}$ such that

$$\mathbf{E} \approx \frac{1}{2} (\mathbf{F}\mathbf{M} + \mathbf{M}^\top\mathbf{F}^\top). \quad (24)$$

Recall that in the Euclidean case, the rank of \mathbf{E} is $m + 2$ where m is the dimension of the original Euclidean space; therefore such a decomposition is possible *without error*, assuming $q \geq m + 2$. In the non-Euclidean case, \mathbf{E} can still be approximated as a low-rank matrix with small error. Shamai et al. [24] proposed to do so using the Nyström method, a standard numerical technique for interpolation. A key advantage of working directly on \mathbf{E} instead of \mathbf{D} is that one can perform classical scaling while keeping \mathbf{E} in factorized form (24) saving both memory and time. For more details, see [24, 25].

Subspace approaches for distance scaling (i.e., stress based) restrict the embedding coordinates \mathbf{X} , or rather the displacement field $\delta \equiv \mathbf{X} - \mathbf{X}_0$, to some linear subspace $\Phi \in \mathbb{R}^{n \times p}$, i.e., $\delta = \Phi\alpha$. In [17], the SMACOF iteration (13) was reformulated to the case where δ is modeled as a p -bandlimited signal on some manifold \mathcal{M}_0 , i.e., it can be approximated by a linear combination of the first p eigenvectors of the Laplace-Beltrami operator. This is justified by the fact that since we are looking for a distance preserving embedding, δ should be smooth in the sense that close points on \mathcal{M}_0 should remain close on the final embedding. The new update step in terms of α is given by

$$\alpha_{k+1} = (\Phi^\top V \Phi)^+ \Phi^\top (\mathbf{B}_k \mathbf{X}_k - V \mathbf{X}_0), \quad (25)$$

where $\mathbf{X}_{k+1} = \mathbf{X}_0 + \Phi\alpha_{k+1}$. Drawing analogy from the famous *noble identity* (Fig. 1), it turns out to be enough to embed a subset of $q \approx 2p \ll n$ points to obtain the coefficients α ,

$$\alpha_{k+1} = (\Phi^\top S^\top V^s S \Phi)^+ \Phi^\top S^\top (\mathbf{B}^s_k S \mathbf{X}_k - V^s S \mathbf{X}_0), \quad (26)$$

where V^s, \mathbf{B}^s are the matrices defined in (9),(10) constructed only from the q sampled points, and S is a sampling matrix. The final embedding is obtained by $\mathbf{X}_* = \mathbf{X}_0 + \Phi\alpha_*$. The entire procedure is called *spectral SMACOF*. A single iteration of (26) consists of two steps: *majorization*, the construction of $\mathbf{B}^s(\mathbf{X}_k)$, which requires $\mathcal{O}(q^2)$ operations, and *minimization*, the solution of (26), which in general requires $\mathcal{O}(p^3)$ for the computation of $(\Phi^\top S^\top V^s S \Phi)^+$ in the first iteration and $\mathcal{O}(p^2)$ operations in the succeeding iterations. A similar approach was carried in [26] using a subspace constructed from the data, akin to PCA, for the purpose of visualizing multidimensional images. These modifications drastically reduce the computation time of the embedding and allow the application of distance scaling to large-scale problems or within iterative procedures that require multiple applications of the SMACOF algorithm (Fig. 2).

Finally, it is possible to use a *nonlinear* parametric model for the embedding, $f_\Theta(\mathbf{x}) : \mathbb{R}^m \rightarrow \mathbb{R}^k$, where Θ is a set of model parameters, whose number is much smaller than n . For example, [27] finds such a parametric mapping by training a neural network to minimize the following loss:

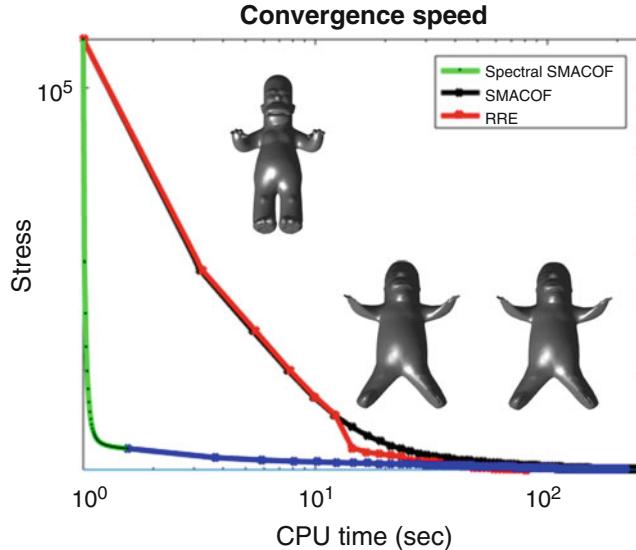

$$\mathcal{L}(\Theta) = \sum_{i>j} (\|f_\Theta(\mathbf{x}_i) - f_\Theta(\mathbf{x}_j)\| - d_{ij})^2. \quad (27)$$

Embeddings found by such a nonlinear parametric model result in smaller metric distortion per number of embedded points compared to their linear counterparts.

Multidimensional Scaling, Fig. 1 The noble identity states the conditions under which the order of down sampling and linear filtering can be exchanged in the Euclidean case. While the order can always be exchanged

in the \Rightarrow direction, the exchange in the \Leftarrow direction is only possible if the filter has a special form: $h[n] = 0 \forall n : \lfloor n/M \rfloor \notin \mathbb{Z}$

M

Multidimensional Scaling, Fig. 2 Runtime comparison between different numerical schemes for minimizing (7). The matrix D contains geodesic distances computed on the *homer* shape between 5103 points. The algorithms compared are the original SMACOF algorithm [10], an RRE vector extrapolation acceleration method [19], and spectral SMACOF [17]. By embedding only 200 points

and extrapolating to the rest using the Laplace-Beltrami eigenbasis (the green line), we achieve significant speedup compared to the other methods. The blue line represents additional SMACOF iterations at full resolution. The figures on the right are the original shape (top) and the results of spectral SMACOF (bottom left) and regular SMACOF (bottom right)

Generalizations

The literature on MDS is extensive, and along the years there have been generalizations of the basic schemes and algorithms in many ways. In this entry we review a few of these generalizations, focusing on those oriented toward computer vision applications.

Variations on the Stress Theme

Robust Classical Scaling As mentioned in section “[Strain-Based Scaling \(Classical Scaling\)](#),” the double centering transform (2) makes the embedding produced by classical scaling very sensitive to outliers in the distance

matrix. Moreover, if D is not a Euclidean distance matrix, (2) might not be positive semi-definite. To cope with these problems, a robust MDS model was proposed by [28]. Note that the following transformation applied to a PSD matrix K produces a squared-Euclidean distance matrix (see also (17)):

$$\text{dist}(K)_{ij} = k_{ii} + k_{jj} - 2k_{ij}. \quad (28)$$

Consider the following optimization problem:

$$\min_{K \in \mathbb{R}^{n \times n}} \|E - \text{dist}(K)\|_1 \text{ s.t. } \begin{cases} K \succeq 0 \\ \text{rank}(K) \leq k. \end{cases} \quad (29)$$

Equation (29) is a form of robust projection of the matrix \mathbf{E} onto the set of matrices whose double centering transform is PSD with rank at most k . The ℓ_1 norm handles the sparse set of outliers, whereas the constraints make sure that the obtained matrix is embeddable into a k -dimensional Euclidean space. Once the solution is obtained, $\text{dist}(\mathbf{K})$ can be represented as $\mathbf{X}\mathbf{X}^\top$ as in the standard classical scaling algorithm.

Problem (29) can be solved by sub-gradient or interior point methods [28] or by combining the alternating direction method of multipliers (ADMM) with manifold optimization techniques

[29]. The latter results in an efficient and simple algorithm that converges fast and scales well. To summarize this algorithm, we first introduce an auxiliary variable \mathbf{Z} and rewrite (29) as follows:

$$\min_{\mathbf{K}, \mathbf{Z}} \|\mathbf{Z}\|_1 \quad \text{s.t.} \quad \begin{cases} \mathbf{K} \succeq 0 \\ \text{rank}(\mathbf{K}) \leq k \\ \mathbf{Z} = \mathbf{E} - \text{dist}(\mathbf{K}) \end{cases} \quad (30)$$

Introducing a (scaled) Lagrange multiplier \mathbf{U} and a scalar μ , this problem can in turn be written in Lagrangian form

$$\min_{\mathbf{K}, \mathbf{Z}} \|\mathbf{Z}\|_1 + \frac{\mu}{2} \|\mathbf{Z} - \mathbf{E} + \text{dist}(\mathbf{K}) + \mathbf{U}\|_F^2 \quad \text{s.t.} \quad \begin{cases} \mathbf{K} \succeq 0 \\ \text{rank}(\mathbf{K}) \leq k \end{cases} \quad (31)$$

Now the standard ADMM method [30] can be invoked:

$$\mathbf{K}_{k+1} = \operatorname{argmin}_{\mathbf{K}} \|\mathbf{Z}_k - \mathbf{E} + \text{dist}(\mathbf{K}) + \mathbf{U}_k\|_F^2 \quad \text{s.t.} \quad \begin{cases} \mathbf{K} \succeq 0 \\ \text{rank}(\mathbf{K}) \leq k \end{cases} \quad (32a)$$

$$\mathbf{Z}_{k+1} = \operatorname{argmin}_{\mathbf{Z}} \|\mathbf{Z}\|_1 + \frac{\mu}{2} \|\mathbf{Z} - \mathbf{E} + \text{dist}(\mathbf{K}_{k+1}) + \mathbf{U}_k\|_F^2 \quad (32b)$$

$$\mathbf{U}_{k+1} = \mathbf{U}_k + (\mathbf{Z}_{k+1} - \mathbf{E} + \text{dist}(\mathbf{K}_{k+1})) \quad (32c)$$

where the optimization over \mathbf{B} can be carried out using manifold optimization techniques [31, 32], and the optimization over \mathbf{Z} is an unconstrained non-smooth optimization problem which has a closed form solution using the shrinkage operator $T_\alpha(x) = (|x| - \alpha)_+ \operatorname{sign}(x)$

$$\mathbf{Z}_{k+1} = T_{\frac{1}{\mu}}(\mathbf{E} - \text{dist}(\mathbf{K}_{k+1}) - \mathbf{U}). \quad (33)$$

Robust Distance Scaling While the least squares stress function defined in (7) is the most common one, it exhibits similar shortcomings to those often encountered when using the ℓ_2 norm in regression problems: the quality of the solution deteriorates quickly with any additional outlier added to the dataset. In order to cope with outliers, one can replace the ℓ_2 stress defined in (7) with a more robust version, say – the ℓ_1 stress

$$\sigma_{\ell_1}(\mathbf{X}) = \sum_{i < j} w_{ij} |\|\mathbf{x}_i - \mathbf{x}_j\| - d_{ij}|. \quad (34)$$

One simple heuristic algorithm for the minimization of (34), and in fact – of any other function of the form

$$\sigma_\rho(\mathbf{X}) = \sum_{i < j} \rho(|\|\mathbf{x}_i - \mathbf{x}_j\| - d_{ij}|) \quad (35)$$

is the *iteratively reweighted least squares* (IRLS) algorithm. The algorithm follows from a comparison between the sufficient condition of optimality for minimizing (7)

$$\nabla \sigma(\mathbf{X})$$

$$= \sum_{i < j} 2w_{ij} (\|\mathbf{x}_i - \mathbf{x}_j\| - d_{ij}) \nabla_{\mathbf{X}} (\|\mathbf{x}_i - \mathbf{x}_j\|) \\ = 0 \quad (36)$$

and (35)

$$\begin{aligned} \nabla \sigma_\rho(\mathbf{X}) &= \sum_{i < j} \rho'(\|\mathbf{x}_i - \mathbf{x}_j\| - d_{ij}) \nabla_{\mathbf{X}} (\|\mathbf{x}_i - \mathbf{x}_j\|) \\ &= 0. \end{aligned} \quad (37)$$

By setting the weights in (36) to

$$w_{ij} = \frac{\rho'(\|\mathbf{x}_i^* - \mathbf{x}_j^*\| - d_{ij})}{2(\|\mathbf{x}_i^* - \mathbf{x}_j^*\| - d_{ij})} \quad (38)$$

we get an equivalent LS-MDS problem to (35). The IRLS algorithm works by solving a series of LS-MDS problems with iteratively updated weights:

1. set

$$w_{ij}^k = \frac{\rho'(\|\mathbf{x}_i^k - \mathbf{x}_j^k\| - d_{ij})}{2(\|\mathbf{x}_i^k - \mathbf{x}_j^k\| - d_{ij})} \quad (39)$$

2. solve

$$\mathbf{X}_{k+1} = \operatorname{argmin}_{\mathbf{X}} \sum_{ij} w_{ij}^k (\|\mathbf{x}_i - \mathbf{x}_j\| - d_{ij})^2. \quad (40)$$

Another way to generalize distance scaling is by adding a regularization term, weighted by some constant $\mu > 0$, to the LS-stress

$$\min_{\mathbf{X}} \sigma(\mathbf{X}) + \mu R(\mathbf{X}). \quad (41)$$

This regularization term can help reject outliers, drive the embedding toward a favorable configuration, or promote any other property that we want the embedding to manifest. Assuming the regularization function $R(\mathbf{X})$ is convex, a small variant of the SMACOF iteration described in section “[Stress-Based Scaling \(Distance Scaling\)](#)” can be used in order to minimize the regularized stress. Instead of using the majorizing function $h(\mathbf{X}, \mathbf{Z})$ defined in (11), we shall use $h(\mathbf{X}, \mathbf{Z}) + \mu R(\mathbf{X})$. The update step (13) now requires the solution of a convex optimization

problem

$$\mathbf{X}_{k+1} = \operatorname{argmin}_{\mathbf{X}} h(\mathbf{X}, \mathbf{X}_k) + \mu R(\mathbf{X}). \quad (42)$$

Non-Euclidean Embeddings

We shall conclude the section by reviewing a few schemes that consider embeddings to domains other than \mathbb{R}^k . The simplest choice of a non-Euclidean domain is a k -dimensional unit sphere $S^m = \{\mathbf{Z} \in \mathbb{R}^{k+1} : \|\mathbf{z}\|_2 = 1\}$. Embedding into a sphere can be formulated as follows (using the LS-stress):

$$\min_{\mathbf{Z}} \sum_{i < j} w_{ij} (d_{S^m}(\mathbf{z}_i, \mathbf{z}_j) - d_{ij})^2 \text{ s.t. } \|\mathbf{z}_q\| = 1 \forall q, \quad (43)$$

and can be solved by parametrizing \mathbf{z} in spherical coordinates and using gradient descent. Embedding into a sphere with a different radius r amounts to scaling the dissimilarities by $1/r$.

Bronstein et al. [33] introduced *generalized MDS* (GMDS) – an algorithm for isometric embedding of one Riemannian manifold into another. The algorithm works as follows: given two such manifolds \mathcal{X}, \mathcal{Y} , discretized as triangular meshes, we compute the geodesic distances between all pairs of vertices on each of the meshes – $\mathbf{D}_{\mathcal{X}}, \mathbf{D}_{\mathcal{Y}}$. These distances can be used to interpolate the distance between any two points on the faces of the meshes. The embedding of one manifold into the other is represented in barycentric coordinates $\mathbf{U}^{n \times 3}$, and the generalized stress

$$\sigma_{GMDS}(\mathbf{U}) = \sum_{i < j} \|d_{\mathcal{X}}(\mathbf{u}_i, \mathbf{u}_j) - d_{\mathcal{Y}}(\mathbf{u}_i, \mathbf{u}_j)\|^2 \quad (44)$$

is minimized using gradient descent, subject to $\mathbf{U}\mathbf{1} = \mathbf{1}$. A spectral version of GMDS is developed in [34], following the spectral MDS algorithm [21].

Another form of non-Euclidean embedding is given in [35], who suggested to decompose the distance matrix \mathbf{D} into $\mathbf{X}\mathbf{X}^\top$. Since \mathbf{D} is symmetric, such a decomposition is always possible, based on the spectral decomposition of \mathbf{D}

$$\mathbf{D} = \mathbf{U} \Lambda_D \mathbf{U}^\top. \quad (45)$$

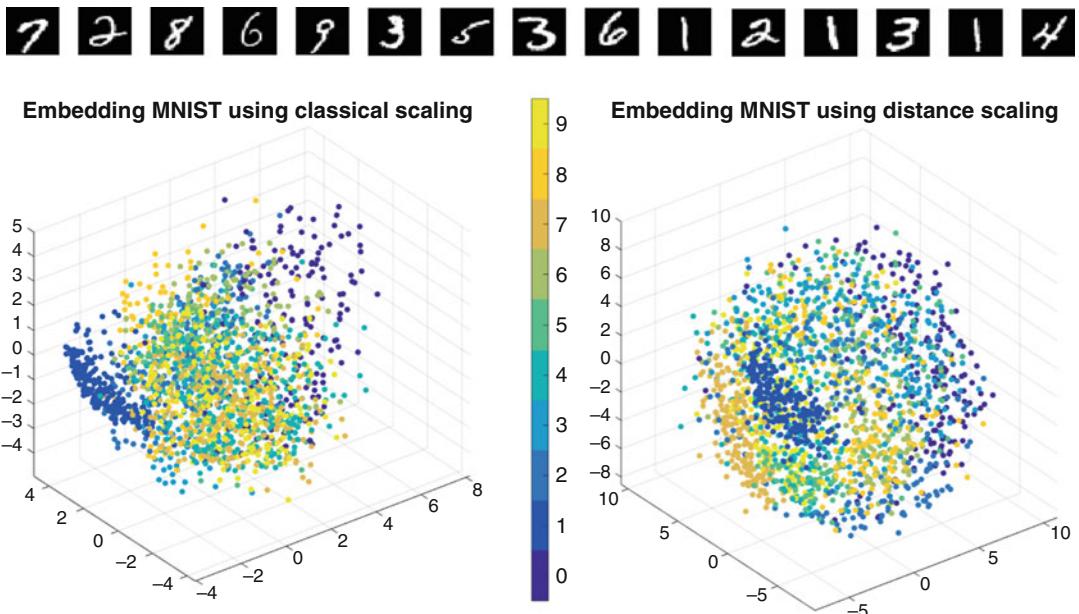

$X \equiv \mathbf{U} \Lambda_D^{\frac{1}{2}}$ is an embedding of \mathbf{D} into the complex domain \mathbb{C}^n without error. Since most of the eigenvalues of \mathbf{D} are of small magnitude [7], the metric distortion introduced by truncating the eigen-expansion is small, leading to highly accurate embeddings at the cost of working in the complex domain.

Applications

Multidimensional scaling (MDS) is one of the most popular methods in data analysis, and it would be impossible to provide a complete set of applications in this short review. We will focus on a few applications of MDS in computer vision. Some of these applications are also detailed in Fig. 4.

The main use of MDS algorithms is for dimensionality reduction. It is popularly used for visualization of high-dimensional signals by embedding their dissimilarities into two or three-

dimensional Euclidean spaces. For example, [26] uses it to visualize multidimensional images, and [36] explores multiple visualization techniques on the MNIST dataset of handwritten digits [12] (Fig. 3). Apart from visualization, low-dimensional isometric embedding is used as a preprocess for algorithms that rely on Euclidean distances. Many classical image processing and computer vision algorithms have been developed to work on RGB color images. A simple way to adapt these algorithms to be used with high-dimensional features is to embed these features into a three-dimensional Euclidean space, represented as a color image. For example, [37] uses MDS to embed features that integrate local color and gradient value distribution, and [38] uses it to embed the co-occurrence statistics of pixels in an image (Fig. 4a). These embeddings are later used in classical segmentation and optical flow estimation algorithms. Other image processing tasks such as image retargeting can be carried out efficiently with the subspace version of MDS [17], where the idea is to rescale an image in a way that preserves distances in the salient regions and concentrate

Multidimensional Scaling, Fig. 3 Top – a few examples of 28×28 images of handwritten digits from the MNIST dataset [12]. Bottom – embeddings in \mathbb{R}^3 of Euclidean

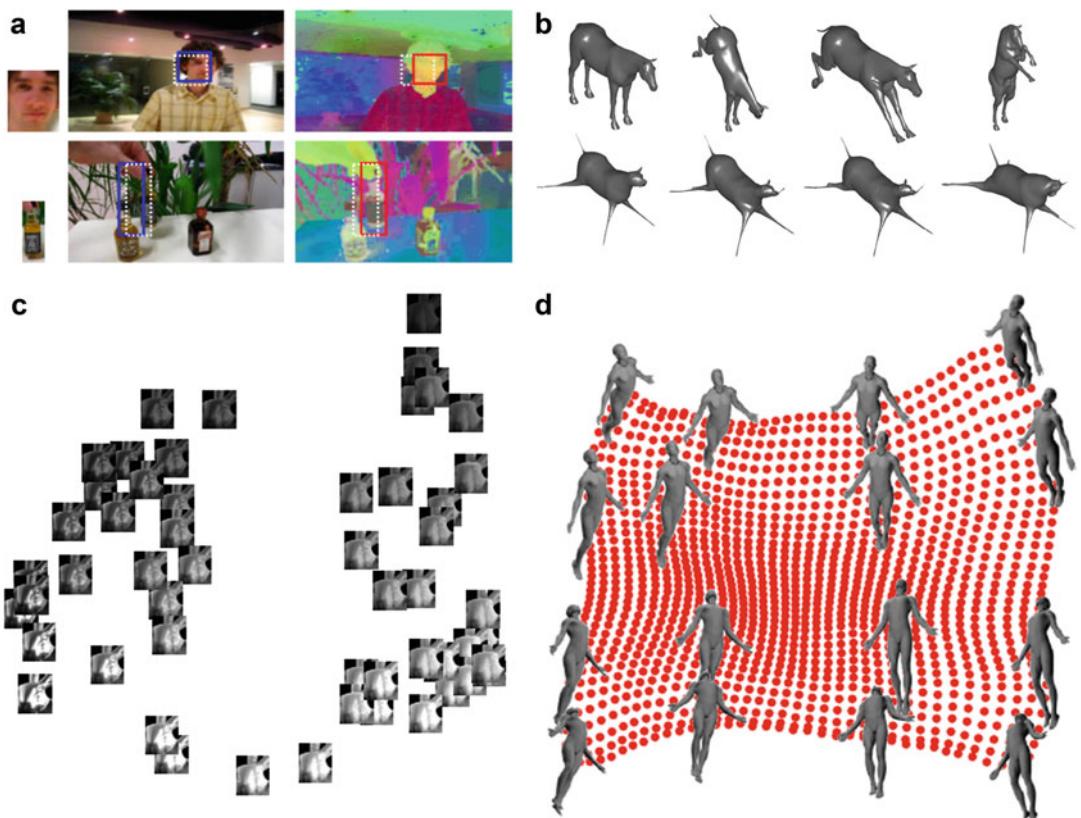

distances between 2000 MNIST digits using classical scaling (left) and distance scaling (right)

the distortions in other parts while preventing flip-overs.

In the field of geometry processing, MDS found applications in tasks such as texture mapping [39], shape analysis [8], and shape synthesis [40]. Classification of surfaces that is invariant to isometric transformation is achieved by embedding the surfaces to a Euclidean domain, creating for each surface a “canonical form” (Fig. 4b). These canonical forms can be aligned with a rigid transformation, and a threshold on the alignment mismatch rules whether two shapes

belong to the same class or not. This idea has been carried out using multiple versions of the MDS algorithms [8, 21, 23, 24, 35]. Alternatively, the generalized MDS scheme (44) [33] or its spectral version [34] can compare two surfaces directly, without passing through an intermediate embedding space. More recent works [41] use the GMDS cost (44) as a loss function of a neural network that is trained in an unsupervised way to find optimal descriptors for shape matching.

In [40], MDS was used as part of the surface-from-operator problem. MDS plays a part in

Multidimensional Scaling, Fig. 4 Applications of MDS in computer vision. (a) Template matching. The template on the left is found in the image on the right with Lucas-Kanade optical flow. Using an embedded image of co-occurrence scores (right) outperforms the matching obtained with the regular RGB image (left). (Image[©] taken from [38] with permission of the authors). (b) Canonical forms. Embedding the geodesic metric computed on the four approximately isometric horses on top, results in canonical representations of these shapes (bottom), related to each other by a rigid transformation

[8, 11, 23]. (The horse shape is taken from [42]). (c) Perceptual embedding of BRDF maps (i.e., governing the reflectance properties of a surface) using generalized non-metric MDS. (Image[©] taken from [13] with permission of the authors). (d) A three-dimensional embedding of the *camera pose manifold* (images of the same object taken with different elevation and azimuth) from a small subset of distances using a machine learning-based nonlinear parametric MDS model [27]. (Image courtesy of the authors)

reconstructing a surface from its discrete metric, i.e., the lengths of the edges of the polygons comprising the mesh.

Agarwal et al. [13] developed a generalized nonmetric MDS model, able to cope with missing and contradictory data, and used it for visualizing dissimilarities between reflectance maps of objects (Fig. 4c). Since nonmetric MDS models are mostly used to perform perceptual embeddings, they are rarely used in computer vision applications. Nevertheless, there is a great potential for using them in problems that rely only on rank order of dissimilarities such as correspondence problems between non-isometric shapes.

Open Problems

One of the big and presently unsatisfactorily solved problems related to MDS methods is out-of-sample extension. We believe that more research into the use of modern machine learning tools, in particular, deep learning, could bring new efficient solutions to this problem.

Multi-focus Images

Amit Agrawal

[Focus bracketing](#)

Definition

Multi-focus images are a set of images of the same scene focused at different depths in the scene.

Background

Conventional imaging systems have a finite depth of field (DOF), which depends on the aperture size and the focal length of the lens. The DOF is the depth range within which the scene points appear sharp in the captured image. For scene points within the DOF, the size of the defocus blur is smaller than the minimum acceptable circle of confusion. Often, a single photo is unable to capture the entire scene in sharp focus.

DOF can be increased by decreasing the aperture size (increasing the F-number). However, reducing the aperture size decreases the light throughput, resulting in a dark and noisy image. Multi-focus images offer a solution to increase the DOF without decreasing light throughput. By capturing different photos focused at different depths in the scene and combining them, the entire scene can be brought into focus. This capture procedure is also called “focus bracketing.” This is similar to “exposure bracketing,” where images are taken under different exposures and combined to obtain a high dynamic range image. However, a disadvantage with focus bracketing is that the entire scene has to remain static during the capture process.

Theory

For a thin lens with focal length f and lens to sensor plane distance u , the plane of focus is at a distance v from the lens, where

$$\frac{1}{v} = \frac{1}{f} - \frac{1}{u}. \quad (1)$$

Let c be the size of the acceptable circle of confusion and A be the aperture diameter. Then, f-number $N = f/A$. The DOF is then spanned between D_n and D_f , where

$$D_n = \frac{vf^2}{f^2 + Nc(v-f)}, \quad (2)$$

$$D_f = \frac{vf^2}{f^2 - Nc(v-f)}. \quad (3)$$

As shown in Fig. 1 the DOF region in front of the plane of focus is not equal to the DOF region behind it. Multi-focus images can be obtained by capturing several images, each under a different focus setting of the lens (change of u). Note that other camera parameters such as aperture size, exposure time, and zoom can also be modified along with the focus setting of the lens during the capture.

Minimizing the Capture Time

Since multi-focus images require the entire scene to remain static during the capture process, it is important to decrease the overall capture time. In [1], the problem of imaging a scene with a given depth of field at a given exposure level in the shortest amount of time was considered. The criteria for optimal capture sequence were derived. Since the light throughput is quadratic with respect to the aperture size but linear with respect to the exposure time, increasing the aperture size is more beneficial to reduce the overall capture time. Intuitively, one should use a large aperture and sweep the focus such that all scene points are sharp in at least one of the captured image.

Combining Multi-focus Images

Multi-focus images can be combined to generate an image with larger DOF than any of the individual source images. This is also known as focus stacking and is especially useful in macro photography and optical microscopy. The resultant image is equivalent to the photo captured using a small aperture but will be significantly less noisy. Haeberli [2] showed how to combine multi-focus images by choosing each pixel intensity from the image where it appears to be the sharpest. The sharpness measure can be defined using local variance or local image gradients. Recent approaches have used an energy minimization framework to combine multi-focus images using fast techniques such as graph-cuts [3].

Depth from Defocus and Focus

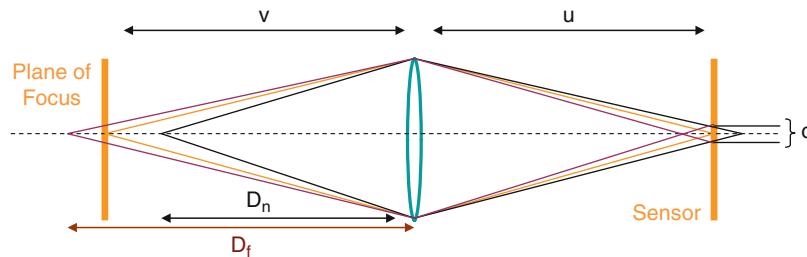

An additional advantage of multi-focus images is that they can be used to estimate the scene depths, since the defocus blur of a scene point is related to its depth. Depth from defocus is an active area of research in computer vision. Depth from defocus techniques model the relationship between depth and defocus blur using a parametric function and use it to estimate depth from several defocused images. See [4] for a review on such techniques. On the other hand, depth from focus [5, 6] approaches use a focus measure to identify the focus setting for each pixel, which is converted to the metric depth via calibration.

Extended Depth of Field

Focus bracketing is an easy and practical solution to increase the DOF of imaging systems without any hardware modifications. The underlying problem of extending depth of field has several other interesting solutions such as (a) aperture modification [7, 8], (b) light-field based digital refocusing [7, 9–12], (c) lens modifications [13–15], and (d) sensor motion [16].

Application

Extending the DOF has applications in consumer and sports photography, as well as scientific imaging. Multi-focus images offer a viable

Multi-focus Images, Fig. 1 DOF for a thin lens with focal length f lies between D_f and D_n

solution if the scene is changing slowly compared to the capture time required for focus bracketing.

Open Problems

Applying multi-focus images to a dynamic scene is an open and interesting problem.

Multiplexed Illumination

Marina Alterman

Department of Electrical Engineering,
Technion – Israel Institute of Technology, Haifa,

Multiplexed sensing

Definition

In multiplexed illumination, multiple light sources are used simultaneously in different measurements of intensity data arrays. Then, the intensity under individual sources is derived by computational demultiplexing. This scheme enhances the results: it increases the signal-to-noise ratio of intensity data arrays, without increasing acquisition resources such as time. It also improves dynamic range.

Background

Measuring a set of variables is a common task. For example, in computer vision and graphics, there is a need to acquire multiple images under various lighting conditions; in spectroscopy, there is a need to measure several wavelength bands; in tomography, measurements are taken at a set of different directions; in microscopy, there is a set of focal planes or a set of measurements under several fluorescence excitation wavelength bands. Usually these variables are measured sequentially.

The measurements are subjected to noise, which may yield a low signal-to-noise ratio

(SNR). In many cases, the SNR cannot be improved simply by increasing the illumination of individual sources or the exposure time. Simultaneously combining signals corresponding to multiple variables into a single multiplexed measurement may be more efficient. This way, in some cases, the total intensity of multiplexed signals increases relative to the noise. The acquired multiplexed measurements are demultiplexed by a computer, yielding an array of intensity values with a higher SNR.

Theory

Basic Multiplexing

Often, sensors seek measurement of a vector of observable intensity variables \mathbf{n} . Generally, the acquired raw measurements form a vector \mathbf{a} of length n . This raw vector is related to \mathbf{i} by

$$\mathbf{a} = \mathbf{W}\mathbf{i} + \boldsymbol{\eta}, \quad (1)$$

where $\boldsymbol{\eta}$ is a vector of measurement noise (the noise is uncorrelated in different measurements). Here \mathbf{W} is a weighting matrix, referred to as a *multiplexing code*. One case is $\mathbf{W} = \mathbf{I}$, where \mathbf{I} is the identity matrix. This special case is referred to as *trivial sensing*: only a single component of \mathbf{i} is acquired at a time. More generally, multiple components of \mathbf{i} can be simultaneously summed up (multiplexed) and acquired in each raw measurement. The components of \mathbf{i} included in the m th measurement are determined by the m th row of \mathbf{W} . After the measurements are taken, the vector \mathbf{i} of intensities corresponding to the individual source can be decoded from the vector of measurements \mathbf{a} , using

$$\hat{\mathbf{i}} = \mathbf{W}^{-1}\mathbf{a} \quad (2)$$

(when \mathbf{W} is invertible) or by an estimator such as least squares.

A simple case in which $N_{\text{sources}} = 3$ is depicted in Fig. 1. There, two sources are used simultaneously per acquired measurement. For general number of sources, the vectors \mathbf{i} and \mathbf{a} are related

by a linear superposition as in Eq. (1). The elements $w_{m,s}$ of \mathbf{W} represent [13] the normalized radiance of source s in measurement m . If $w_{m,s} = 0$, then source s is turned off completely at measurement m ; if $w_{m,s} = 1$, then this source irradiates the object, at the source's maximum power. Generally, $0 \leq w_{m,s} \leq 1$.

The mean squared error (MSE) [5] of $\hat{\mathbf{i}}$ is

$$\text{MSE}_{\mathbf{i}} = \frac{\sigma^2}{N_{\text{sources}}} \text{tr} \left[(\mathbf{W}^T \mathbf{W})^{-1} \right], \quad (3)$$

where tr is a trace operation and σ^2 is the variance of η . Based on Eqs. (2) and (3), \mathbf{i} can be reconstructed, with a potentially higher SNR [5, 11, 13] than \mathbf{i} which is trivially sensed using \mathbf{I} . The gain of using multiplexing (termed multiplex advantage) is defined [5] as

$$\text{GAIN}_{\mathbf{i}} = \sqrt{\sigma^2 / \text{MSE}_{\mathbf{i}}}. \quad (4)$$

Most related studies have aimed to maximize the SNR of the recovered images $\hat{\mathbf{i}}$. Thus, Refs. [5, 9, 11, 13] sought a multiplexing matrix that minimizes Eq. (3):

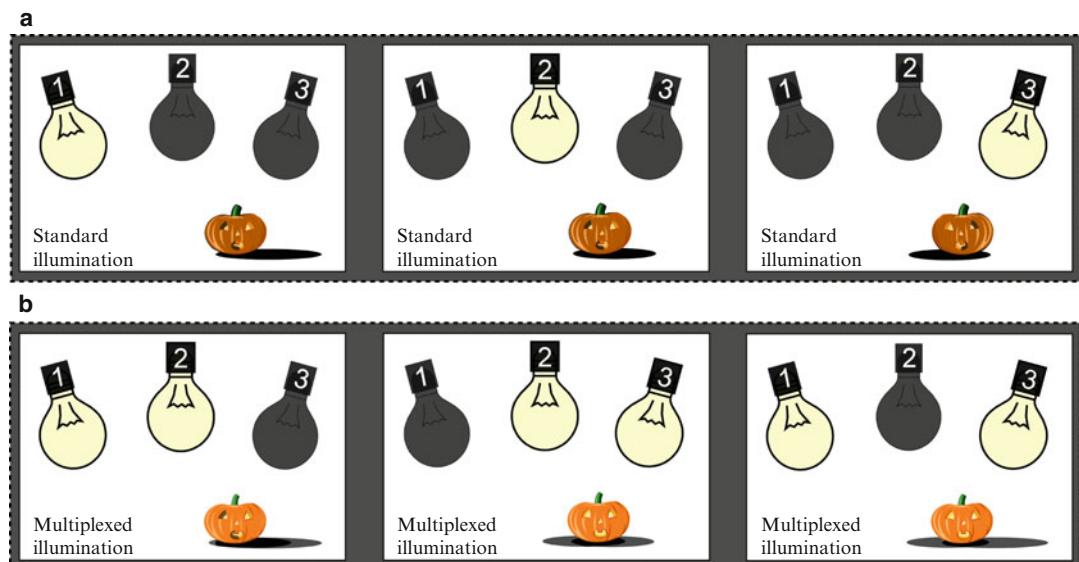

$$\hat{\mathbf{W}}_{\mathbf{i}} = \arg \min_{\mathbf{w}} \text{MSE}_{\mathbf{i}}. \quad (5)$$

An optimal multiplexing code should yield the highest SNR of the demultiplexed values. When the signal dependency of noise is not considered, the optimal multiplexing codes are based on Hadamard matrices [5].

According to the affine noise model [11], the detector noise variance is composed of two components, signal dependent and signal independent. The gray-level variance of the signal-independent noise is denoted by k_{gray}^2 . Considering a diffuse object, each light source yields a similar object radiance. Therefore, each source yields a similar level of noise. If C sources are activated in their maximum power, the total noise variance of the measured gray level is [11, 14]

$$\sigma^2 = k_{\text{gray}}^2 + C\mu^2, \quad (6)$$

where μ^2 is the photon noise variance, caused by object irradiance from a single source activated at its maximum power. If photon noise dominates the noise ($C\mu^2 \gg k_{\text{gray}}^2$), Hadamard multiplexing codes degrade the decoded images. The reason is that simultaneous sources increase

Multiplexed Illumination, Fig. 1 Three light sources illumination [13]. (a) Standard (trivial) illumination: single light source is active in each measurement. (b) Multiplexed illumination: two light sources are active in each measurement

the image intensity, which in turn increases the photon noise. Therefore, there is a need for generalization of the multiplexing model to obtain new and improved multiplexing codes.

Generalized Multiplexing

References [11, 12] derive optimal multiplexing codes considering photon noise and saturation. Saturation occurs when the total illumination radiance exceeds a certain threshold. If all light sources yield a similar object radiance, then this threshold C_{sat} is expressed in units of light sources ($C = C_{\text{sat}}$). It is preferable to exploit the maximum radiance for every measurement. Thus, to account for saturation, the constraint

$$\sum_{s=1}^{N_{\text{sources}}} w_{m,s} = C_{\text{sat}} \quad (7)$$

is added to the optimization problem in Eq. (5). By scanning a range of C_{sat} values in Eq. (7) and using $C = C_{\text{sat}}$ in Eqs. (3) and (6), the value that yields the maximum gain Eq. (4) is found. This accounts both for saturation and photon noise.

However, is a demultiplexed array \mathbf{i} the true goal of a vision system? Often not. Usually, the recovered intensity or reflectance array \mathbf{i} is by itself an input to further analysis. For example, a multispectral imager may recover a scene's spectral datacube, and multiplexing is helpful in this. But the resulting multispectral datacube itself is of little interest *per se*: usually (e.g., in remote sensing) the user is interested in the underlying spatial distribution *of materials* or objects that created the spectral data. This is formulated as a mixing model

$$\mathbf{i} = \mathbf{X} \mathbf{c}, \quad (8)$$

where \mathbf{X} is a *mixing* matrix. The end product of interest in this example is *not* demultiplexed intensities or spectral reflectance (\mathbf{i}) but a distribution of materials (\mathbf{c}). Similarly, in multispectral imaging of fluorescing specimen, intensities (\mathbf{i}) are just a means to obtain information about molecular distributions in the specimen (\mathbf{c}). Recovery of \mathbf{c} based on \mathbf{i} is called *unmixing*.

Reference [2] showed that unmixing can (and should) be fully integrated when optimizing the multiplexing codes. Otherwise, the true underlying variables of interest may *be harmed* by multiplexing. Let multiple sources be active in each measurement (intentional multiplexing). Using Eqs. (1) and (8), \mathbf{c} can be estimated, for example, by using weighted least squares

$$\hat{\mathbf{c}} = \left[(\mathbf{W}\mathbf{X})^T \sum_{\text{noise}}^{-1} (\mathbf{W}\mathbf{X}) \right]^{-1} (\mathbf{W}\mathbf{X})^T \sum_{\text{noise}}^{-1} \mathbf{a}, \quad (9)$$

where \sum_{noise} is the covariance matrix of the raw measurement noise η . Then, the MSE of \mathbf{c} is

$$\text{MSE}_{\mathbf{c}} = \frac{1}{N_{\text{materials}}} \text{tr} \left\{ \left[(\mathbf{W}\mathbf{X})^T \sum_{\text{noise}}^{-1} (\mathbf{W}\mathbf{X}) \right]^{-1} \right\}, \quad (10)$$

where $N_{\text{materials}}$ is the number of materials to unmix. To multiplex measurements in a way that optimally recovers \mathbf{c} (*multiplexed unmixing*), a multiplexing matrix \mathbf{W} that minimizes the MSE of \mathbf{c} Eq. (10) is sought,

$$\hat{\mathbf{W}}_{\mathbf{c}} = \arg \min_{\mathbf{W}} \text{MSE}_{\mathbf{c}}. \quad (11)$$

Application

Multiplexed illumination is used in multispectral imaging (array of spectral bands) [3, 9], spectroscopy [4], and lighting (reflection from an array of light sources) [8, 11, 13]. It also has analogue formulations in coded apertures (array of spatial positions or viewpoints) and coded shuttering [1, 6, 7, 10] (array of spatiotemporal pixel values).

Definition

Multiview stereo (MVS) refers to the task of reconstructing the 3D shape of the scene from multiple color or intensity images captured from different viewpoints such that the field of view of the associated cameras overlaps. Typically, the cameras are assumed to be fully calibrated. Various choices of 3D shape representations are possible for the estimated 3D scene reconstruc-

tion. For example, dense 3D point cloud or surface mesh representations are common in applications that synthesize a new photorealistic image of the scene using computer graphic rendering techniques. The topics of multiview stereo and multi-baseline stereo matching share key concepts related to the recovery of dense 2D pixel correspondences in multiple images.

Background

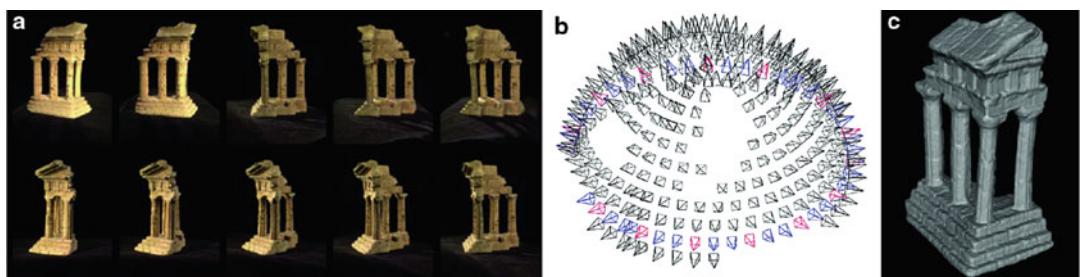

Reconstructing 3D geometry from images (often referred to as *3D photography* or *image-based 3D modeling*) involves using cameras or optical sensors (and optionally illumination) to acquire the 3D shape and appearance of objects and scenes in the real world. Existing methods can be broadly divided into two categories – *active* and *passive* methods. Active methods usually require additional special light sources, whereas passive methods work with natural lighting. Active methods often use special-purpose sensors such as laser range scanners and depth sensors (Kinect, time-of-flight cameras) and can often capture high-quality 3D models. However, developing passive methods for ordinary cameras is also important because of their greater ease, flexibility, and wider applicability.

Multiview stereo is a popular and well-studied passive 3D reconstruction technique. It is based on the principle that dense pixel correspondences in multiple calibrated images captured from different viewpoints make it possible to estimate the 3D shape of the scene via triangulation. Triangulation refers to the step where rays backpro-

jected from the corresponding pixels in different images are intersected to estimate the position of the associated 3D point in the scene. Multiview stereo therefore requires the camera calibration parameters to be known. Specifically, the intrinsic parameters are precomputed off-line or can be computed along with the extrinsic parameters (camera pose) from the input images using structure from motion algorithms. Furthermore, the input images are typically warped to remove the effect of radial distortion before using them for multiview stereo matching. The distortion is removed by applying a suitable lens distortion model and parameters that are included in the camera intrinsic parameters. Figure 1 shows a 3D reconstruction obtained using multiview stereo.

The main challenge in multiview stereo lies in computing precise, dense pixel correspondence between overlapping images. Difficulties arise due to ambiguities in matching pixels in two images of the same scene. Multiview stereo works best when surfaces are textured and *Lambertian*, i.e., when the local appearance of a surface patch does not depend on the viewing angle. Glossy or specular surfaces are non-Lambertian and are more difficult to handle compared to diffuse surfaces. Occlusions can complicate the situation even further, especially in the *wide baseline* setting where the camera viewpoints are farther compared to the *narrow baseline* setting, where the effect of occlusions is less pronounced.

For reconstructing a static scene with multiview stereo, a single camera can be used to capture images from multiple viewpoints over time. Sometimes, images are captured with a

Multiview Stereo, Fig. 1 Images captured with a camera rig. Calibrated cameras and the final 3D model produced by a state-of-the-art multiview stereo method rendered as a triangulated mesh

static camera with the object placed on a rotating turntable [11]. These techniques can also be applied to dynamic scenes, provided multiview video is captured from a calibrated, synchronized multi-camera rig. The Virtualized Reality project at CMU [16] was the first to demonstrate multi-view 3D reconstruction of dynamic events within a large scene.

Theory

A taxonomy was recently introduced to broadly categorize multiview stereo approaches [24]. It proposed studying various methods based on the following properties: 3D shape representations, the photoconsistency measure, visibility handling, shape priors, and the reconstruction algorithm. A recent tutorial [5] and an earlier survey [26] are also excellent sources of information on this topic.

3D Shape Representation

Many multiview stereo methods represent the 3D scene at an intermediate stage as a set of depth maps, one for each calibrated viewpoint, and recover the 3D shape that is most consistent with all the depth maps [7, 8, 20]. Other methods use explicit surface-based representations. Polygonal meshes are used both as an internal representation in some methods [11] and as the representation for the final 3D shape. Volumetric representations such as a uniform 3D voxel grid where each voxel is labeled as occupied or empty are common as well for their flexibility in approximating a wide variety of shapes [18, 19, 29]. Other volumetric representations such as adaptive tessellation of 3D space into tetrahedral cells can be more compact [13, 25]. Or the voxel grids could be used to store discrete samples of the estimated signed distance function of the 3D shape, from which the final surface is extracted by computing the zero-crossing iso-surface [2]. Finally, patch-based representations are also very common in multiview stereo [6, 9]. Recent multiview stereo methods represent scenes using a finite set of locally planar, oriented 3D patches, referred to as *surfels*. No connectivity information is stored as in a sur-

face mesh. While surface meshes and volumetric representations are advantageous for reconstructing closed surfaces or 3D objects, depth maps or patch-based representations are often better choices for reconstructing large and extended scenes [4, 6, 7, 20, 22].

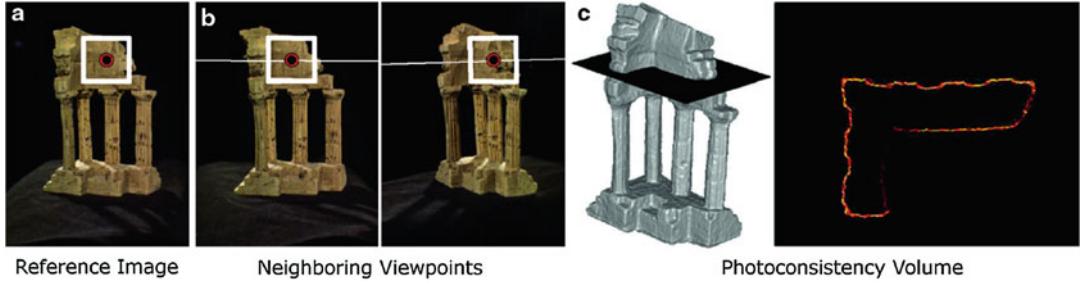

Photoconsistency

The notion of photoconsistency is a fundamental ingredient in all multiview stereo methods. It is a measure for the photometric similarity of the 2D projections of any 3D scene point in a set of calibrated images. For 3D points on surfaces visible in a set of cameras, the 2D projections in those images are expected to be similar or photometrically consistent. Such points are said to have high photoconsistency. On the other hand, arbitrary 3D scene points not on any surface are likely to have low photoconsistency in most situations. Earlier MVS methods computed the photoconsistency of a 3D point by measuring the variance in pixel colors in images at 2D locations where the 3D point projects and is visible. However, comparing individual pixels can be ambiguous. Therefore, a more reliable approach is to compare the similarity of image patches centered at the pixel where a 3D point projects (see Fig. 2). For narrow baselines, it is sufficient to compare square-shaped patches centered on the image pixels and aligned with the image axes. However, by incorporating the geometry of the 3D patch, the matching patch windows can be correctly adjusted to account for scale differences in the images and slanted surfaces.

A pair of 2D image patches can be compared using normalized cross correlation (NCC) after resampling a $n = k \times k$ 2D grid at each patch and comparing the vector of color values denoted here as u and v , respectively:

$$\text{NCC}(u, v) = \frac{\sum_{j=0}^n (u_j - \bar{u}) \cdot (v_j - \bar{v})}{\sqrt{\sum_{j=0}^n (u_j - \bar{u})^2 \cdot \sum_{j=0}^n (v_j - \bar{v})^2}} \quad (1)$$

The NCC values lie in the range $[-1, 1]$ where a value closer to 1 indicates that the vectors are similar in appearance. Other similarity measures such as the sum of absolute differences (SAD),

Multiview Stereo, Fig. 2 (a) A pixel in a reference image and a *square patch* around it. (b) Corresponding pixels and associated patches in the nearby images that lie on respective *epipolar lines*. In calibrated images, the

search for correspondences reduces to 1D, i.e., along the *epipolar line*. (c) A horizontal slice of the 3D cost volume is shown, where the photoconsistency measure is the one proposed in [29]

the sum of squared differences (SSD), or non-parametric measures can be used to compute photoconsistency as well. Unlike NCC, SAD or SSD are affected by brightness changes across images.

Photoconsistency Volume Computation

Many multiview stereo methods require the photoconsistency function to be evaluated densely on a 3D voxel grid for the volume containing the scene which is then referred to as the *cost volume*. Figure 2 shows an example. One simple way to construct this cost volume is to evaluate the photoconsistency of all 3D points (or voxels) using a pairwise similarity measure such as NCC and then compute the average NCC score from multiple pairs of nearby images. There also exist direct methods to compute the cost volume [14] or approaches that are better at minimizing noise in the photoconsistency estimates [29]. Being able to estimate the visibility of a 3D point allows one to select which images contribute to its photoconsistency measure. Such visibility estimation can be done on a per-point basis within the scene [9, 22]. A coarse approximation of the shape such as the visual hull reconstruction obtained from silhouettes is often sufficient when reconstructing closed objects [11, 25, 29]. However, when a large number of images are available, explicit visibility reasoning is typically not needed. Instead, a more robust variant of photoconsistency can be computed, and measurements involving occluded views can be treated as outliers [9, 29].

Another general approach to construct the cost volume involves first estimating depth maps from each camera's viewpoint using a state-of-the-art multi-baseline stereo matching algorithm and then merging them into a consistent volumetric representation. Such an aggregation scheme incorporates visibility information induced by the independently estimated depth maps. Intuitively, this can be seen as a way of probabilistically carving out the 3D volume [8, 12], an idea that is closely related to the problem of fusion of range images [2].

Plane Sweep Stereo and Depth Map Fusion

A class of methods referred to as plane sweep stereo methods avoid building the cost volume on a uniform 3D grid. Instead, they sweep the scene with a set of parallel planes corresponding to the candidate depths considered for pixels in the reference image. These planes are typically fronto-parallel to the reference camera, and their spacing is selected in uniform intervals with respect to their inverse depth from the camera. Neighboring images are warped onto these planes using 2D homographies, and the photoconsistency measure is computed at each pixel for each candidate depth plane. Plane-sweeping strategies are often chosen by incorporating some knowledge of scene structure and are popular for 3D reconstruction in urban scenes [7]. Their main advantage over uniform voxel grids or other 3D tessellations lies in the fact that they represent large working volumes more efficiently, which is important for reconstructing large open scenes.

Plane sweep stereo can be combined with depth map fusion which can be implemented using an image space representation [20]. Artifacts in the original depth maps are reduced in the fused depth maps from which triangulated surface meshes can be directly extracted. The fusion step works better when per-pixel confidence estimates associated with the depth estimates are available.

Optimization Methods

Broadly all multiview stereo methods formulate the reconstruction task in terms of a *local* or *global* optimization problem. A local method such as space carving [19] starts with an overestimate of the 3D scene and uses a greedy strategy to remove voxels that are not photoconsistent one at a time. Similarly, in fast plane sweep stereo [7], each pixel's depth is computed independent of other pixels. These local methods are susceptible to noise and outliers and cannot easily reconstruct smooth geometric shapes. Part of the difficulty is that the 3D reconstruction task is inherently ill-posed since different 3D scenes can be consistent with the same set of images. By assuming that surfaces in the scene are primarily smooth, various global optimization methods seek the optimal 3D shape which maximizes both photoconsistency and smoothness. This is achieved by formulating multiview stereo as a global optimization problem with geometric regularization terms in the objective function or energy function. These are minimized either in the discrete or in the continuous setting.

Global methods for depth map estimation incorporate image-based smoothness constraints into the formulation by designing suitable energy functions that encourage neighboring pixels to take on identical or similar depth values. Such methods are often based on a 2D Markov Random Field (MRF) framework for which efficient optimization algorithms have been developed in recent years. The MRF framework can also be used for enforcing surface regularization in volumetric methods on a 3D uniform grid [29] where any binary labeling of voxels in the grid corresponds to some 3D shape. The optimal surface corresponding to

the global minimum of the energy function can be efficiently computed using graph cut algorithms in many situations [11, 12]. In case of [13, 25], the minimal surface computed using graph cuts directly produces a triangulated mesh. These methods first solve a discrete optimization problem to obtain a globally consistent solution and then perform local refinement using continuous optimization to recover finer geometric details [11, 25]. Continuous optimization methods based on convex relaxations have also been developed to reduce discretization artifacts common in graph cut-based methods [18].

Variational methods can also be used to extract an optimal smooth surface from the cost volume using multiple iterations that progressively minimize a global objective function. In [11], this was achieved by evolving a deformable surface mesh using photoconsistency cues. However, a good initial guess for the 3D shape was required. Methods based on level sets are more flexible as the surface topology is allowed to change during the iterations. These approaches represent the surface as the zero level set of an evolving implicit function [21]. The energy function is minimized by modeling the evolution of the function using partial differential equations. These level-set methods have the advantage of producing smooth surface reconstructions but have the disadvantage of being susceptible to local minima unless a good initialization is available.

M

Patch-Based Multiview Stereo

Another class of popular multiview stereo approaches represent surfaces as a set of oriented patches without storing any connectivity information. This makes the representation flexible and suitable for reconstructing both closed 3D shapes and open scenes. A watertight surface mesh can be extracted using the Poisson surface reconstruction algorithm as a post-processing step. Patch-based methods are related to region-growing methods as they typically start from a few seed 3D points with known depth. The algorithm proposed in [9] starts with a sparse structure from motion 3D point cloud and iteratively optimizes the depth and normals

of the oriented patches using an NCC-based photoconsistency measure. The pixels in the reference image are processed in a matching score-based priority order that ensures that confident estimates are propagated first in the surface-growing phase. This step produces semi-dense depth maps which are then merged to generate a global set of oriented 3D patches. This method was used to perform 3D reconstruction from Internet images of popular places and showed that dense correspondences could be reliably computed from large heterogenous image collections.

Patch-based multiview stereo (PMVS) [6] is another popular algorithm that also uses a seed and grow reconstruction strategy and consists of three important steps. First, seed patches are created from sparse 2D keypoint correspondences in neighboring overlapping views which can be matched with high confidence. These patches are iteratively expanded using a locally planar model to generate new patches. This is followed by a patch optimization and filtering step which refines the position and orientation of the patches and then removes noisy or outlier samples based on photoconsistency and visibility constraints. A publicly available implementation of this algorithm is available as part of the PMVS library [6]. Recently, this library was also extended to support large-scale reconstructions from Internet collections [4].

Robustness is a key challenge in MVS and becomes crucial when dealing with MVS datasets containing images in the wild such as Internet photo collection datasets. The main difficulty in computing dense correspondences lies in dealing with noticeable changes in illumination and viewpoint in the images. Moreover, the images could be captured with different cameras and may have very different image resolutions. Schoenberger et al. [22] proposed a MVS method that deals with these challenges. The main idea behind their technique is to use the PatchMatch scheme to perform joint inference of a depth map and a normal map for each viewpoint and also explicitly estimate a per-pixel visibility and view selection based on geometric and photometric cues. PatchMatch [1] is a general-purpose method to compute dense correspondence between images that

is based on a randomized search scheme involving sampling and optimization and has been used in many different tasks in computer vision.

Learned MVS

Recent advances in using machine learning techniques and, specifically, convolutional neural networks (CNNs) models have led to new improved MVS techniques. A small CNN-based model was proposed to compute a learned matching cost to evaluate the similarity of multiple patches to replace the traditional photoconsistency metric [10]. Their learned model considers a set of patches as input where each patch is sampled from an image captured from a different viewpoint. The shallow model applies on each input patch two sets of successive convolution, tanh nonlinearity and max pooling operations. Subsequently the feature vectors are averaged and passed through three more convolutional layers which outputs the final similarity score. The averaging step provides some flexibility in applying the model on inputs where the number of patches is not fixed. Their model computes a high similarity score when all the patches are corresponding and the underlying 3D point is visible in all the views. Finally, the learned matching cost is used with a standard plane sweep stereo method to compute a depth map for a reference view.

Another notable learned MVS technique is MVSNet [30]. In contrast to [10], theirs is a full CNN model that directly outputs a depth map for a reference view and is end-to-end trainable in a supervised setting. In particular, the MVSNet model extracts deep feature vectors and then computes the 3D cost volume with respect to the reference camera frustum using a differentiable homography warping operation. Next, 3D convolutions are applied to regularize and regress the depth map, which is then refined with the reference image to generate the final output. Their framework can also handle an arbitrary number of input views using a variance-based cost metric that maps multiple features into one cost feature. The differentiable homography warping operation is crucial for encoding camera projections indirectly in a way that makes end-to-end training possible.

Efficiency and Parallelism

Some MVS methods strive for high-fidelity reconstructions and can be very computationally intensive especially with high-resolution images [4, 6, 9, 11, 28]. The main computational bottleneck in multiview stereo lies in the photoconsistency computation or computing matching cost over many pairs of windows. Typically, this can be accelerated by orders of magnitude on massively parallel hardware and is also perfectly suitable for the data parallelism supported on modern programmable graphics hardware (GPUs) with SIMD architectures. Many variants of multiview stereo ranging from plane sweep stereo [7] to depth map fusion [20] have been successfully ported to the GPU, and one or two orders of magnitude speedup have been demonstrated. Modern deep MVS methods [10, 30] also require powerful GPUs to compute the forward pass of the network.

Benchmarks

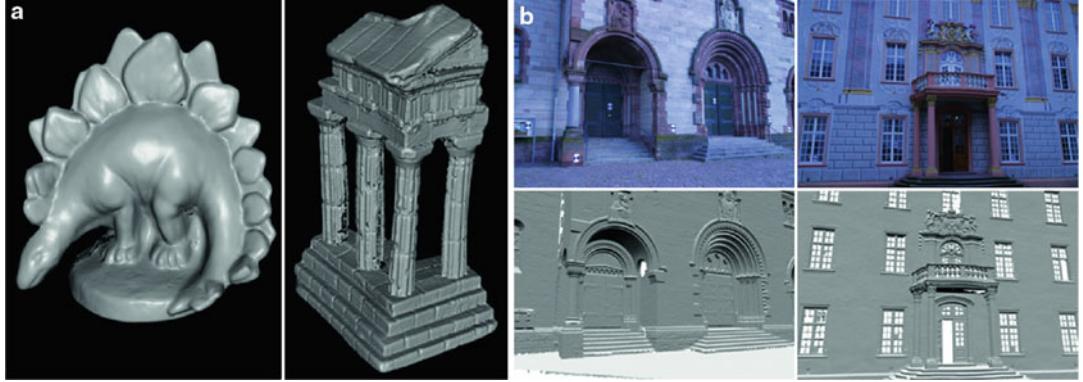

In this section, we discuss datasets available for benchmarking MVS methods.

Middlebury mview benchmark [24] This dataset shown in Fig. 3a contains ground-truth 3D models created by scanning the models using a laser stripe scanner and registering the 3D mesh to the calibrated images captured with a gantry. The benchmark has recently been quite popular for evaluating multiview stereo algorithms. It uses two criteria to evaluate the reconstructions – *accuracy* and *completeness*. The model’s accuracy is calculated by computing the distance between the points sampled on the reconstructed model and the nearest points on the ground-truth model and reporting the distance (in mm) such that 90% of the points on the reconstructed model are within that distance from the ground-truth model. Similarly, the completeness measure is computed for a given threshold by finding the nearest point on the reconstructed mesh for each vertex in the ground-truth mesh and the percentage of points on the ground-truth model that is within a distance threshold of the reconstructed model.

Strecha MVS Datasets [27] Another benchmark for evaluating multiview stereo reconstruction of large scenes is also available. Precise laser-scanned models are provided for ground-truth comparisons. Unlike Middlebury where the scanned models are quite small (only 16 cm on the longest dimension), these datasets consist of high-resolution images and much larger outdoor scenes. Two of the scenes captured in this benchmark are shown in Fig. 3b. Several multiview stereo methods have demonstrated accurate result on these datasets.

Tanks and Temples (<https://www.tanksandtemples.org/>) [17] This benchmark provides a total of 21 sequences captured in indoor and outdoor scenes under uncontrolled conditions. Ground-truth data was acquired using a laser scanner. The benchmark is designed to test dense 3D reconstruction algorithms on high-resolution video sequences. The MVS benchmark is set up in a way such that the ground-truth data geometry for 7 out of 21 datasets is provided as training data. The remaining 14 datasets are used for testing and benchmarking, with 8 and 6 datasets in the *Intermediate* and *Advanced* groups, respectively. Results of MVS algorithms are evaluated by comparing the estimated dense 3D point cloud with the ground-truth 3D point cloud and reporting precision, recall, and F Score metrics.

DTU [15] This benchmark contains several datasets of objects captured in a controlled setting using a robotic arm. The scenes include a wide range of objects and materials with different lighting conditions from directional to diffuse. To collect ground-truth shape information, an industrial robot arm was mounted with a structured light scanner and the images were taken by one of the cameras in the structured light scanner. The dataset consists of 124 different scenes out of which 44 consist mainly of scenes that have been rotated and scanned 4 times with 90 degree intervals which can be used to reconstruct complete 3D models of the objects. The image resolution is 1600×1200 , and accurate camera calibration data is available.

Multiview Stereo, Fig. 3 Multiview stereo benchmarks used for quantitative evaluation: (a) Middlebury *Dino* and *Temple* datasets from the Middlebury multiview stereo benchmark (<http://vision.middlebury.edu/>)

ETH3D [23] Similar to [17], this dataset focuses on outdoor and uncontrolled scenes. Specifically, the dataset contains 13 datasets with 454 high-resolution multiview DSLR images and 5 datasets with 4796 low-resolution multiview video frames. Finally, there are 32 low-resolution two-view stereo pairs captured with rig cameras. For all these datasets, the ground truth is captured using a Faro Focus X 330 laser scanner.

Software

There are now several publicly available open-source MVS implementations as well as commercial photogrammetry packages implementing MVS algorithms. MVS algorithms are being increasingly used for aerial 3D scanning and photogrammetry, 3D object scanning, and general-purpose 3D content creation aimed at games and VR. PMVS2 [6] and CMVS [4] were some of the earlier open-source MVS implementations. Recently, COLMAP (<https://demuc.de/colmap/>) and MVE (<https://www.gcc.tu-darmstadt.de/home/proj/mve/>) [3] were publicly released and provide complete high-quality 3D photogrammetry pipelines including MVS implementations with some interoperability with other structure-from-motion and dense reconstruction pipelines and software. OpenMVS (<http://cdcsseacave.github.io/openMVS/>) is another full pipeline

mview). (b) Large scenes from the outdoor multiview stereo benchmark (<http://cvlab.epfl.ch/strecha/multiview/denseMVS.html>)

for 3D reconstruction of scenes from images. OpenMVS provides MVS implementations in addition to implementations of techniques for the subsequent steps, namely, mesh construction, mesh refinement, and texturing. Some notable examples of commercial photogrammetry tools include those provided by Pix4D (<https://www.pix4d.com>), Agisoft (<https://www.agisoft.com>), and Altizure (<https://www.altizure.com>).

Definition

Two numerical approximations of curvature-driven flows are described for use in computer vision and image processing. The level-set methodology of Osher-Sethian that dominates the field is of particular interest, and a more recent, alternative interpretation of curvature flow, based

on a stochastic evolution of density functions, is also presented.

Background

Two separate methods for the numerical approximation and computer implementation of curvature-driven flows in the plane are described. The first has become, perhaps, the standard in the field: the level-set methodology of Osher and Sethian [1–4]. This approach and its variants (fast marching, narrow banding, etc.) dominate the literature and practice in computer vision and image processing.

There are, however, other possibilities that may be useful when estimation is necessary. For example, when tracking in a noisy, uncertain environment, the lack of a geometric prior tends to result in undesired topological changes (e.g., merging and breaking of contours) in response to noise in the image data. There are several possibilities that may be considered for such scenarios described in books [5, 6]. A completely stochastic method from [7, 8] also acts as a useful approximation in many circumstances. A stochastic interpretation of curve-shortening flows is formulated, bringing together the theories of curve evolution and hydrodynamical limits, and thus impacts the growing use of joint methods from probability and PDEs in image processing and computer vision.

It is emphasized that the various ways of numerically implementing curvature-driven flows in vision described above should be regarded as complementary: each approach has its own advantages depending on the application. Thus, it is not intended to compare or critique the methods in the present work; rather, they described in some detail and give the interested reader a guide to the relevant literature. Thus, this entry will have a strong tutorial flavor. Finally, derivations herein are not considered in complete generality. For most of the entry, simply consider the simplest case of Euclidean curve shortening [9–11].

Theory

Evolution Equations

This section reviews mathematical background on the basic evolution equations used in computer vision. For complete details, the interested reader is referred to books [12, 13] that also have an extensive list of references.

Consider the families of embedded closed curves $\mathcal{C} : S^1 \times (0, T) \rightarrow \mathbb{R}^2$ evolving according to functions of the curvature. Here, S^1 denotes the unit circle. (Since this discussion is informal, strong restrictions are not placed of the families of curves under consideration. See [9–11, 14] a formal mathematical treatment.) More precisely, in vision problems, the general deformation of a curve in the plane of interest is given by

$$\frac{\partial \mathcal{C}}{\partial t} = \alpha(p, t) \mathcal{T} + \hat{\beta}(p, t) \mathcal{N}, \quad (1)$$

where \mathcal{N} is the unit (inward) normal, \mathcal{T} is unit tangent, and $\alpha, \hat{\beta}$ are smooth functions. Note that positive orientation of a curve is defined such that the interior is to the left when traversing the curve. The *curvature*, *orientation*, and *length* are defined in the standard way. The normal is taken to point inward, where the inward or outward directions are determined by the interior or equivalently by the orientation of the curve. Notice that since only shape is of interest, it is admissible to take $\alpha = 0$; changing α only changes the curve's parametrization and not its shape. Furthermore, as is typical in this area, the deformations are constrained to be determined by the local geometry of the curve, that is, $\hat{\beta}(p, t) = \beta(\kappa)$ where $\kappa(p, t)$ denotes the Gaussian curvature of the curve $\mathcal{C}(p, t)$. The following basic equations are obtained for curve evolution under curvature-driven flow:

$$\frac{\partial \mathcal{C}}{\partial t} = \beta(\kappa) \mathcal{N}. \quad (2)$$

In the mathematics literature, a number of cases for the function β have been explored. For example, there has been a great deal of work in connection with the geometric heat equation in which $\beta(\kappa) = \kappa$. In this case, the

isoperimetric ratio L^2/A (L is the length of the closed curve and A is the area enclosed by the curve) approaches 4π as the enclosed area approaches 0; in other words, the curve shrinks to a *round point* as shown in [9, 10]. In computer vision problems, the function $\beta(\kappa)$ typically takes the form

$$\beta(\kappa) = a\kappa + 1, \quad (3)$$

where $a \geq 0$. The case $a = 0$, that is, $\beta \equiv 1$ is very important; Eq. (2) reduces to an equation that has been studied in relation to problems in geometric optics [15], flame propagation [16], and shape morphology [17], as well as shape decomposition. Indeed, this is the differential equation for the Blum prairie fire model. In (3), $a\kappa$ adds a diffusive effect, while the constant part adds a wave (hyperbolic) effect, which tends to create singularities and break a shape into its constituent parts. This point is elaborated below.

Some general properties of Eq. (2) are presented, beginning with some standard notation. Let

$$\rho(p, t) := \left\| \frac{\partial C}{\partial p} \right\| = \left[x_p^2 + y_p^2 \right]^{1/2} \quad (4)$$

denote the length along the curve. The arc-length parameter s is then defined as

$$s(p, t) := \int_0^p \rho(\xi, t) d\xi. \quad (5)$$

Then it follows that

$$\mathcal{T} := \frac{\partial \mathcal{C}}{\partial s} = \frac{1}{\rho} \frac{\partial \mathcal{C}}{\partial p}, \quad (6)$$

$$\kappa := \frac{1}{\rho} \left\| \frac{\partial \mathcal{T}}{\partial p} \right\|, \quad (7)$$

$$\mathcal{N} := \frac{1}{\kappa \rho} \frac{\partial \mathcal{T}}{\partial p}, \quad (8)$$

$$L(t) := \int_0^1 \rho(p, t) dp. \quad (9)$$

Finally, let

$$\bar{\kappa}(t) := \int_0^1 |\kappa(p, t)| \rho(p, t) dp \quad (10)$$

denote the total absolute curvature.

Behavior of the classical solutions to Eq. (2) has been thoroughly analyzed and a number of useful results (from the applied point of view) have been proved [2, 3, 14, 18]; the results are summarized below. Let $\mathcal{C}(p, t)$ be a classical solution of Eq. (2) for $t \in [0, t')$ and suppose that $\kappa\beta(\kappa) \leq M$ for all $\kappa \in \mathbf{R}$ (regarding β as a function of κ). Then,

$$L(t) \leq L(0)e^{M t}. \quad (11)$$

In the case $\beta(\kappa) = a\kappa + 1$,

$$L(t) \leq \min \left(L(0) + 2\pi t, L(0)e^{\frac{t}{4a}} \right). \quad (12)$$

Let $\mathcal{C}^{(t)}(p) := \mathcal{C}(p, t)$ be a classical solution of (2) for $t \in [0, t')$. Suppose that $\kappa\beta(\kappa) \leq M$ and $\beta_\kappa \leq 0$. Then,

$$\bar{\kappa}(t) \leq \bar{\kappa}(0). \quad (13)$$

Moreover, if $(0, t')$ is an interval on which a classical solution exists, one may also show that

$$d_H \left(\mathcal{C}^{(t)}, \mathcal{C}^{(0)} \right) \leq \sqrt{4at}, \quad (14)$$

where d_H denotes the Hausdorff metric on compact subsets of \mathbb{R}^2 . The above facts easily imply that

$$\lim_{t \rightarrow t'} \mathcal{C}^{(t)} = \mathcal{C}^* \quad (15)$$

in the Hausdorff metric, and curve \mathcal{C}^* , regarded as a mapping $S^1 \rightarrow \mathbb{R}^2$, is Hölder continuous with exponent 1/2. In vision, a major area of interest is weak solutions of equations of type (2), whose details follow in section “Geometric Heat Equation”.

Geometric Heat Equation

In this section, a key flow for nonlinear scale space and active geometric contours is presented. This flow is achieved by setting $\beta(\kappa) = \kappa$ in (2).

So, when $\beta(\kappa) = \kappa$, where κ is the curvature, and \mathcal{N} the inward unit normal, a plane curve evolves according to the *geometric heat equation*

$$\frac{\partial \mathcal{C}}{\partial t} = \kappa \mathcal{N}. \quad (16)$$

This equation has a number of properties which make it very useful in image processing and in particular, the basis of a nonlinear scale space for shape representation [19].

Indeed, Eq. (16) is the Euclidean curve-shortening flow in the sense that the Euclidean perimeter shrinks as quickly as possible when the curve evolves according to Eq. (16) [9–11]. Since similar argument is needed for the snake model discussed in the next section, details are presented.

Let $\mathcal{C} = \mathcal{C}(p, t)$ be a smooth family of closed curves where t parameterizes the family and p the given curve, say $0 \leq p \leq 1$. (Assume that $\mathcal{C}(0, t) = \mathcal{C}(1, t)$ and similarly for the first derivatives.) Consider the length functional

$$L(t) := - \int_0^1 \left\| \frac{\partial \mathcal{C}}{\partial p} \right\| dp.$$

After differentiating and using integration by parts,

$$\begin{aligned} L'(t) &= \int_0^1 \frac{\left\langle \frac{\partial \mathcal{C}}{\partial p}, \frac{\partial^2 \mathcal{C}}{\partial p \partial t} \right\rangle}{\left\| \frac{\partial \mathcal{C}}{\partial p} \right\|} dp \\ &= - \int_0^1 \left\langle \frac{\partial \mathcal{C}}{\partial t}, \frac{1}{\left\| \frac{\partial \mathcal{C}}{\partial p} \right\|} \frac{\partial}{\partial p} \left[\frac{\partial \mathcal{C}}{\partial p} \right] \right\| \frac{\partial \mathcal{C}}{\partial p} \right\rangle dp \end{aligned}$$

(multiplying and dividing by $\left\| \frac{\partial \mathcal{C}}{\partial p} \right\|$ in the latter integral). Observing that

$$\left\| \frac{\partial \mathcal{C}}{\partial p} \right\| dp =: ds$$

is (Euclidean) arc length, and using the definition of curvature, the last integral becomes

$$-\int_0^{L(t)} \left\langle \frac{\partial \mathcal{C}}{\partial t}, \kappa \mathcal{N} \right\rangle ds$$

and

$$L'(t) = - \int_0^{L(t)} \left\langle \frac{\partial \mathcal{C}}{\partial t}, \kappa \mathcal{N} \right\rangle ds.$$

Using the Cauchy-Schwartz inequality,

$$\left\langle \frac{\partial \mathcal{C}}{\partial t}, \kappa \mathcal{N} \right\rangle \leq \|\mathcal{C}_t\|_{L^2} \|\kappa \mathcal{N}\|_{L^2};$$

therefore, the direction in which $L(t)$ is decreasing most rapidly is given by

$$\frac{\partial \mathcal{C}}{\partial t} = \kappa \mathcal{N}.$$

Thus, (16) is precisely a gradient flow.

A much deeper fact is that simple closed curves converge to *round points* when evolving according to (16) without developing singularities; see [9, 10]. This fact is key for geometric active contour models considered below.

Level Curve Representations

When applying curvature-driven flows, as above, to images, it is necessary to move from curves to (gray-scale) images. Thus, it is essential to be able to relate curve evolution theory to operations on 2D images. Fortunately, the powerful algorithms developed by Osher and Sethian for curve evolution allow precisely this. In this section, a sketch is given of the beautiful work of Osher and Sethian on level curve evolutions. For more details, see [1, 2, 4].

Let $\mathcal{C}(p, t) : S^1 \times (0, T) \rightarrow \mathbb{R}^2$ be a family of curves satisfying the following evolution equation:

$$\frac{\partial \mathcal{C}}{\partial t} = \beta(\kappa) \mathcal{N}. \quad (17)$$

There are a number of problems which must be resolved when implementing curve evolution

equations such as (17) numerically. For example, singularities may develop. Note for $\beta \equiv 1$ in (17) that even a smooth initial curve can develop singularities. The question is how to continue the evolution after the singularities appear. A natural way is to choose the solution which agrees with the Huygens principle [3, 16], or as Sethian observed, if the front is viewed as a burning flame, this solution is based on the principle that *once a particle is burnt, it stays burnt* [3, 16]. As indicated above that from all the *weak* solutions corresponding to (17), the one derived from the Huygens principle is *unique* and can be obtained via the entropy condition constraint.

In any numerical algorithm, the key requirements of accuracy and stability must be addressed. The numerical algorithm must approximate the evolution equation, and it must be robust. Osher and Sethian [1–4] showed that a simple, Lagrangian difference approximation requires an impractically small time step in order to achieve stability. The basic problem with Lagrangian formulations is that the marker particles on the evolving curve can become unevenly distributed along the curve during the evolution.

The algorithm proposed by Osher and Sethian [1–4] provides a reliable numerical solution for curve (and hypersurface) evolution. It is based on the Hamilton-Jacobi equation and viscosity theory. First, the curve is embedded in a two-dimensional surface, and then, the equations of motion are solved using a combination of straightforward discretization and numerical techniques derived from hyperbolic conservation laws [20].

The embedding step is done in the following manner: the curve $\mathcal{C}(p, t)$ is represented by the zero level set of a smooth and Lipschitz continuous function $\Phi : \mathbb{R}^2 \times [0, \tau) \rightarrow \mathbf{R}$. Assume that Φ is negative in the interior and positive in the exterior of the zero level set. The zero level set defined by

$$\left\{ X(t) \in \mathbb{R}^2 : \Phi(X, t) = 0 \right\}. \quad (18)$$

It is necessary to find an evolution equation of Φ such that the evolving curve $\mathcal{C}(t)$ is given by

the evolving zero level $X(t)$, that is,

$$\mathcal{C}(t) \equiv X(t). \quad (19)$$

By differentiating $\Phi(X, t)$ with respect to t ,

$$\nabla \Phi(X, t) \cdot X_t + \Phi_t(X, t) = 0. \quad (20)$$

Note that at the zero level, the following relation holds:

$$\frac{\nabla \Phi}{\|\nabla \Phi\|} = -\mathcal{N}. \quad (21)$$

In this equation, the left side uses terms of the surface Φ , while the right side is related to the curve \mathcal{C} . Using Eqs. (17)–(21),

$$\Phi_t = \beta(\kappa) \|\nabla \Phi\|, \quad (22)$$

and the curve \mathcal{C} , evolving according to (17), remains equal to the zero level set of the function Φ , which evolves according to (22), throughout the evolution. Osher and Sethian [2] called this scheme an *Eulerian formulation* for front propagation because it is written in terms of a fixed coordinate system. Moreover, notice that Eq. (22) gives the extension of curve evolution equations to gray-scale images when Φ is interpreted as intensity.

The second step of the algorithm consists of discretizing Equation (22). If singularities cannot develop during the evolution, as in the geometric heat equation flow, a straightforward discretization can be performed [2]. If singularities can develop, as in the case of $\beta = 1$, a special discretization must be implemented. In this case, the implementation of the evolution of Φ is based on a *monotone* and *conservative* numerical algorithm derived from the theory of hyperbolic conservation laws [2, 20, 21]. For a large class of functions β of this type, this numerical scheme automatically obeys the entropy condition, that is, the condition derived from Huygens principle [20]. For velocity functions of the form $\beta = a\kappa + 1$, a combination of both methods is used [1, 2, 4].

Of particular interest for handling hyperbolic systems is the *upwinding* discretization [21]. For example, with a second-order upwinding scheme, a flux term $\frac{\partial}{\partial x} F(u) = f(u)u_x$ is discretized at a grid coordinate x_i as

$$\begin{aligned}\frac{\partial}{\partial x} F(u)\Big|_{x_i} &:= f^+ u_x^- + f^- u_x^+, \\ f^+ &:= \max(f(u_i), 0), \\ f^- &:= \min(f(u_i), 0), \\ u_x^- &:= \frac{3u_i - 4u_{i-1} + u_{i-2}}{2\Delta x},\end{aligned}$$

Such an approximation for spatial derivatives enables sharp features in the curve to be preserved while satisfying stability conditions.

It is important to note that the discretization of the evolution equations is performed on a fixed *rectangular grid* [1, 4]. This rectangular grid can be associated with the *pixel* grid of digital images making this discretization method natural for image processing. Since the evolving curve is given by the level set of the function Φ , it is necessary to find this level set (Φ is discrete now). This is done using a very simple contour-finding algorithm described in [1, 4].

Curve Shortening as a Semilinear Diffusion Equation

In this section, stochastic algorithms for implementing curvature-driven flows following [7, 8] are described. In order to formulate a stochastic implementation of the curvature-driven flows described above, it is necessary to reexamine the evolution equations from a different point of view and to modify slightly some previous notation.

As above, let $\mathcal{C} : \mathbb{T} \times (0, T) \rightarrow \mathbb{R}^2$ be a family of plane curves, evolving according to the curve shortening or geometric heat equation [9–11]. As already described, such a family moves by curve shortening

$$\frac{\partial \mathcal{C}}{\partial t} = \frac{\partial^2 \mathcal{C}}{\partial s^2} \quad (23)$$

if and only if its curvature $\kappa(p, t)$ satisfies

$$\frac{\partial \kappa}{\partial t} = \kappa_{ss} + \kappa^3. \quad (24)$$

For a given differentiable curve f in the family \mathcal{C} , the partial derivative with respect to the arc-length variable s is defined by

$$\frac{\partial f}{\partial s} = \frac{1}{g(p, t)} \frac{\partial f}{\partial p}, \text{ with } g(p, t) = \left\| \frac{\partial \mathcal{C}}{\partial p} \right\|. \quad (25)$$

And g evolves by

$$\frac{\partial g}{\partial t} = -\kappa^2 g.$$

The length

$$L(t) = \int_{\mathcal{C}} ds = \int_0^1 g(p, t) dp$$

evolves by

$$L'(t) = - \int_{\mathcal{C}} \kappa^2 ds = - \int_0^1 \kappa(p, t)^2 g(p, t) dp. \quad (26)$$

Renormalized arc length is given by

$$\sigma(p, t) = \frac{1}{L(t)} \int_0^p ds = \frac{1}{L(t)} \int_0^p g(p', t) dp' \quad (27)$$

and evolves according to

$$\begin{aligned}\frac{\partial \sigma}{\partial t} &= -\frac{L'}{L} \sigma - \frac{1}{L} \int_0^p \kappa^2 ds \\ &= -\frac{L'}{L} \sigma - \int_0^p \kappa^2 d\sigma \\ &= - \int_0^p \kappa^2 d\sigma + \sigma \int_0^1 \kappa^2 d\sigma.\end{aligned}$$

The curves are parameterized by σ . The curvature, as a function of σ , is denoted by $\hat{\kappa}$:

$$\hat{\kappa}(\sigma(p, t), t) = \kappa(p, t).$$

Some calculus involving the chain rule shows that

$$\frac{\partial \hat{\kappa}}{\partial t} = \frac{\partial \kappa}{\partial t} - \frac{\partial \sigma}{\partial y} \hat{\kappa},$$

and hence,

$$\frac{\partial \hat{\kappa}}{\partial t} = \frac{1}{L^2} \hat{\kappa}_{\sigma\sigma} + \left(\int_0^\sigma \hat{\kappa}^2 d\sigma' - \sigma \int_0^1 \hat{\kappa}^2 d\sigma \right) \hat{\kappa}_\sigma + \hat{\kappa}^3.$$

Multiplying both sides by $L(t)^3$

$$\begin{aligned} L^3 \frac{\partial \hat{\kappa}}{\partial t} &= (L \hat{\kappa})_{\sigma\sigma} + \left(\int_0^\sigma (L \hat{\kappa})^2 d\sigma' \right. \\ &\quad \left. - \sigma \int_0^1 (L \hat{\kappa})^2 d\sigma \right) (L \hat{\kappa})_\sigma + (L \hat{\kappa})^3 \end{aligned}$$

and defining an (unnormalized) density function according to

$$K(\sigma, t) = L(t) \hat{\kappa}(\sigma, t),$$

the following time derivative is obtained:

$$\frac{\partial K}{\partial t} = L \frac{\partial \hat{\kappa}}{\partial t} + L' \hat{\kappa}.$$

By (26),

$$L'(t) = - \int_{p=0}^1 \kappa^2 ds = -L \int_0^1 \hat{\kappa}(\sigma, t)^2 d\sigma,$$

and so,

$$\begin{aligned} L^2 \frac{\partial K}{\partial t} &= L^3 \frac{\partial \hat{\kappa}}{\partial t} + K(\sigma, t) \int_0^1 K(\sigma', t)^2 d\sigma' \\ &= K_{\sigma\sigma} + \left(\int_0^\sigma K^2 d\sigma' - \sigma \int_0^1 K^2 d\sigma' \right) K_\sigma \\ &\quad + K \left(K^2 - \int_0^1 K^2 d\sigma' \right) \\ &= \frac{\partial}{\partial \sigma} \left\{ \frac{\partial K}{\partial \sigma} + \left(\int_0^\sigma K^2 d\sigma' - \sigma \int_0^1 K^2 d\sigma' \right) K \right\}. \end{aligned}$$

Let

$$b_K(\sigma, t) = \int_0^\sigma K^2 d\sigma' - \sigma \int_0^1 K^2 d\sigma'$$

be the *drift coefficient*; this equation can be written as

$$L^2 \frac{\partial K}{\partial t} = K_{\sigma\sigma} + (b_K K)_\sigma.$$

Note that the total curvature of an embedded closed curve is always 2π , so the following conservation law must hold:

$$\oint k ds = \int_0^1 K(\sigma, \tau) d\sigma = 2\pi. \quad (28)$$

This equation can be turned into an autonomous system by introducing a new time variable

$$\tau(t) = \int_0^t \frac{dt'}{L(t')^2}$$

so that $L^2 \frac{\partial}{\partial t} = \frac{\partial}{\partial \tau}$. Note that this has the effect of pushing the singularity to infinity, that is, the equation does not blow up at all. From the results of [10, 11, 14], this property means that there is no blowup as long as $\tau(t)$ is finite.

Thus,

$$\frac{\partial K}{\partial \tau} = K_{\sigma\sigma} + (b_K K)_\sigma$$

$$\frac{dL}{d\tau} = -L \int_0^1 K^2 d\sigma$$

$$\frac{dt}{d\tau} = L^2.$$

A system which admits only nonnegative densities can be obtained by setting $K = \lambda - \mu$ and letting λ and μ evolve by the following system:

$$\frac{\partial \lambda}{\partial \tau} = \lambda_{\sigma\sigma} + (b_{\lambda-\mu} \lambda)_\sigma \quad (29)$$

$$\frac{\partial \mu}{\partial \tau} = \mu_{\sigma\sigma} + (b_{\lambda-\mu} \lambda)_\sigma \quad (30)$$

$$\frac{dL}{d\tau} = -L \int_0^1 (\lambda - \mu)^2 d\sigma \quad (31)$$

$$\frac{dt}{d\tau} = L^2 \quad (32)$$

in which

$$\begin{aligned} cb_{\lambda-\mu}(\sigma, \tau) &= \int_0^\sigma \{ \lambda(\sigma', \tau) - \mu(\sigma', \tau) \}^2 d\sigma' \\ &\quad - \sigma \int_0^1 \{ \lambda(\sigma', \tau) - \mu(\sigma', \tau) \}^2 d\sigma' \end{aligned} \quad (33)$$

and

$$(b_{\lambda-\mu})_\sigma = (\lambda - \mu)^2 - \int_0^1 (\lambda - \mu)^2 d\sigma \quad (34)$$

are simply the average-free part of $(\lambda - \mu)^2$.

The maximum principle will keep both λ and μ positive as long as $\lambda(\cdot, t_0), \mu(\cdot, t_0) \geq 0$. For any given initial $K(\cdot, t_0)$, a suitable initial partition can be, for example,

$$\begin{aligned} \lambda(\sigma, t_0) &= \max(K(\sigma, t_0), 0), \\ \mu(\sigma, t_0) &= \max(-K(\sigma, t_0), 0) \end{aligned}$$

(which have disjoint support) or

$$\begin{aligned} \mu(\sigma, t_0) &= \mu = -\min_{0 \leq \sigma \leq 1} K(\sigma, t_0), \\ \lambda(\sigma, t_0) &= \mu + K(\sigma, t_0). \end{aligned}$$

Recovering the Curve

Equations (29)–(32) will only determine the curve itself up to rotation and translation. Therefore, given the initial curve \mathcal{C}_0 , it is necessary to couple these equations with the evolution equation

$$\frac{\partial \mathcal{C}}{\partial \tau} = (\lambda - \mu) \mathcal{N}, \quad (35)$$

where \mathcal{N} denotes the (inner) unit normal. Further, it is possible to decompose the evolving curve $\mathcal{C}(\tau)$ into translational $\mathbf{T}(\tau)$ and rotational $\mathbf{R}(\tau)$ components composed with an evolving curve

$\mathcal{C}(\tau)$ whose evolution involves no overall translation or rotation, that is,

$$\mathcal{C}(\tau) = \mathbf{R}(\tau) \mathcal{C}(\tau) + \mathbf{T}(\tau).$$

According to this decomposition, the evolution of \mathcal{C} is given by

$$\frac{\partial \mathcal{C}}{\partial \tau} = \mathbf{R}' \mathcal{C} + \mathbf{R} \frac{\partial \mathcal{C}}{\partial \tau} + \mathbf{T}' = (\lambda - \mu) \mathcal{N}. \quad (36)$$

Thus, starting from an initial \mathcal{C} (and initial $\mathbf{R} = \mathbf{I}$ and $\mathbf{T} = \mathbf{0}$), it is possible to solve for \mathbf{R}' and \mathbf{T}' using Eq. (36) at two or more points on the curve in order to completely specify the evolution of \mathcal{C} .

Stochastic Implementation

A stochastic implementation can be created by the evolution of a *density* corresponding to Eqs. (29), (30). Accordingly, using parametrization σ , the quantities λ and μ are interpreted as densities.

The approximations used here are based on so-called interacting particle systems as described in [22]. Notice that because of the special parametrization, the diffusion terms of Eqs. (29) and (30) are linear. In this case, there will be two types of particles, one simulating the λ and the other the μ , and the particles interact through the drift rate.

Let $T_N = \mathbb{Z}/N\mathbb{Z}$ denote the discrete torus. The configuration of particles at time τ is given by the pair of functions $(\eta_\tau^\lambda(\cdot), \eta_\tau^\mu(\cdot)) : T_N \rightarrow \mathbb{N}^2$, and the construction is such that $(\eta_\tau^\lambda([\sigma N]), \eta_\tau^\mu([\sigma N]))$ converges to $(\lambda(\sigma, \tau), \mu(\sigma, \tau))$.

Let the *diffusion rates* $\mathbb{N} \rightarrow \mathbb{R}_+$ (with $g(0) = 0$) and the *drift rate* $h^\lambda, h^\mu : T_N \times \mathbb{R}_+^{N^2} \rightarrow \mathbb{R}$ be given and define the Markov generator on the particle configuration $E_N = \mathbb{N}^{T_N} \times \mathbb{N}^{T_N}$ by

$$\begin{aligned} (\mathcal{L}^N f)(\eta^\lambda, \eta^\mu) &= N^2 (\mathcal{L}_0 f)(\eta^\lambda, \eta^\mu) \\ &\quad + N (\mathcal{L}_1 f)(\eta^\lambda, \eta^\mu), \quad f \in C_b(E_N), \end{aligned}$$

where

$$\begin{aligned} (\mathcal{L}_0 f)(\eta^\lambda, \eta^\mu) = & \frac{1}{2} \sum_{i \in T_N} g(\eta^\lambda(i)) \left[f(\eta^{i,i+1,\lambda}, \eta^\mu) \right. \\ & + f(\eta^{i,i-1,\lambda}, \eta^\mu) - 2f(\eta^\lambda, \eta^\mu) \Big] \\ & + \frac{1}{2} \sum_{i \in T_N} g(\eta^\mu(i)) \left[f(\eta^\lambda, \eta^{i,i+1,\mu}) \right. \\ & \left. + f(\eta^\lambda, \eta^{i,i-1,\mu}) - 2f(\eta^\lambda, \eta^\mu) \right] \end{aligned}$$

and

$$\begin{aligned} (\mathcal{L}_1 f)(\eta^\lambda, \eta^\mu) = & \sum_{i \in T_N} h^\lambda(i, \eta^\lambda, \eta^\mu) \\ & + \left[f(\eta^{i,i+\text{sgn}(h^\lambda(i, \eta^\lambda, \eta^\mu)), \lambda}, \eta^\mu) - f(\eta^\lambda, \eta^\mu) \right] \\ & + \sum_{i \in T_N} h^\lambda(i, \eta^\lambda, \eta^\mu) \left[f(\eta^\lambda, \eta^{i,i+\text{sgn}(h^\mu(i, \eta^\lambda, \eta^\mu)), \mu}) \right. \\ & \left. - f(\eta^\lambda, \eta^\mu) \right], \end{aligned}$$

where, with $\star \in \{\lambda, \mu\}$,

$$\begin{aligned} \eta^{i,i\pm 1,\star}(j) &= \begin{cases} \eta^\star(j) + 1, & j = i \pm 1, \eta^\star(i) \neq 0, \\ \eta^\star(j) - 1, & j = 1, \eta^\star(i) \neq 0, \\ \eta^\star(j), & \text{else} \end{cases} \\ \eta^{i,+,\star}(j) &= \begin{cases} \eta^\star(j) + 1, & j = i, \\ \eta^\star(j), & \text{else} \end{cases} \\ \eta^{i,-,\star}(j) &= \begin{cases} \eta^\star(j) - 1, & j = i, \eta^\star(i) > 0, \\ \eta^\star(j), & \text{else} \end{cases} \end{aligned}$$

Note that \mathcal{L}_0 will be used to approximate the diffusion term of Eqs. (29), (30), while \mathcal{L}_1 will be used to approximate the drift term.

Recall that for a Poisson random variable X of parameter α , one has

$$E(X^2) = \alpha^2 + \alpha, E(X) = \alpha.$$

Thus, referring to Eq. (34), in order to define the rates, set the function $B : E_N \times T_N \rightarrow \mathbb{R}_+$ as

$$\begin{aligned} B(\eta, \eta')(j) = & \frac{1}{N} \sum_{i=1}^j \left([\eta(i) - \eta'(i)]^2 \right. \\ & \left. - [\eta(i) + \eta'(i)] - c \right), \\ c = & \frac{1}{N} \sum_{i=0}^{N-1} \left([\eta(i) - \eta'(i)]^2 \right. \\ & \left. - [\eta(i) + \eta'(i)] \right). \end{aligned} \tag{37}$$

Note that if $\eta(j), \eta'(j)$ are taken as independent Poisson variables of rates $\lambda(j/N, \tau), \mu(j/N, \tau)$, respectively, then

$$E(B(\eta, \eta')(j)) = b_{\lambda(j/N, \tau) - \mu(j/N, \tau)}.$$

Following [7, 22], for (29), the rates can be taken as follows:

$$\begin{aligned} g(k) = k, h^\lambda(i, \eta, \eta') &= -B(\eta, \eta')(i)\eta(i), \\ h^\mu(i, \eta, \eta') &= -B(\eta, \eta')(i)\eta'(i). \end{aligned}$$

Note that it is necessary to take the minus sign in the drift since the equation describes a forward diffusion. The rate for g is, of course, classical, and the drift rate h is similar to [22], when one takes into account the extra averaging due to the nonlocal nature of the function $b_{\lambda-\mu}$.

Conclusions

Geometric-based partial differential equations and curve evolution theory have proven to be powerful tools for a number of key topics in computer vision and image processing. In this note, the theory and practice of two numerical approaches used to implement these flows on a computer have been introduced: the first is based on level sets, and the second is based on a stochastic interpretation of certain equations as zero-range birth-death diffusion processes.

These equations are straightforward to implement in code and extend naturally to the case of Lagrangians driven by image or video data. The ease of implementation coupled with the natural ability to regularize intrinsic geometry and deal with topological changes has contributed to the popularity of these methods. Some of the key applications include active contours for segmentation and tracking, which may be found in works such as [6, 23, 24].

Definition

Object detection involves detecting instances of objects from one or several classes in an image.

Background

The goal of object detection is to detect all instances of objects from one or several known classes, such as people, cars, or faces in an image. Typically only a small number of objects are present in the image, but there is a very large number of possible locations and scales at which they can occur and that need to somehow be explored.

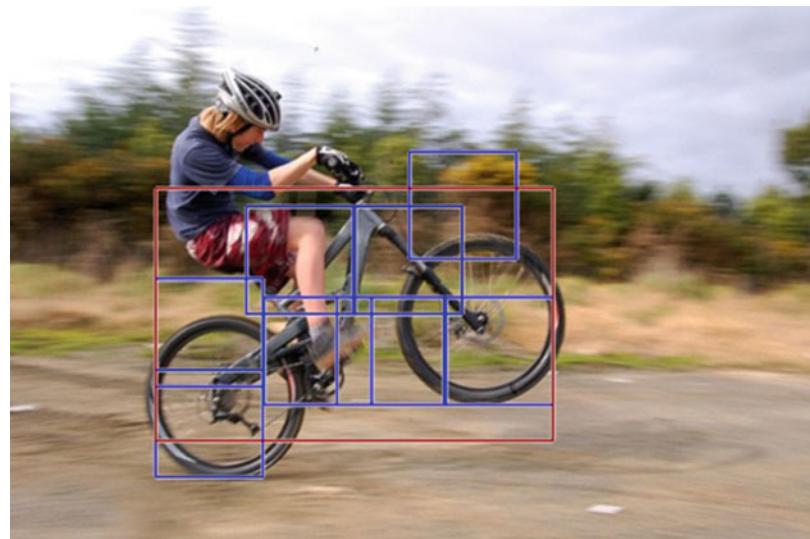

Each detection is reported with some form of *pose* information. This could be as simple as the location of the object, a location and scale, a bounding box, or a segmentation mask. In other situations the pose information is more detailed and contains the parameters of a linear or nonlinear transformation. For example a face detector may compute the locations of the eyes, nose, and mouth, in addition to the bounding box of the face. An example of a bicycle detection that specifies the locations of certain parts is shown in Fig. 1. The pose could also be defined by a three-dimensional transformation specifying the location of the object relative to the camera.

Object detection systems construct a model for an object class from a set of training examples. In the case of a fixed rigid object, only one example may be needed, but more generally multiple training examples (often hundreds or thousands) are necessary to capture certain aspects of class variability. Broadly speaking, less training data is needed when more information about class variability can be explicitly built into the model. However, it may be difficult to specify models that capture the vast variability found in images. An alternative approach is to use methods such as convolutional neural networks [1] that learn about class variability from large datasets.

Object detection approaches typically fall into one of two major categories, *generative* methods (see, e.g., [2–6]) and *discriminative* methods (see, e.g., [7–11]). A generative method consists of a probability model for the pose variability of the objects together with an appearance model:

Object Detection, Fig. 1

A bicycle detection specified in terms of the locations of certain parts

a probability model for the image appearance conditional on a given pose, together with a model for background, i.e., non-object images. The model parameters can be estimated from training data, and the decisions are based on ratios of posterior probabilities. A discriminative method typically builds a classifier that can discriminate between images (or sub-images) containing instances of the target object classes and those not containing them. The parameters of the classifier are selected to minimize mistakes on the training data, often with a regularization bias to avoid overfitting.

Other distinctions among detection algorithms have to do with the *computational* tools used to scan the entire image or search over possible poses, the type of image *representation* with which the models are constructed, and what type and how much training data is required to build a model.

Theory

Images of objects from a particular class are highly variable. One source of variation is the actual imaging process. Changes in illumination and changes in camera position as well as digitization artifacts all produce significant variations

in image appearance, even in a static scene. The second source of variation is due to the intrinsic appearance variability of objects within a class, even assuming no variation in the imaging process. For example, people have different shapes and wear a variety of clothes, while the handwritten digit 7 can be written with or without a line through the middle, with different slants, stroke widths, etc. The challenge is to develop detection algorithms that are *invariant* with respect to these variations and are computationally efficient.

Invariance

The brute force approach to invariance assumes training data is plentiful and represents the entire range of object variability. Invariance is implicitly learned from the data while training the models. In recent years, with the increase in annotated dataset size and computational acceleration using GPUs, this has been the approach of choice in the context of the multi-layer convolutional neural network paradigm, as discussed later in this article.

When training data is limited, it is necessary to build invariance into the models. There are two complementary methods to achieve this. One involves computing invariant functions and features; the other involves searching over latent variables. Most algorithms contain a combination

of these approaches. For example many algorithms choose to apply local transformations to pixel intensities in such a way that the transformed values are invariant to a range of illumination conditions and small geometric variations. These local transformations lead to *features*, and the array of feature values is the *feature map*. More significant transformations are often handled through explicit search of latent variables or by learning the remaining variability from training data.

Invariant functions and features This method constructs functions of the data that are invariant with respect to the types of variability described above and can still distinguish between object and background images. This may prove difficult if object variability is extensive. Invariant functions that produce the same output no matter the pose and appearance of the object necessarily have less discriminative power.

There are two common types of operations leading to invariant functions. The first involves computing local features that are invariant to certain image transformations. The second operation involves computing geometric quantities that are invariant to some or all three-dimensional pose variation. For example the cross-ratio among distinguished points is a projective invariant that has been used to recognize rigid objects (see, e.g., [12]).

An example of a local feature, invariant to certain photometric variations and changes in illumination, is the *direction* of the image gradient, from which a variety of *edge* features can be computed. More complex features capture the appearance of small image patches and are often computed from edge features. An example would be the histogram of gradient (HOG) features [10]. Local features are usually computed at a *dense* grid of locations in the image, leading to a dense feature map. Features such as HOG were designed by practitioners based on a variety of considerations involving the desired invariance and at times were motivated by certain analogies to biological processing in the visual system. An alternative approach, implemented in multi-layer convolutional neural networks, learns the local

features as well as intermediate and higher-level features as part of the training process. Interestingly, the low-level features learned by such networks often resemble oriented edge detectors, like the designed features.

Local pooling of features is commonly used to introduce some degree of invariance to small geometric variations. A typical example is the *max* or *sum* operation [2, 13]. In this case a quantity that is to be computed at a pixel is replaced by the maximum or sum of the quantity in a neighborhood of the pixel. When the region is extended over the entire window, the result is a *bag of features* model [14], which counts the number of binary features of different types that occur within a window. In this case all spatial information is lost, leading to models that are invariant to fairly large geometric transformations.

For computational reasons it is often useful to sparsify the feature map by applying local decisions to find a small set of *interest points*. The assumption is that only certain features are useful (or necessary) for object detection. The approach yields *sparse* feature maps that can be processed much more efficiently. Examples of commonly used sparse features are SIFT descriptors [15], corner detectors, and edge conjunctions [2]. One drawback of sparse features is that hard decisions are being made on their presence, and if some are missed, an algorithm may fail to detect an instance of the object.

Note that it is possible to predefine a very large family of features that is never fully computed, rather, in training an informative subset is selected that can produce the required classification for a particular object class. One example are the Haar features that compute differences of intensity averages in adjacent rectangles of varying sizes and locations [8]. Another example are geometric edge arrangements of increasing complexity.

Latent variables An explicit parameterization of the object variability can be defined via *latent* variables that are not directly observable from the image data. These are not necessarily needed for the final report on the object detections, but

their values simplify the solution of the detection problem. For example to detect faces at a range of orientations, at each candidate region, one could decide, for *each* possible orientation, whether or not the region contains a face at that orientation. In general a set Θ defines latent parameters that could capture global illumination parameters, a linear or nonlinear map from a model domain into the image domain, or specify the locations of a finite set of object parts. The last case is common in part-based models where latent part placements are used to decide if the object might be present at a particular location in the image [11]. The set of possible latent values, Θ , can be quite large or infinite. This leads to computational challenges that have been addressed by a variety of methods including coarse-to-fine computation, dynamic programming, and geometric alignment.

Detection via Classification

The most common approach to object detection reduces the problem to one of classification. Consider the problem of detecting instances from one object class of fixed size but varying positions in the image. Let W denote a reference window size that an instance of the object would occupy. Let L denote a grid of locations in the image. Let X_{s+W} denote the image features in a window (sub-image) with top-left corner at $s \in L$. One can reduce the object detection problem to binary classification as follows. For each location $s \in L$ classify X_{s+W} into two possible classes corresponding to windows that contain an object and windows that do not contain an object. The sliding-window approach to object detection involves explicitly considering and classifying every possible window. Note that the same approach can be used to detect objects of different sizes by considering different window sizes or alternatively windows of fixed size at different levels of resolutions in an image pyramid. Clearly the number of windows where the classifier needs to be computed can be prohibitive. Many computational approaches find ways to narrow down the number of windows where the classifier is implemented.

Generative Models

A general framework for object detection using generative models involves modeling two distributions. A distribution $p(\theta; \eta_p)$ is defined on the possible latent pose parameters $\theta \in \Theta$. This distribution captures assumptions on which poses are more or less likely. An appearance model defines, the distribution of the image features in a window *conditional* on the pose, $p(X_{s+W}|\text{object}, \theta; \eta_a)$. The appearance model might be defined by a *template* specifying the probability of observing certain features at each location in the detection window under a canonical choice for the object pose, while θ specifies a transformation of the template. Warping the template according to θ leads to probabilities for observing certain features at each location in X_{s+W} [2, 3, 5].

Training data with images of the object are used to estimate the parameters η_p and η_a . Note that the images do not normally come with information about the latent pose variables θ , unless annotation is provided. Estimation thus requires inference methods that handle unobserved variables, for example, the different variants of the expectation maximization algorithm [4, 5]. In some cases a probability model for background images is estimated as well using large numbers of training examples of images not containing the object.

The basic detection algorithm then scans each candidate window in the image, computes the most likely pose under the object model, and obtains the “posterior odds,” i.e., the ratio between the conditional probability of the window under the object hypothesis at the optimal pose and the conditional probability of the window under the background hypothesis. This ratio is then compared to a threshold τ to decide if the window contains an instance of the object

$$\frac{p(X_{s+W}|\text{object}, \theta; \eta_a)p(\theta; \eta_p)}{p(X_{s+W}|\text{background})} > \tau.$$

When no background model has been trained offline, a simple *adaptive* background model can be estimated online for each window being tested.

In this case no background training data is needed [5]. Alternative background models involve sub-collections of parts of the object model [16].

Discriminative Models

If no explicit latent pose variables are used, the underlying assumption is that the training data is sufficiently rich to provide a sample of the entire variation of object appearance. The discriminative approach trains a standard classifier to discriminate between image windows containing the target object classes and a broad background class. This is done using large amounts of data from the object classes and from background. Many classifier types have been used, including neural networks, SVMs, boosted decision trees, and radial basis functions.

Cascades Because of the large size of the background population and its complexity, discriminative methods are often organized in *cascades* [8]. An initial classifier is trained to distinguish between the object and a manageable amount of background data. The classifier is designed to have very few false negatives at the price of a larger number of false positives. Then a large number of background examples are evaluated, and the misclassified ones are collected to form a new background data set. Once a sufficient number of such false positives is accumulated, a new classifier is trained to discriminate between the original object data and the new “harder” background data. Again this classifier is designed to have no false negatives. This process can be continued several times.

At detection time the classifiers in the cascade are applied sequentially. Once a window is classified as background the testing terminates with the background label. If the object label is chosen, the next classifier in the cascade is applied. Only windows that are classified as object by all classifiers in the cascade are labelled as object by the cascade.

Pose variables Certain discriminative models can also be implemented with latent pose parameters [11]. Assume a generic classifier defined in terms of a space of classifier functions

$f(x; u)$ parameterized by u . Usual training of a discriminative model consists of solving an equation of the form

$$\min_u \sum_{i=1}^n D(y_i, f(x_i; u)) + C(u),$$

for some regularization term $C(u)$ which prevents overfitting and a loss function D measuring the distance between the classifier output $f(x_i; u)$ and the ground truth label $y_i = 1$ for object and $y_i = 0$ for background.

The minimization above can be replaced by

$$\begin{aligned} \min_u \sum_{y_i=1} \min_{\theta \in \Theta} D(1, f(\theta(x_i); u)) \\ + \sum_{y_i=0} \max_{\theta \in \Theta} D(0, f(\theta(x_i); u)) + C(u). \end{aligned}$$

Here $\theta(x)$ defines a transformation of the example x . Intuitively for a positive example, one would like there to be some transformation under which x_i is classified as object, while for a negative example one would like it to be the case that there is no transformation under which x_i is classified as object.

Convolutional neural networks Due to the limitations of low-level local features and the difficulty of manually specifying higher-level features, neural networks have become increasingly popular as a method to learn effective feature representations, from low-level to high-level, using large annotated datasets. These networks are composed of a hierarchy of layers indexed by grids of decreasing resolution. The input layer is the raw pixels of the input image. Each subsequent layer computes a vector output at each grid point using a list of local filters applied to the data in the preceding layer. This linear operation is typically followed by a nonlinear operation applied coordinate-wise and at certain layers the grid resolution is reduced by subsampling following a local max or averaging operation. The network terminates in one or more output layers that make predictions according to the design of the model (e.g., an object category

classifier and a pose estimator, if the model outputs pose information).

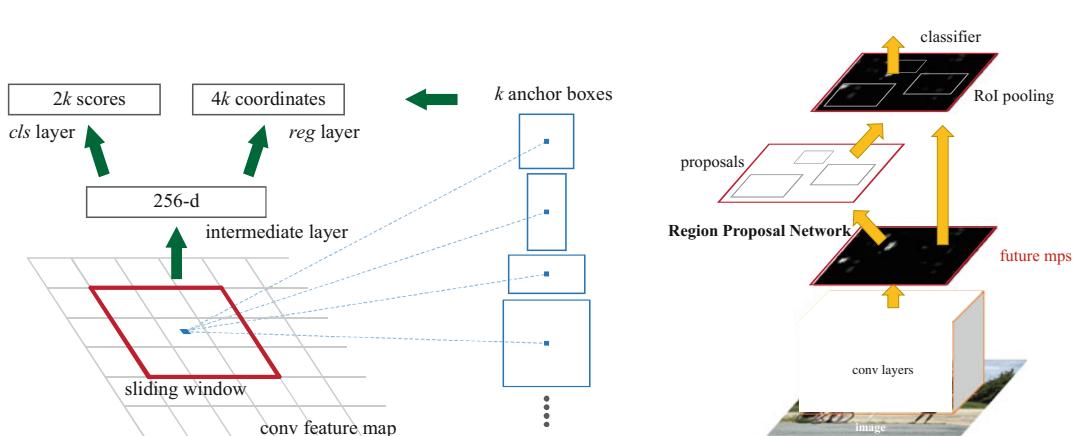

All of the filter coefficients and the parameters of the output layers are trainable. Training is done through stochastic gradient descent on a loss function defined in terms of the output layers and the labels in the dataset. Thus the network jointly learns linear classifiers and a complex hierarchy of nonlinear features that yield the final feature representation. Such networks were demonstrated to work for large-scale image classification tasks [17] and then subsequently for the more complex task of object detection [18].

Networks for image classification have a relatively straightforward design since they terminate with a single classification output for the entire image. Networks for object detection involve additional components that are designed to address the more complex nature of object detection. There are two dominant designs: *one stage* (e.g., [19]) and *two stage* (e.g., [20]), both of which are based on a sliding-window approach, described next.

In both of these designs, two convolutional sub-networks are applied in parallel. At each location on a relatively coarse feature grid, one of these sub-networks acts as a classifier and the other as a pose predictor (see Fig. 2 left

“cls layer” and “reg layer,” for classification and box regression, respectively). The pose estimator predicts a relative shift and scaling of a detection window, while the classifier predicts if it is an object or background. By creating multiple pairs of such layers, with each pair specializing to a window of a specific size and aspect ratio, the set of predefined sliding windows can better approximate the set of all possible image windows. The pose estimator is tasked with predicting the residual error between the quantized windows and the ground-truth object bounding boxes. In the first design paradigm, often termed “one-stage” methods, the sliding window classifier makes a multi-class prediction over the set of all object categories and background. These predictions, together with the refined windows, comprise the output of the model.

In the second design paradigm, the sliding-window classifier performs two-class classification between object (of any category) *vs.* background. The refined windows are then used as candidate object locations, often called regions of interest (RoIs), for a subsequent classification and window refinement stage. This second stage, as is typical in cascaded processing, only receives high-scoring RoIs from the object *vs.* background classifier. The input features to the

Object Detection, Fig. 2 Left: A sliding-window Region Proposal Network (RPN) that performs classification (“cls layer”) and window shift and scaling regression (“reg layer”) for a set of reference windows (“anchor boxes”) at each grid position. Right: The Faster R-CNN

system that uses RPN to generate candidate object proposals for processing in a second stage as a part of an overall convolutional neural network for object detection. (The figure is reproduced with permission from [20])

second stage are typically computed by extracting features within each ROI from a feature map. The ROI feature extraction process may involve quantizing the ROI coordinates and using max pooling [20] or bilinear interpolation of the feature map without performing quantization [21]. The output of the second stage is a multi-class classification prediction and window refinement (shift and scaling) for each ROI. See Fig. 2 right. Two-stage methods can also be extended in a straightforward manner to predict a binary segmentation mask for each ROI [21]. In either case, all parameters of these networks are trained jointly using stochastic gradient descent on a multi-task loss function that includes terms for classification and pose estimation.

Computational Methods

The basic detection process consists of searching over pose parameters to classify each hypothesis. At a minimum this usually involves searching over locations and sizes and is clearly a very intensive computation. There are a number of methods to make it more efficient.

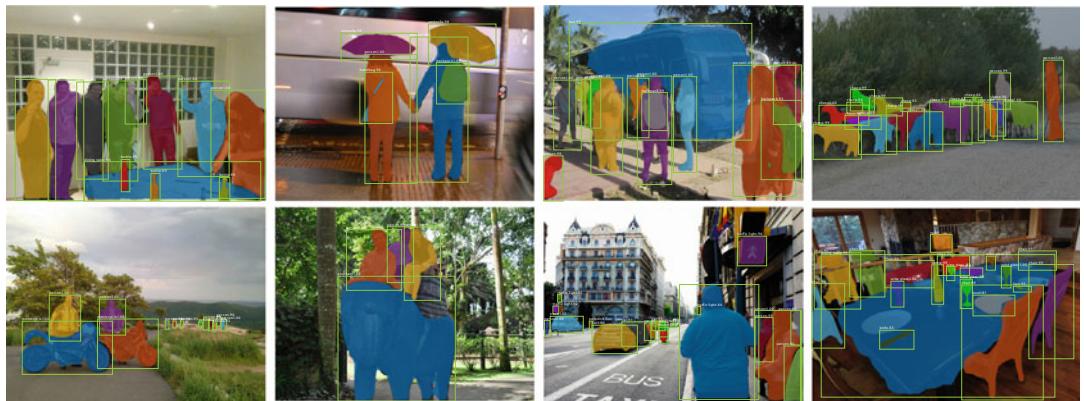

Sparse features When sparse features are used, it is possible to focus the computation only in regions around features. The two main approaches that take advantage of this sparsity are *alignment* [22] and the *generalized Hough transform*. Alignment uses information regarding the relative locations of the features on the object. In this case the locations of some features determine the possible locations of the other features. Various search methods enable a quick decision on whether a sufficient number of features were found to declare object, or not. The Hough transform typically uses information on the location of each feature type relative to some reference point in the object. Each detected feature votes with some weight for a set of candidate locations of the reference point. Locations with a sufficiently large sum of weighted votes determine detections. This idea can also be generalized to include identification of scale as well. The voting weights can be obtained either through discriminative training or through generative training [2].

Cascades As mentioned above the cascade method trains a sequence of classifiers with successively more difficult background data. Each such classifier is usually designed to be simple and computationally efficient. When the data in the window X_{s+W} is declared background by any classifier of the cascade, the decision is final, and the computation proceeds to the next window. Since most background windows are rejected early in the cascade, most of the windows in the image are processed very quickly.

Coarse to fine The cascade method can be viewed as a coarse to fine decomposition of background that gradually makes finer and finer discriminations between object and background images that have significant resemblance to the object. An alternative is to create a coarse to fine decomposition of object poses [9]. In this case it is possible to train classifiers that can rule out a large subset of the pose space in a single step. A general setting involves a rooted tree where the leaves correspond to individual detections and internal nodes store classifiers that quickly rule out all detections below a particular node. The idea is closely related to branch-and-bound methods [14] that use admissible lower-bounds to search a space of transformations or hypotheses.

Dynamic programming There are a number of object detection algorithms that represent objects by a collection of parts arranged in deformable configurations or as hierarchies of such arrangements of parts of increasing complexity. When the hierarchies and the arrangements have the appropriate structure, dynamic programming methods can be used to efficiently search over the spaces of arrangements [2, 3].

Convolutional neural networks Object detection systems based on convolutional networks make use of many classical techniques for reducing computation, including cascades as previously described. Coarse-to-fine approaches are also common. By progressively reducing spatial resolution, these networks operate on a coarse grid of object locations. The loss in resolution is compensated by predicting pose parameters that

Object Detection, Fig. 3 Bounding boxes and segmentation masks produced by Mask R-CNN. The system is trained to detect and segment 80 object categories from the COCO dataset. (Reproduced with permission from [21])

Object Detection, Fig. 4 Bounding boxes, segmentation masks, and joint positions produced by Mask R-CNN. The system is trained to detect, segment, and predict

pose on the *person* categories from the COCO dataset. (Reproduced with permission from [21])

recover some of the quantization error, resulting in fine predictions. The progressive reduction in spatial resolution can also be used to efficiently construct a multi-scale pyramid representation from a single input image scale [23], which is more efficient than processing multiple input image scales independently. These networks also share nearly all the computation of the hierarchy of features across all object categories, rather than retraining a separate hierarchy for each one *vs.* rest binary classification models, one for each object category. The shared computation enables such networks to scale to thousands of object categories; the marginal per category cost grows linearly but is small relative to the computation shared between categories. Finally, typical convolutional networks can be accelerated both algorithmically via fast convolution methods and with specialized hardware that

makes extensive use of parallel computation (e.g., GPUs).

Application

Object detection methods have a wide range of applications in a variety of areas including robotics, medical image analysis, surveillance, and human computer interaction. Current methods work reasonably well in constrained domains but still rely on thousands of training examples per category in order to achieve reasonable results.

A popular benchmark for object detection is the COCO object detection challenge [24]. The goal of the challenge is to detect objects from 80 common categories such as people, cars, horses, and tables in photographs. The challenge has

attracted significant attention in the computer vision community over the last few years, and the performance of the best systems has been steadily increasing each year by a significant amount.

Detection methods that segment objects are also steadily improving and are now deployed for various applications, particularly in augmented and virtual reality scenarios. Figure 3 shows example output of Mask R-CNN [21]. Models that additionally predict human joint locations, in addition to bounding boxes and segmentation masks, are also useful in many applications including video conferencing systems that can automatically keep participants framed within the video stream. Mask R-CNN can be extended to predict human pose, as illustrated in Fig. 4.

Hazard detection

Definition

Obstacle detection is the process of using sensors, data structures, and algorithms to detect objects or terrain types that impede motion.

Background

Obstacle detection is applicable to anything that moves, including robot manipulators and manned or unmanned vehicles for land, sea, air, and space; for brevity, these are all called *vehicles* here. Obstacle detection and hazard detection are synonymous terms but are sometimes applied in different domains; for example, obstacle detection is usually applied to ground vehicle navigation, whereas hazard detection is often applied to aircraft or spacecraft in the process of landing, as in “landing hazard detection.” Obstacle detection is a system problem that encompasses sensors that perceive the world, world models that represent the sensor data in a convenient form, mathematical models of the interaction between objects and the vehicle, and algorithms that process all of this to infer obstacle locations. Obstacle detection algorithms use the world model and the interaction model to locate obstacles, to characterize the degree to which the obstacles impede motion, and to produce an *obstacle map* for use by path planning algorithms. The complexity of obstacle detection systems varies greatly, depending on the domain of operation, the size and cost of the vehicle, and the degree of reliability required.

Because sensor data is noisy and incomplete, often it is necessary to combine many sensor measurements into the world model to reduce noise and fill in gaps in the world model before applying obstacle detection algorithms; this makes obstacle detection related to mapping. Obstacles may completely block motion of the vehicle or just make it more difficult to move, such as having to move slowly over rough ground; this makes obstacle detection related to terrain classification.

Development of obstacle detection systems has accelerated in the past decade, due to rapid progress in sensors, embedded computing, and growing markets for intelligent vehicles. The rising commercial importance of automated driver assist systems (ADAS) and self-driving cars and trucks has propelled development of obstacle detection systems for vehicles on roads [1, 2]. This includes low-cost sensors, abilities to detect

and predict the paths of moving obstacles, and abilities to classify the types of obstacles (e.g., fence, pedestrian, bicycle, car) to better understand how to react to them. The potential commercial importance of unmanned air vehicles (UAVs) similarly fuels development of small, lightweight obstacle detection systems, as well as other techniques, to allow such vehicles to fly safely in shared airspace [3, 4]. At the most remote end of the application spectrum, obstacle detection has become important in planetary exploration for rovers and landers [5, 6].

Sensors for Obstacle Detection

An early introduction to a broad range of sensors for obstacle detection is included in [7]. Three-dimensional perception plays a central role in obstacle detection, because the geometry of the world is a major factor in determining what constitutes an obstacle. Three-dimensional sensors include active ranging techniques, like lidar [8–10], radar [11], and sonar [12], and passive ranging techniques, like stereovision [13] and structure from motion [14]. Appearance can also be useful for discriminating obstacles from non-obstacles, so color, texture, polarization, and radiant temperature can also be important sensor attributes. Since all 3-D sensors have limited range, appearance attributes are especially important for detecting obstacles at long range. The very wide range of illumination present in outdoor scene has been a challenge for selecting cameras both for human viewing and for automated obstacle detection; this is being addressed by advances in high dynamic range imagers [15, 16].

Mechanical properties like the stiffness of objects or terrain often are important to obstacle detection, as well as geometric properties. This requires sensors that directly or indirectly give insight into mechanical properties of the scene. These can be proprioceptive sensors, like inertial sensors, wheel encoders, or instrumented bumpers, that sense aspects of the vehicle-world interaction as it occurs or remote sensors that perceive the terrain ahead of the vehicle.

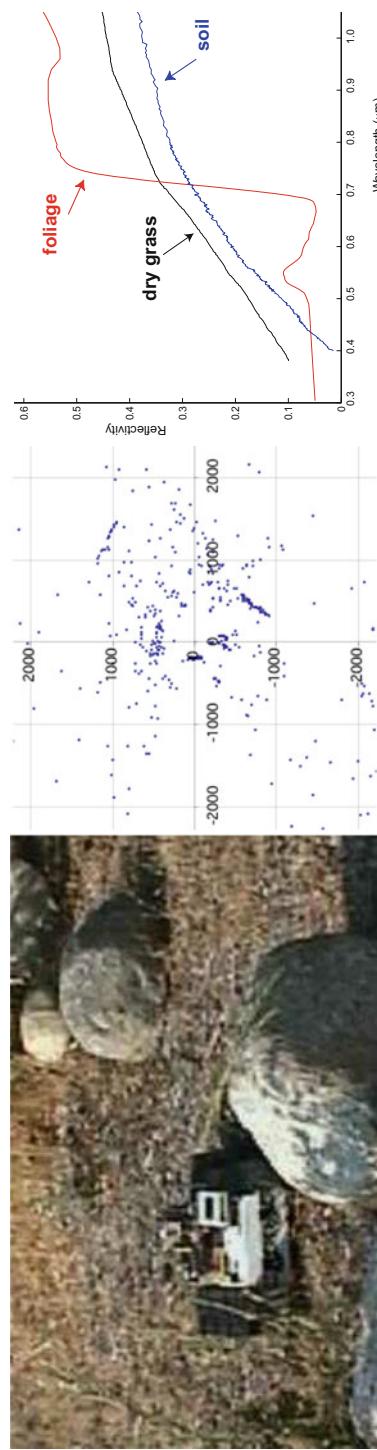

Examples of remote sensing to predict terrain mechanical properties are using lidar [17] or multispectral imagery [18] to infer whether material is vegetation that can be pushed through by the vehicle or is something more solid that must be avoided (Fig. 1).

Environmental conditions like ambient illumination and atmospheric obscuration also impact obstacle detection sensors [19, 20]. For example, fog, smoke, and night operation may require active sensors or thermal infrared cameras, while thick dust or heavy precipitation may require radar (Fig. 2). Dynamic environments require sensors that measure the velocity of obstacles as well as their size and location.

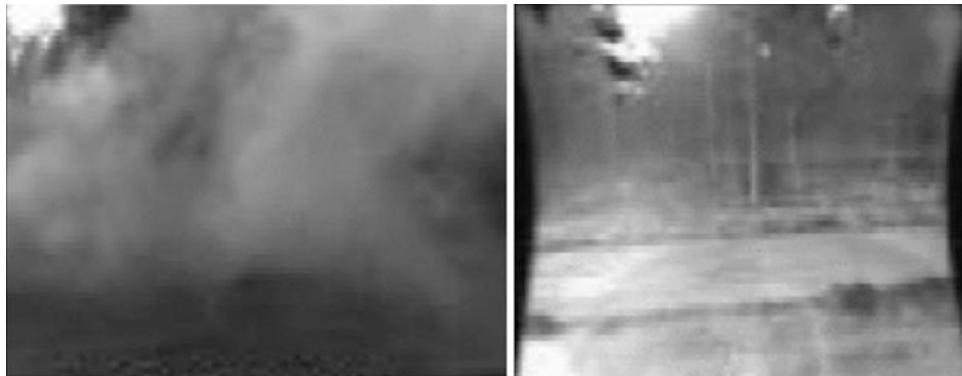

Choosing appropriate sensors is a critical first step in obstacle detection, to ensure that the sensors can discriminate obstacles under the required conditions. This can be difficult; for example, operation in high levels of airborne dust requires use of sensors that measure range to solid objects behind the dust, instead of to the dust. It can also be very challenging to obtain appropriate sensors that fit within the size, weight, power, and cost constraints of the application.

Data Structures for Obstacle Detection

Obstacle detection algorithms can be developed to process raw sensor data or data that has been transformed into another representation. Raw data is often expressed in *sensor space* (also called *image space* for some sensors); these are data structures that are indexed by the natural coordinate system of the sensor, such as [row, column] or [azimuth, elevation]. With two-axis lidar, for example, surface normals, range discontinuities, and height aboveground can be computed directly from range images provided by the sensor, and obstacle locations can be inferred from these quantities. Operating in image space preserves pixel adjacency information, which can be convenient for segmentation. Performing obstacle detection in sensor space minimizes computational cost and obstacle detection latency, which is important for

Obstacle Detection, Fig. 1 Left: small robot in sparse grass, carrying a single-axis scanning lidar. Middle: range data from the lidar (scale in millimeters), with lidar at the origin. The two large rocks to the right of the robot are apparent as linear structure among the scattered returns from vegetation. Right: spectral reflectivity vs. wavelength (in microns) of soil, dry grass, and green foliage, showing the high contrast of green foliage between visible and near-infrared bands

Obstacle Detection, Fig. 2 Smoke seen with visible spectrum and thermal infrared cameras; thermal infrared penetrates smoke and fog far better than visible wavelengths

vehicles with limited computational resources or that move very fast and must react very quickly [21, 22].

An alternative to working in image space is to work in a *map space*. These are often expressed in a Cartesian reference frame that is either vehicle-centered or has a fixed origin in the world; they can also be expressed in polar coordinates with a vehicle-centered origin. Map representations can simply accumulate raw data from many sensors or many points in time, such as point clouds from range imaging sensors like lidar or stereovision. Alternatively, they may be discrete grids that are used to summarize range data over time, such as elevation maps and 2-D or 3-D occupancy grids. Elevation maps record the height of the ground surface in each cell of a discretized map of the ground plane; multiple heights or intervals of heights may also be recorded for each map cell in the ground plane. Occupancy grids record a probability that each cell of the map is occupied by solid material, instead of empty. These can be defined in 2-D or 3-D; in 3-D, they are often called *voxel maps*. Concepts of height maps and voxels have also been combined in the same system [24, 25]. Important issues for map data structures are that they allow rapid access to and update of information in each cell, rapid access to neighborhoods, and efficient use of memory for mapping large regions, including sparse representations. Trees, allocatable map tiles, voxel hashing, and multi-resolution variants on these themes

are examples of techniques used to address these issues [23, 24, 26, 27] (Fig. 3).

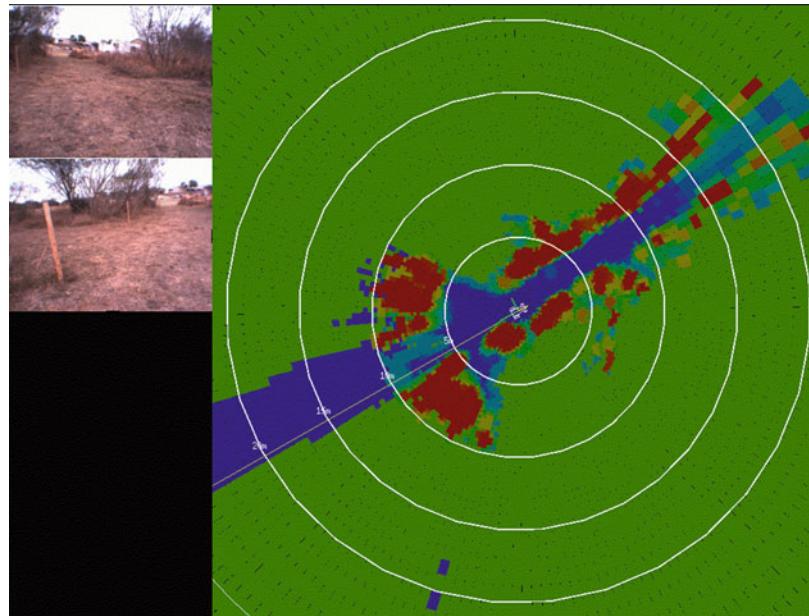

Shape of the raw sensor uncertainty distribution also can drive the choice of world model representation, particularly for sensors with wide beams (leading to polar representations) and for passive triangulation from images, where inverse range parameterizations can be useful, particularly for image space representations [21]. Robot-centered, 2-D polar-perspective maps are another inverse range representation, where the radial axis of 2-D polar maps is parameterized with inverse range to match the spatial and range resolution characteristics of stereovision [28].

Geometric representations fit geometric primitives, like line segments or polygons for 2-D maps and planar surfaces or bounding boxes for 3-D maps, to the raw sensor data or to segmented gridded data. These are less commonly used for obstacle detection than for visualization or for strictly mapping purposes, but they have often been used as compact world models for motion planning algorithms. Other methods of compressing raw point cloud data into a more compact representation include clustering the points and fitting the clusters with a mixture of Gaussian distributions [29].

Map space representations are used for several purposes. First, they are used to accumulate data over time, which is valuable to “fill in” gaps that may occur in individual frames of sensor data. Second, they facilitate noise reduction, because

Obstacle Detection,

Fig. 3 Hybrid 2-D cost map [23], with a Cartesian map closest to the robot and a polar map further away to reflect resolution characteristics of stereovision. White rings are 5 m intervals. Blue codes low cost, while red is high cost, revealing corridor between the bushes in the upper left image

the accumulated data can be averaged or filtered for outliers. Third, they can effectively interpolate higher-resolution representations of the world than are available from individual frames of sensor data; an example is when occupancy grids are used to build world models from wide-angle sonar data [30]. Finally, they can be in a coordinate system that makes some aspects of obstacle detection easier; for example, transforming range data from image space to a Cartesian map space data structure makes it possible to use shift-invariant algorithms to detect fixed-size obstacles.

Uncertainty is inherent in sensors, therefore also in maps and in obstacle detections, so modeling that uncertainty is an important issue. Common approaches to this include recursive filtering of Gaussian models of uncertainty in range or height measurements [31], and updating map cell occupancy inferences is the use of occupancy grids to estimate the probability that map cells contain obstacles. Efforts to improve elevation mapping have used Gaussian process [34] and Markov random field formulations [35]. Several techniques have been explored to extend occupancy grids to improve their spatial fidelity and/or statistical model, including normal distributions transform occupancy maps

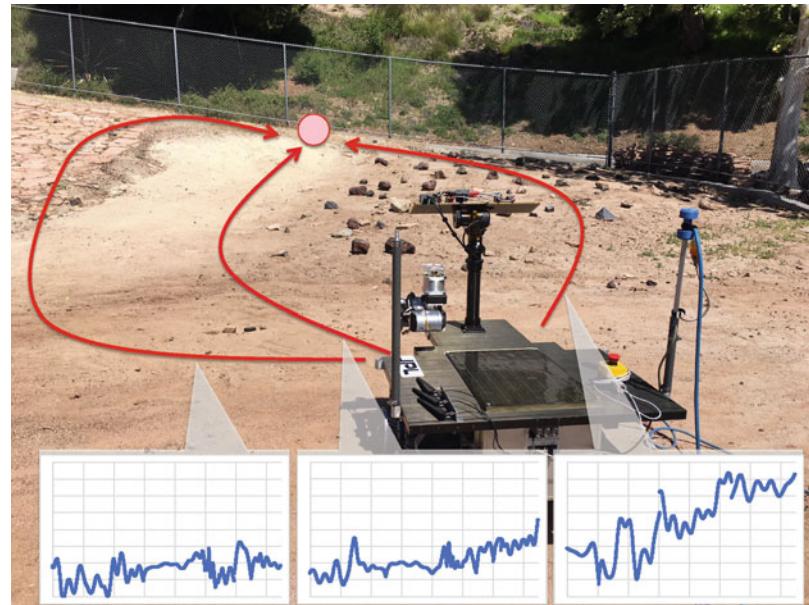

(NDT-OM) [32] and Hilbert maps [33]. Gaussian mixture models have been applied to temporal fusion of depth maps [36].

Vehicle-World Interaction Models for Obstacle Detection

Obstacle detection algorithms implicitly or explicitly use a model of how the vehicle interacts with the world to determine where obstacles exist. In the simplest case, the model may be just a binary decision based on raw sensor data, such as when single-axis scanning lidars are used for obstacle detection indoors and any object that produces a range measurement counts as an obstacle. For outdoor navigation, the size of an object affects whether or not it is considered an obstacle; for example, small bumps on the ground may be ignored, but large rocks are obstacles. This distinction depends on characteristics of the vehicle, such as wheel diameter, ground clearance, velocity, and suspension stiffness. In this context, interaction modeling can take into account just the geometry of the vehicle and world or varying levels of fidelity in the dynamics of the interaction [37, 38], the energy cost of a robot path [39], or other metrics [40] (Fig. 4).

Obstacle Detection,

Fig. 4 Predictions of driving energy for three different vehicle paths encountering different slopes and predicted slippage [39]

Algorithms and Systems for Obstacle Detection

Obstacle detection algorithms use the vehicle-world interaction model to transform the sensor data and the world model into an intermediate representation that enables efficient path planning. There are many approaches to this, which depend on the application context. The summary here focuses on ground vehicles to illustrate the diversity of issues and approaches involved; methods tailored for maritime vehicles, flying vehicles, and robot manipulators can be found in the relevant literature.

Among the simplest and oldest methods are those that apply to indoor ground vehicles with 2-D world models. Off-road vehicles require more complex methods to cope with the 2.5-D world model and the spectrum between rigid and compliant obstacles. On-road vehicles face complexities of other traffic, high speed, and a wide range of illumination, weather, and seasonal conditions that stress the need to address obstacle detection algorithms in the context of a multisensor autonomous driving system.

For indoor vehicles with 2-D world models, binarized occupancy grids and analogous data structures can be the obstacle map. The simple

abstraction of treating the vehicle as circular enables expanding the obstacles by the radius of the vehicle to allow motion planning algorithms to treat the vehicle as a point in the 2-D ground plane. Similar concepts have been applied to stereo disparity maps to allow motion planning with image space representations for ground and air vehicles [21, 41].

For off-road vehicles, the world model must be at least 2.5-D, the degree of rigidness versus compliance of materials in the environment is significant, and the effects of vehicle dynamics are important at high speed. For Mars rovers, which move very slowly in desert terrain with no vegetation or moisture, obstacle detection algorithms can test for ground clearance by “kinematic settling” of an articulated vehicle model onto an elevation map of the terrain [5]. Limited onboard computational power may lead to using such algorithms in a hierarchical scheme that uses simpler methods to conduct initial terrain triage, for example, by fitting planes to vehicle-sized patches of the elevation map to distinguish regions that are very smooth or very rough from those that need more careful analysis of ground clearance. Sand dunes are compliant terrain that increase wheel slippage and can get the vehicle stuck. Research is in progress on

terrain classification methods that use onboard cameras to allow rovers to discriminate this terrain type from rigid terrain like bedrock [43].

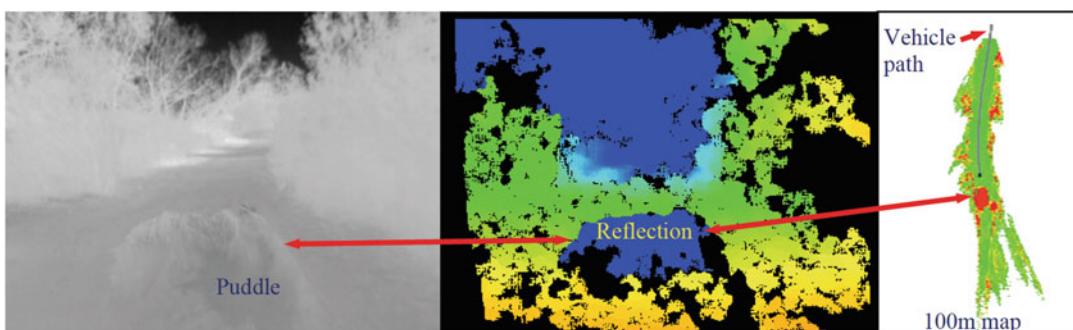

Off-road vehicles on Earth face a much greater variety of terrain types and a wider range of illumination and atmospheric conditions that degrade sensor performance. Besides soft sand, terrain types include other compliant materials like vegetation, mud, and water bodies. A variety of sensors and detection algorithms have been explored for identifying these terrain types, including image classification, reasoning about 3-D point cloud statistics, detecting polarized reflections, and reasoning about temperature of the scene as revealed by thermal images [19, 44, 45] (Fig. 5). Manmade obstacles like wire may be present, which are thin and hard to see; specialized analysis of 3-D point cloud data has been used to detect these [44]. Holes in the ground of various sizes, including potholes and ditches, are collectively referred to as *negative obstacles*; these are hard to detect because they project to a small area in image space. Under some conditions, visible portions of the interiors of negative obstacles have temperatures that contrast with the surrounding terrain; this has led to thermal cues being included in specialized detectors for negative obstacles [47]. A variety of self-supervised and imitation learning algorithms have been explored for enabling vehicles to learn about terrain types from their own experience and from observing human driving examples [48, 49].

Dynamic effects of vehicle interaction with off-road terrain types is still a fairly immature topic, especially for high-speed driving.

On-road driving generally has simpler vehicle-terrain interaction than off-road driving, but it has more demanding requirements for coping with high speed; navigating among moving objects that include motor vehicles, bicycles, pedestrians, and other objects; being robust to degraded seeing conditions (night, bad weather); and doing all of this while respecting many rules of the road. This requires detecting and classifying objects that may be in the path of the vehicle, tracking moving objects, and semantic labeling and segmentation of the scene as a whole. Cameras and lidars are primarily used for these tasks. Learning-based algorithms using deep convolutional neural networks have become very prominent in this domain. Survey articles provide a good introduction to this complex problem [50].

Open Problems

The complexity of understanding the on-road driving environment and the level of reliability required in that environment continues to have open problems, which strongly overlap other computer vision problems like object recognition, object tracking, and semantic segmentation. Off-road driving also presents difficult challenges for perceiving material types

Obstacle Detection, Fig. 5 Potential water hazard detection based on geometric reasoning about reflections in image and stereovision-based point cloud data [19]. Left: thermal image from a stereo image pair, with a puddle in the foreground. Center: false color depth map

from stereo, with anomalous large range measured to the reflection. Right: cost map for 100 m ahead of the vehicle, with the puddle properly placed in the map after reasoning about range around its borders

and inferring whether they constitute obstacles that must be avoided or compliant terrain that can be driven over at some appropriate speed. There currently is a heavy reliance on 3-D perception with lidar for obstacle detection, but there is strong interest in being able to do more with cameras, because of potential for reducing cost and reducing signals emitted by the sensors. Poor seeing conditions (e.g., night, bad weather) present challenges that are not fully addressed. Obstacle detection in these domains is very computationally intensive; there is a perpetual interplay between development of more efficient algorithms and higher performance onboard computing systems to address this challenge.

- Occlusion Detection
- Occlusion Handling

Definition

In computer vision, the term *occlusion* refers to the phenomenon which occurs when a portion of a 3D scene is not visible from the camera or another sensor. Visual rays from 3D points in such portions of the scene are obstructed or blocked from reaching the camera by another non-transparent surface or object that lies between the obstructed region and the image plane of the camera. Occlusion is a consequence of the nature of 3D projections and arises from the depth ordering of surfaces in the scene from a particular viewpoint. The region which is occluded, i.e., not visible from the camera, is often referred to as the *occluded region*, whereas the obstructing objects or surfaces are referred to as *occluders*. Finally, the visible edge or boundary of the occluder or occluding surface is often referred to as the *occlusion boundary*.

Occlusions in Object Tracking

Occlusion occurs naturally in most 3D scenes where multiple objects and complex geometric shapes are present in arbitrary configurations or when the scene is dynamic and objects deform or move within the scene. The extent of the occlusion may be higher in cluttered scenes compared to scenes which contain very few objects. The degree of occlusion may also depend on the camera viewpoint in the scene. For example, in an open outdoor scene, an upright camera slightly above ground level may have significantly more occlusion compared to a camera looking downward into the scene from a greater height.

The presence of occlusion leads to a wide range of challenges for a class of computer vision techniques that solve various visual recognition tasks, namely, object detection, object tracking, segmentation, and visual recognition. Let us briefly discuss why occlusions make object tracking challenging. Figure 1a–c shows a person in three video frames from a single camera. The person's face is occluded by the magazine in two of the frames. In this case, the goal is to track

the person's face. Specifically, the tracker should estimate the corners of a 2D rectangle that fits around the face on each frame, and we would like these predictions to be robust to occlusion as shown in Fig. 1d–f.

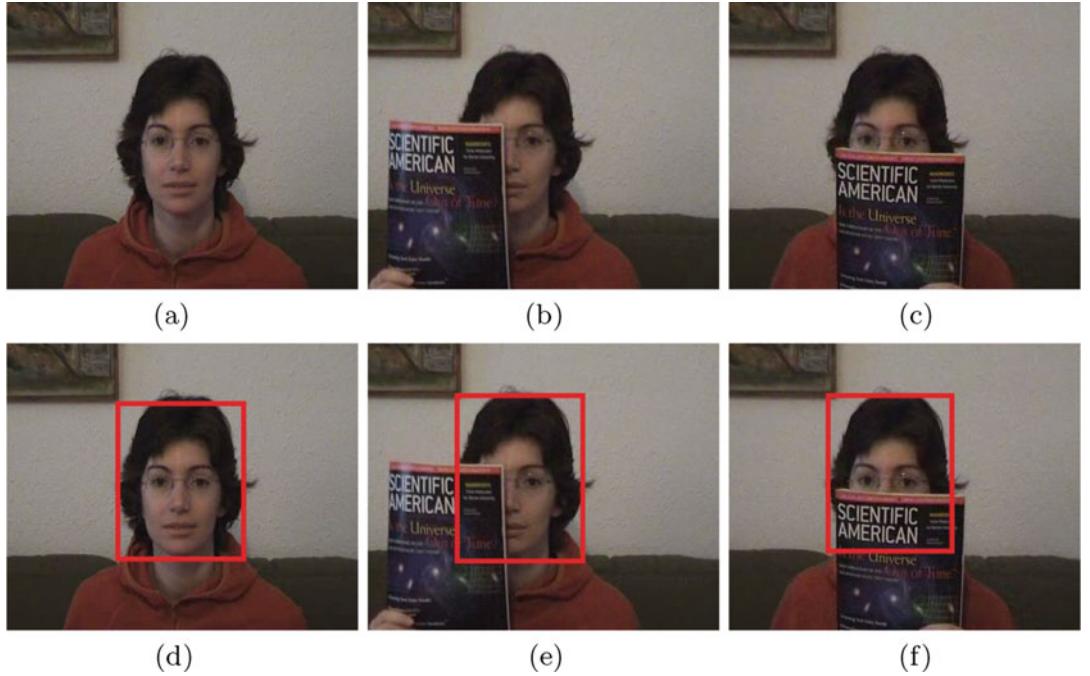

Most object tracking approaches construct and maintain an adaptive appearance model of the object being tracked. If the appearance model is global, i.e., represents the appearance of the complete object, a tracking approach that uses such a model would be more susceptible to tracking failure due to occlusions. Note that the appearance or shape of the occluder cannot be assumed to be known and the tracking algorithm cannot assume any knowledge of which parts of the person's face or to what extent it will be occluded.

To solve the problem more robustly in the presence of occlusion, a more flexible appearance model is typically used, one which constructs and adaptively maintains multiple redundant appearance representations of different parts of the object. The basic principle is that when the object is occluded, it will be assumed that at least some of its parts are visible and this will allow the detector or tracker to find the object under a modest degree of occlusion.

Occlusions may cause object trackers to lose track of an object in a long sequence. This may in fact be inevitable if the object is completely occluded behind some other scene objects and disappears from the camera view. However, when the object is visible again, an occlusion-aware tracking approach will redetect the object and recognize it to be the same object instance observed before and tracking can be reestablished.

Occlusion in Stereo and Optical Flow Estimation

We now discuss how occlusion presents some challenges in low-level image correspondence recovery tasks such as stereo matching and optical flow. In stereo matching, the goal is to estimate a dense set of pixel correspondences in two or more images where the scene is assumed to be rigid. This is possible, either with multiple

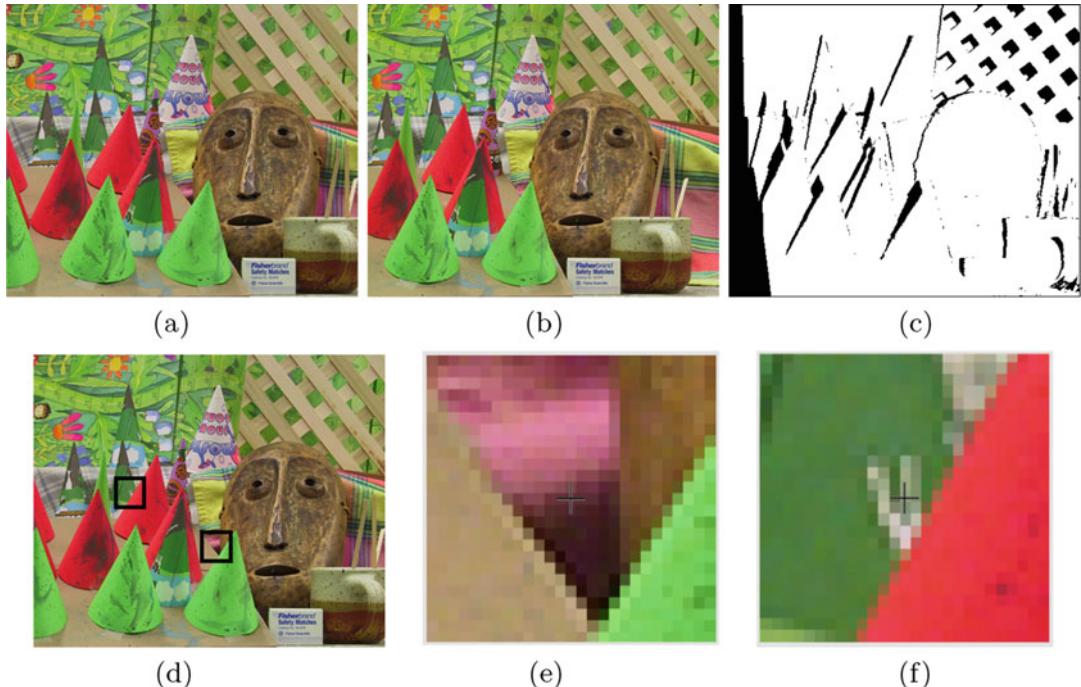

Occlusion, Fig. 1 Occlusion creates some challenges in object tracking. (a) A frame from the FACEOCC1 sequence showing a person, taken from the visual tracking benchmark [10]. (b) A different frame from the video where the person’s face is considerably occluded.

(c) Another frame where a different part of the person’s face is occluded. (d–f) Object tracking results that can be expected on these images from a tracking technique which is robust to occlusion

cameras in the scene or using a single moving camera but by assuming the scene to be stationary. Similarly, in optical flow estimation, one also seeks a dense set of pixel correspondences in multiple images such as from consecutive frames of video. In optical flow, general pixel motion is allowed as would occur in a nonrigid scene or a scene with rigid objects that are moving independently.

Figure 2 shows an example of occlusion in the binocular stereo problem. The leftmost and center image depicts a pair of stereo-rectified images where the corresponding pixels lie on identical horizontal scanlines of the two images. Figure 2c depicts a binary mask where the white pixels in the mask image correspond to pixels in the left image that are visible in the right image whereas the black pixels in the mask image are not visible in the right image. This binary mask is often referred to as the *occlusion mask*.

Occlusion in the stereo matching setting arises from the effect of parallax and is associated with edges in the scene that form depth discontinuities, i.e., where the depth of pixels changes abruptly. While the fraction of occluded pixels in a stereo pair depends on the scene geometry and range of parallax, one typically observes a higher degree of occlusion when the baseline between the stereo cameras is increased. Scenes where occlusion occurs more frequently are typically more challenging for stereo matching. Estimating the disparity (or scene depth) of occluded pixels requires reasoning using monocular cues instead of stereo cues. Similarly, in the case of optical flow estimation, occlusion is associated with edges that form motion discontinuities, and computing optical flow for sequences with fast and large motion is typically more challenging as they are likely to produce more occluded pixels.

Occlusion, Fig. 2 Occlusion makes stereo matching more challenging. (a–b) The left and right image from CONES, a pair of rectified stereo images from the Middlebury stereo matching benchmark [5]. (c) The occlusion mask for the pixels in the left image. The white pixels in the mask are visible, i.e., non-occluded in the right image,

whereas the black pixels are not visible, i.e., occluded in the right image. (d) The left image shown again with two occluded regions marked by black squares. (e–f) Images showing zoom-ins of the patches within the black squares

It is possible to explicitly model the occlusion phenomena in stereovision using geometric reasoning. Such stereo matching methods typically infer the disparity map in both left and right images [2, 7] and may involve explicit estimation of the left and right occlusion maps. Typically such techniques require multiple phases, where during the initial phase the occlusion maps are estimated whereas in the subsequent phases the estimated occlusion maps are used to adjust appropriate terms in the objective function in an occlusion-aware manner.

However, many stereo matching and optical flow estimation methods avoid explicitly modeling occlusions and instead treat the occurrence of occlusions as outliers. These methods implicitly deal with occlusion by either using robust cost functions in the algorithmic formulation or employing robust optimization

procedures to infer the correspondence. This idea is quite effective in the multi-view stereo task when several overlapping viewpoints are available [9]. Most learning-based methods also model occlusions implicitly and rely on many examples in the training set to indirectly achieve robustness to occlusions.

Occlusion Reasoning and Scene Understanding

Reasoning about occlusions in a scene and detecting occlusion boundaries can provide indirect cues about the 3D scene geometry. It can also help to decompose the scene into a set of discrete layers which may aid 3D scene understanding. For example, it is possible to detect occlusion boundaries by performing background segmenta-

tion on a moving object in a stationary scene and then analyzing the edge and boundary statistics of the foreground or object segments over time. When the object has been observed to move within the scene for a sufficiently long time, the boundary statistics may reveal not just the location of the occlusion boundaries but distinct layers in the scene geometry (from the camera's viewpoint) and the relative ordering of these layers [6]. Finally, occlusion reasoning can also be performed on videos captured using multiple calibrated cameras with overlapping viewpoints. By segmenting moving objects from the respective background images in multiple views, it is possible to both infer the 3D shape of the stationary occluders in the scene and reconstruct the dynamic objects more accurately based on explicit geometric occlusion reasoning using a probabilistic formulation [3].

Several other approaches have also been investigated to solve the occlusion boundary detection problem in single images using supervised learning approaches [4], by utilizing low-level motion cues based on optical flow computation on video [8] and based on the detection of T-junctions in images [1].

Definition

Occlusion detection refers to the set of techniques employed to detect which areas of the images are occlusion boundaries or areas that appear occluded in views of the scene.

Background

Occlusion is one of the fundamental phenomenon that limits the information available in an image. Given a 3-dimensional scene containing non transparent objects, a projection of the scene into the image will not include information about all the surfaces in the scene. The backside of the nontransparent objects will be occluded by the frontside, and the foreground objects will occlude the background surfaces. Which areas are occluded and which ones are visible depends on the position of the camera with respect to the scene.

In natural images, occlusions are prevalent. Knowing which are the occlusion boundaries in an image helps segmenting pixels at the object's level and thus help processes such as objects detection or relative depth estimation. The occlusion areas depend on the camera position; thus, most algorithms matching two or more images are concerned with occlusion detection; since not all the surface points visible in image I_1 will be visible in image I_2 , not all pixels in I_1 will have a corresponding pixel I_2 . Due to this stereo matching, optical flow and object tracking algorithms are particularly concerned with occlusion detection.

Theory

For occlusion detection two cases should be distinguished: single image or multiple images. When a single image is available, no direct observation of occlusion boundaries can be done, and thus, the nature of the problem is quite different from the multiple images case.

Single Image

If the depth assigned to each pixel was known, then the occlusion boundaries would correspond to where the depth is discontinuous. Without any additional information but a single image, estimating the occlusion boundaries corresponds to estimating depth discontinuities when depth information is not available. Without priors, such problem cannot be solved. A common assumption (in stereo matching and optical flow estimation literature) is that depth discontinuities generate color discontinuities. Classical edge detection algorithms can be used to find the color discontinuities and the occlusion detection problem becomes a classification problem; given the detected edges of the image, one wants to know which one corresponds to depth discontinuities and which ones correspond to texture gradient over the same surface. Such classification problem can be addressed using machine learning techniques such as the one described in [1].

Multiple Images

When multiple images are available, there are means to access partial depth information. Such information allows to have a more reliable estimate of the occlusion boundaries. Multiple images of the same scene may come from multiple cameras observing the scene (multi-view imaging, stereo imaging) or from one moving camera observing the scene at two consecutive instants.

Detecting Occlusion Areas via Pixel Matching

When multiple views of the scene are available, it is possible to do pixel-level matching between the multiple images. This is an instance of a data association problem, and it is commonly instantiated as a labeling problem in the vision community. Each pixel in image I_1 will be either visible in I_2 , and thus should be matched or it may be part of an occluded area in I_2 and thus will be rejected during the matching. This strategy is effective for stereo matching (multi-view can be reduced to a set of pair-wise matching problems), and for optical flow cases.

Simultaneously deciding which is the displacement/disparity of each pixel and which pixel is occluded or not is a difficult optimization problem (see, for instance, [2]). A common strategy to relax the problem is to focus on symmetry constraints. Non-occluded pixels are visible in both images; by definition occluded pixels are visible in only one image or none. Thus, a common strategy to detect occluded pixels consists on matching first I_1 to I_2 (disregarding occlusion issues), then matching I_2 to I_1 , and finally verifying which displacements are consistent between the two matching results. Occluded pixels are expected to have inconsistent displacement.

This strategy has shown acceptable results for stereo matching and optical flow problems [3, 4].

Detecting Occlusion Boundaries via Flow Cues

In the case of optical flow, there are additional cues available other than simply pixel matching. Due to parallax effects or actual object motion, different objects will appear in the image with different (2-dimensional) motion vectors. Assuming object rigidity, it is then possible to delineate objects boundaries by finding areas where the optical flow is divergent [5]. Such objects boundaries estimates are also occlusion boundaries estimates.

Detecting Occlusions During Object Tracking

Previous sections describe occlusion detection at the pixel level. Occlusion detection is also a common concern when trying to track whole objects across multiple frames (i.e., trying to solve the object tracking problem). In its common formulation objects tracking is a data association problem of the same kind as pixel-level matching for depth estimation or optical flow. In its simplest form object-level occlusion detection will be done either via a threshold on the appearance similarity (if the appearance of the expected object location is too different from the object template, the object is considered occluded) or

via a temporal threshold on the objects detector (if an object nearby the expected location has not been detected for too long, it is considered occluded) [6].

Application

When computing depth maps, optical flow, or objects tracks for decision making, it is important to know which areas are reliable and which ones are not. By definition occluded areas offer unreliable information (no data) and thus must be detected. Once unreliable areas are detected, the decision process is improved. In applications when the output must be complete (e.g., in computer graphics), knowing which areas are occluded, enables applying infilling/interpolation algorithms over them to provide pleasing results. Occlusion areas and occlusion boundaries are linked to object boundaries, and as such are also an useful clue for object segmentation and detection.

Definition

Occlusion handling refers to the set of techniques employed to mitigate the effects of occlusion when doing inference from image.

Background

Occlusion is a fundamental phenomenon that limits the information that can be extracted from a camera observing a scene. Either when computing depth maps, optical flow, or tracking objects, occlusion will interfere with the inference process and create blank areas. In many applications, simply knowing which areas are occluded is good enough for the desired output. In other applications, it is desired to have an infilled/interpolated output without any blank. Occlusion handling makes reference to the latter case.

Theory

How to tackle the occluded areas is an application-specific problem. The three most common tasks that have to deal explicitly with occlusion are stereo matching, optical flow, and objects tracking. Other applications, such as visual odometry, also suffer from occlusion, but

they simply ignore it and consider it as input noise.

Occlusion Handling in Pixel Matching

For stereo matching and optical flow, the common strategy is to do extrapolation. Due to occlusion only a partial (non-occluded) view of the background object/surface is available. It is commonly assumed that the background surface is large, and thus covers also the occluded area. Given this assumption, the occluded area is simply infilled using extrapolations from the surrounding connecting background area.

For stereo matching, this can be done by simply infilling row per row the occluded area using the same disparity value as the lowest one (farthest from the camera) between the right and left side of the occlusion area. More sophisticated approaches try to fit local planes to infill the disparity map [1, Chap. 5].

For optical flow, the inpainting is done via an edge-sensitive anisotropic smoothing, that will naturally infill the blank areas using the surrounding flow [2].

Occlusion Handling in Object Tracking

In object tracking, one must distinguish the online case (only previous frames are available) and the offline case (all image frames of a video sequence are available).

For the online case, the appearance similarity is the main clue available. When no data association is found between a current track and the elements in the current frame, then the object position is extrapolated using the motion model. If too much time passes since the last successful detection, then the track is aborted. Should the object reappear later in the video, it will be annotated with a different object identifier (identity switch) unless a life-long set of detected objects is kept, and the match between the re-appearance and the object model is strong [3]. When objects are re-detected and associated after occlusions,

the track trajectory can be adjusted based on the new evidence [4].

For the offline case, a global optimization problem can be cast [5]. In such setup, the time of occlusion is trade-off with the strength of the global appearance similarity; it is then possible to track objects through longer occlusions without loosing the object identifier.

Definition

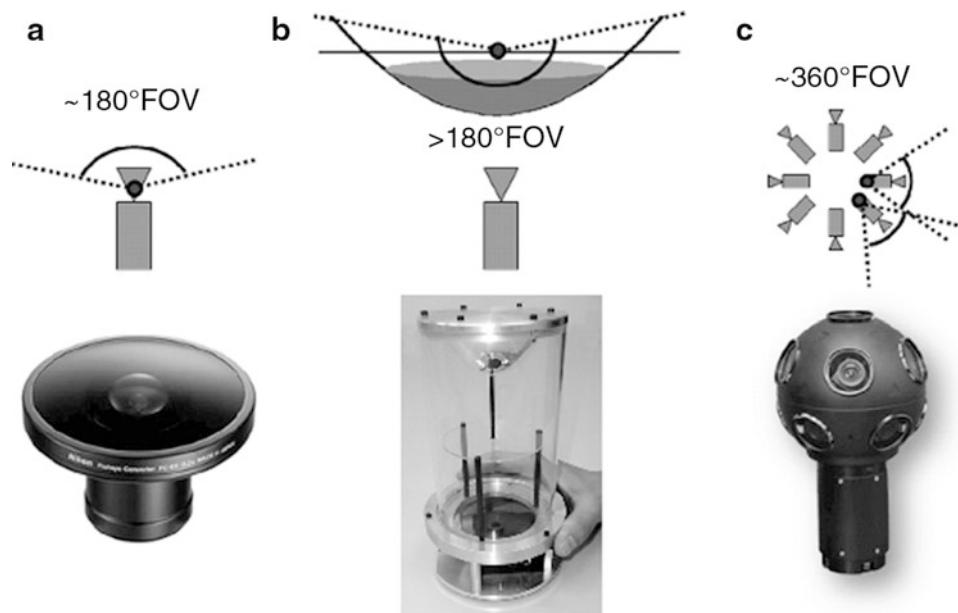

An omnidirectional camera (from *omni*, meaning all) is a camera with a 360-degree field of view in the horizontal plane or with a visual field that covers a hemisphere or (approximately) the entire sphere.

Background

Most commercial cameras can be described as pinhole cameras, which are modeled by a perspective projection. However, there are projection systems whose geometry cannot be described using the conventional pinhole model because of the very high distortion introduced by the imaging device. Some of these systems are omnidirectional cameras.

There are several ways to build an omnidirectional camera. Dioptric cameras use a combination of shaped lenses (e.g., fisheye lenses; see Fig. 1a) and can reach a field of view even bigger than 180° (i.e., slightly more than a hemisphere). Catadioptric cameras combine a standard camera with a shaped mirror – such as a parabolic, hyperbolic, or elliptical mirror – and provide 360-degree field of view in the horizontal plane and more than 100° in elevation. In Fig. 1b, you can see an example catadioptric camera using a hyperbolic mirror. Finally, polydioptric cameras use multiple cameras with overlapping field of view (Fig. 1c) and so far are the only cameras that provide a real omnidirectional (spherical) field of view (i.e., 4π steradians).

Catadioptric cameras were first introduced in robotics in 1990 by Yagi and Kawato [1], who used them for localizing robots. Fisheye cameras

Omnidirectional Camera, Fig. 1 (a) Dioptric camera (e.g., fisheye); (b) catadioptric camera; (c) an example polydioptric camera produced by Immersive Media

started to spread over only in 2000 thanks to new manufacturing techniques and precision tools that led to an increase of their field of view up to 180° and more. However, it is only since 2005 that these cameras have been miniaturized to the size of 1–2 cm and their field of view has been increased up to 190° or even more (see, for instance, Fig. 2a).

In the next sections, an overview on omnidirectional camera models and calibration will be given. For an in-depth study on omnidirectional vision, the reader is referred to [2–4] and to [5] for a more detailed survey on omnidirectional camera models.

Theory

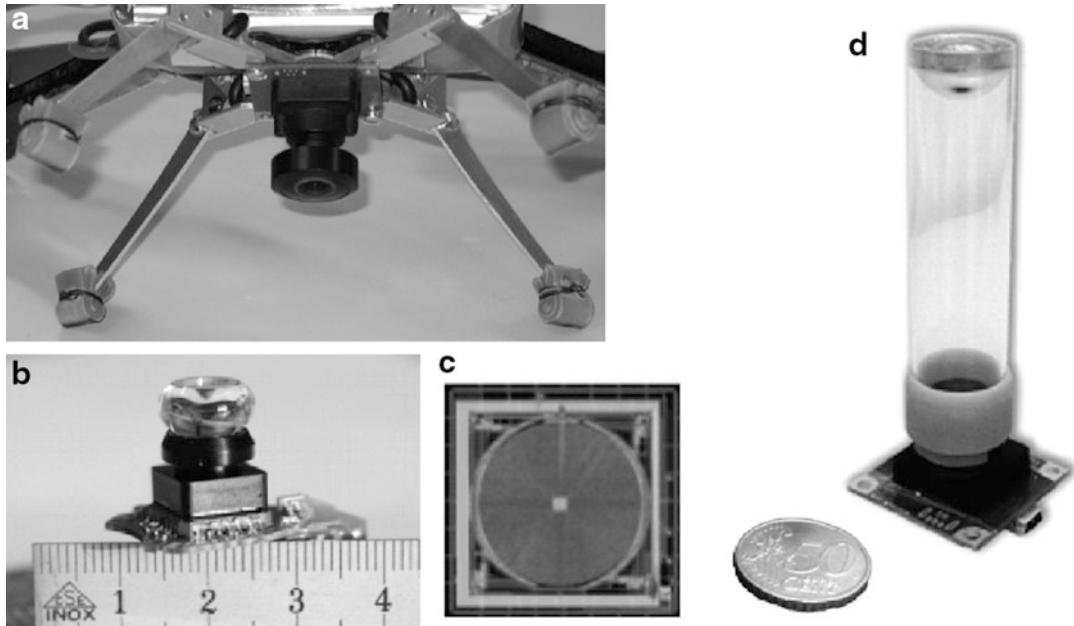

Central Omnidirectional Cameras

A vision system is said to be central when the optical rays to the viewed objects intersect in a single point in 3D called projection center or single effective viewpoint (Fig. 3). This property is called single effective viewpoint property. The perspective camera is an example of a central projection system because all optical rays inter-

sect in one point, that is, the camera optical center.

All modern fisheye cameras are central, and hence, they satisfy the single effective viewpoint property. Central catadioptric cameras conversely can be built only by opportunely choosing the mirror shape and the distance between the camera and the mirror. As proven by Baker and Nayar [6], the family of mirrors that satisfy the single viewpoint property is the class of rotated (swept) conic sections, that is, hyperbolic, parabolic, and elliptical mirrors. In the case of hyperbolic and elliptical mirrors, the single view point property is achieved by ensuring that the camera center (i.e., the pinhole or the center of the lens) coincides with one of the foci of the hyperbola (ellipse) (Fig. 4). In the case of parabolic mirrors, an orthographic lens must be interposed between the camera and the mirror; this makes it possible that parallel rays reflected by the parabolic mirror converge to the camera center (Fig. 4).

The reason a single effective viewpoint is so desirable is that it allows the user to generate geometrically correct perspective images from the pictures captured by the omnidirectional camera

Omnidirectional Camera, Fig. 2 (a) The fisheye lens from Omnitech Robotics (www.omnitech.com) provides a field of view of 190°. This lens has a diameter of 1.7 cm. This camera has been used on the sFly autonomous helicopter at the ETH Zurich, [18]. (b) A miniature catadioptric camera built at the ETH Zurich, which is also used for autonomous flight. It uses a spherical mirror and

a transparent plastic support. The camera measures 2 cm in diameter and 8 cm in height. (c) The muFly camera built by CSEM, which is used on the muFly helicopter at the ETH Zurich. This is one of the smallest catadioptric cameras ever built. Additionally, it uses a polar CCD (d) where pixels are arranged radially

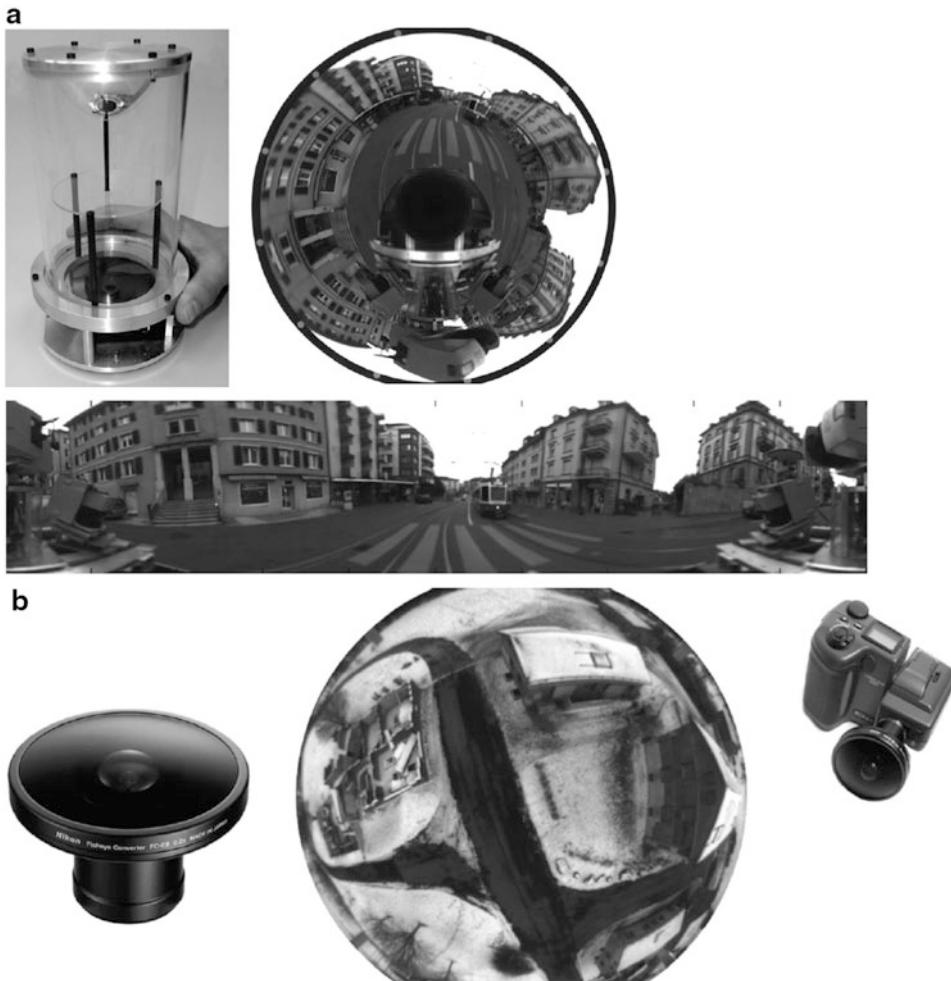

(Fig. 5). This is possible because, under the single view point constraint, every pixel in the sensed image measures the irradiance of the light passing through the viewpoint in one particular direction. When the geometry of the omnidirectional camera is known, that is, when the camera is calibrated, one can precompute this direction for each pixel. Therefore, the irradiance value measured by each pixel can be mapped onto a plane at any distance from the viewpoint to form a planar perspective image. Additionally, the image can be mapped on to a sphere centered on the single viewpoint, that is, spherical projection (Fig. 5, bottom).

Another reason why the single view point property is so important is that it allows the user to apply the well-known theory of epipolar geometry, which is extremely important for structure from motion. Epipolar geometry holds for any central camera, both perspective and omnidirectional.

Omnidirectional Camera Model and Calibration

Intuitively, the model of an omnidirectional camera is a little more complicated than a standard perspective camera. The model should indeed take into account the reflection operated by the mirror in the case of a catadioptric camera or the refraction caused by the lens in the case of a fisheye camera. Because the literature in this field is quite large, this entry reviews two different projection models that have become standards in omnidirectional vision and robotics. Additionally, Matlab toolboxes have been developed for these two models, which are used worldwide by both specialists and nonexperts.

The first model is known as the unified projection model for central catadioptric cameras. It was developed in 2000 by Geyer and Daniilidis [7] (later refined by Barreto and Araujo [8]), who have the merit of having proposed a model that encompasses all three types of central

Omnidirectional Camera, Fig. 3 (a) A catadioptric omnidirectional camera using a hyperbolic mirror. The image is typically unwrapped into a cylindrical panorama.

The field of view is typically 100° in elevation and 360° in azimuth. (b) Nikon fisheye lens FC-E8. This lens provides a hemispherical (180°) field of view

catadioptric cameras, that is, cameras using a hyperbolic, parabolic, or elliptical mirror. This model was developed specifically for central catadioptric cameras and is not valid for fisheye cameras. The approximation of a fisheye lens model by a catadioptric one is usually possible – however, with limited accuracy only – as investigated in [9].

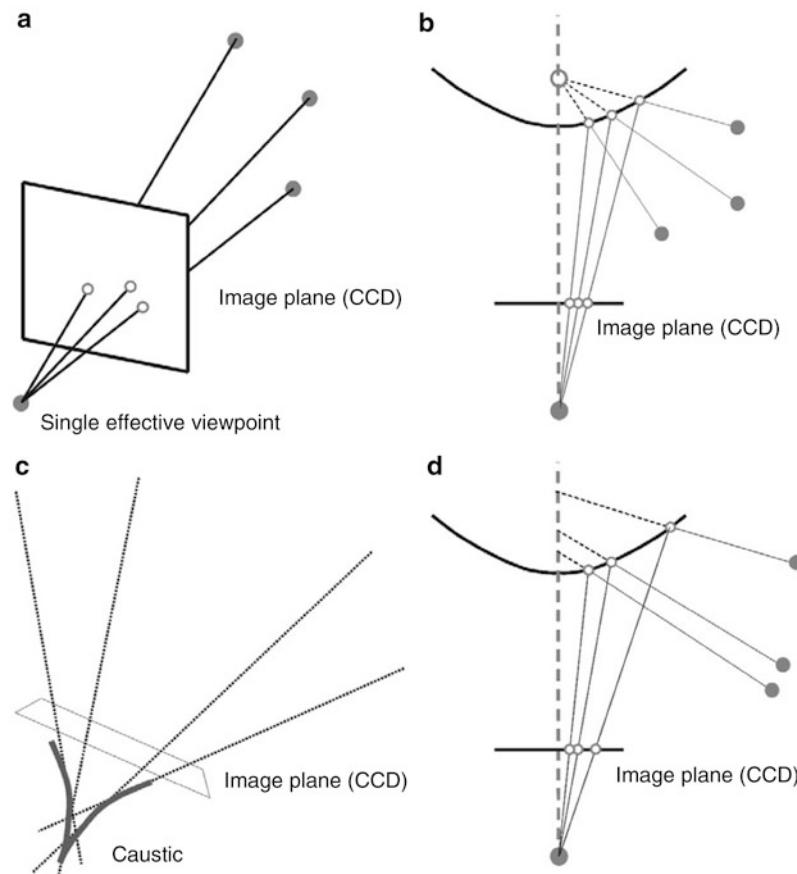

Conversely, the second model unifies both central catadioptric cameras and fisheye cameras under a general model also known as Taylor model. It was developed in 2006 by Scaramuzza et al. [10, 11] and has the advantage that

both catadioptric and dioptric cameras can be described through the same model, namely, a Taylor polynomial.

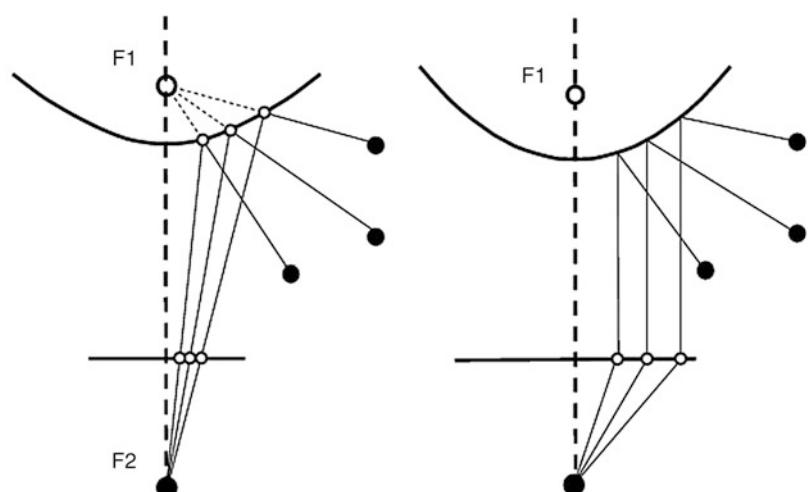

Unified Model for Central Catadioptric Cameras

With their landmark paper from 2000, Geyer and Daniilidis showed that every catadioptric (parabolic, hyperbolic, elliptical) and standard perspective projection is equivalent to a projective mapping from a sphere, centered in the single viewpoint, to a plane with the projection center on the perpendicular to the plane and distant ε from

Omnidirectional Camera, Fig. 4 (a) and (b) Example of central cameras: perspective projection and catadioptric projection through a hyperbolic mirror. (c) and (d) Example of noncentral cameras: the envelope of the optical rays forms a caustic

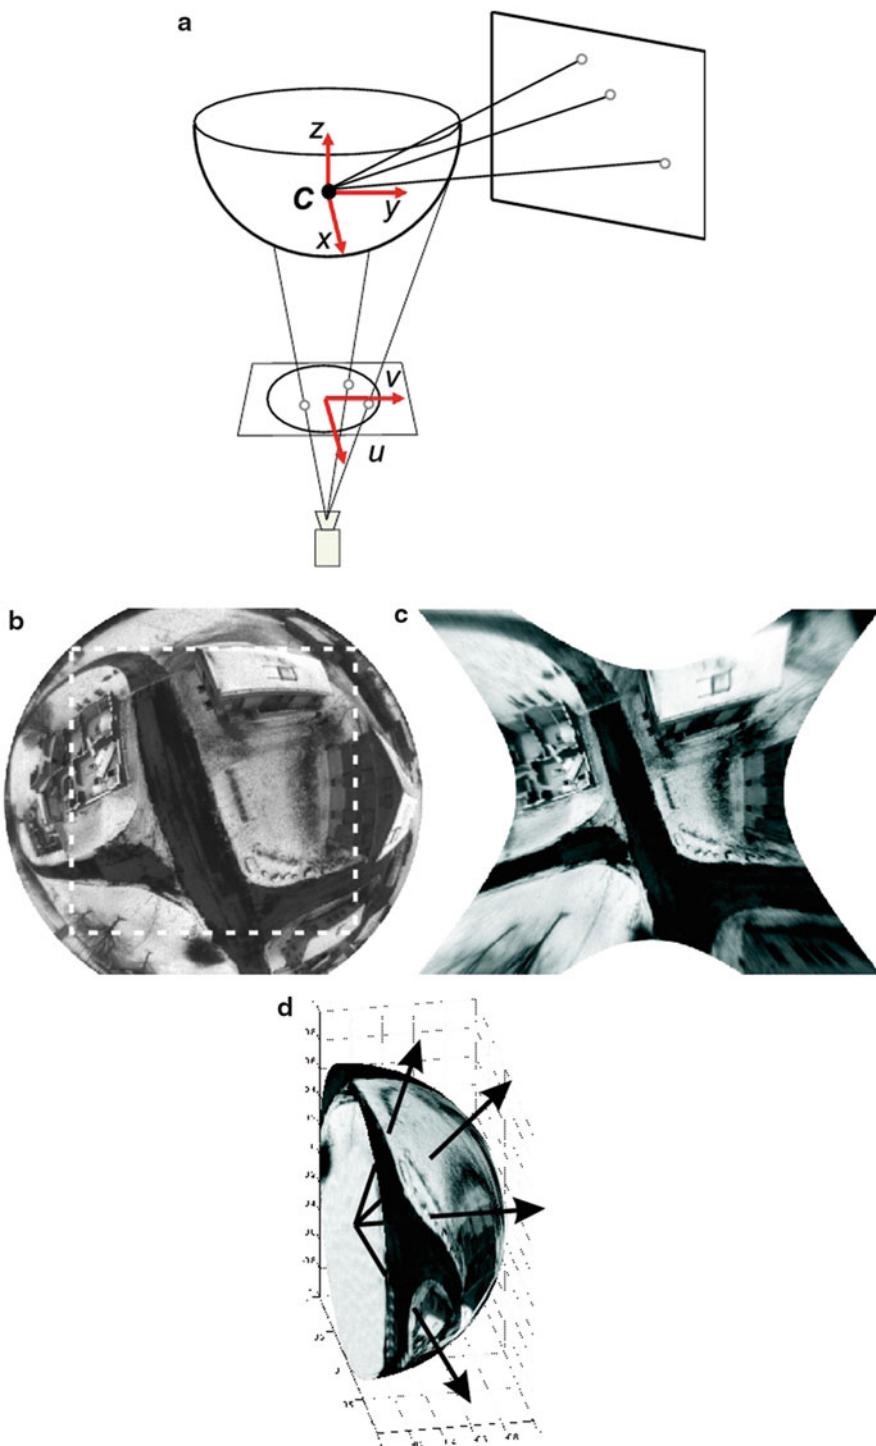

Omnidirectional Camera, Fig. 5 Central catadioptric cameras can be built by using hyperbolic and parabolic mirrors. The parabolic mirror requires the use of an orthographic lens

the center of the sphere. This is summarized in Fig. 6.

The goal of this section is to find the relation between the viewing direction to the scene point and the pixel coordinates of its corresponding

image point. The projection model of Geyer and Daniilidis follows a four-step process. Let $P = (x, y, z)$ be a scene point in the mirror reference frame centered in C (Fig. 6). For convenience, we assume that the axis of symmetry of the mirror

Omnidirectional Camera, Fig. 6 Central cameras allow the user to remap regions of the omnidirectional image into a perspective image. This can be done straightforwardly by intersecting the optical rays with a plane specified arbitrarily by the user (a). For obvious reasons,

we cannot project the whole omnidirectional image onto a plane but only subregions of it (b–c). Another alternative is the projection onto a sphere (d). In this case, the entire omnidirectional image can be remapped to a sphere

is perfectly aligned with the optical axis of the camera. We also assume that the x and y axes of the camera and mirror are aligned. Therefore, the camera and mirror reference frames differ only by a translation along z .

- The first step consists in projecting the scene point onto the unit sphere; therefore,

$$P_s = \frac{P}{\|P\|} = (x_s, y_s, z_s). \quad (1)$$

- The point coordinates are then changed to a new reference frame centered in $C_\varepsilon = (0,0,-\varepsilon)$; therefore,

$$P_\varepsilon = (x_s, y_s, z_s + \varepsilon). \quad (2)$$

Observe that ε ranges between 0 (planar mirror) and 1 (parabolic mirror). The correct value of ε can be obtained knowing the distance d between the foci of the conic and the latus rectum l as summarized in Table 1. The latus rectum of a conic section is the chord through a focus parallel to the conic section directrix.

- P_ε is then projected onto the normalized image plane distant 1 from C_ε ; therefore,

$$\begin{aligned} \tilde{m} &= (x_m, y_m, 1) \\ &= \left(\frac{x_s}{z_s + \varepsilon}, \frac{y_s}{z_s + \varepsilon}, 1 \right) = g^{-1}(P_s). \end{aligned} \quad (3)$$

- Finally, the point \tilde{m} is mapped to the camera image point $\tilde{p} = (u, v, 1)$ through the intrinsic parameter matrix K ; therefore,

Omnidirectional Camera, Table 1 ε values for different types of mirrors

| Mirror type | ε |
|------------------|-----------------------------|
| midrule Parabola | 1 |
| Hyperbola | $\frac{d}{\sqrt{d^2+4l^2}}$ |
| Ellipse | $\frac{d}{\sqrt{d^2+4l^2}}$ |
| Perspective | 0 |

$$\tilde{p} = K \tilde{m}, \quad (4)$$

where K is

$$K = \begin{bmatrix} \alpha_u & \alpha_u \cot(\theta) & u_0 \\ 0 & \alpha_v & v_0 \\ 0 & 0 & 1 \end{bmatrix} \quad (5)$$

- It is easy to show that function g^{-1} is bijective and that its inverse g is given by:

$$P_s = g(m) \propto \begin{bmatrix} x_m \\ y_m \\ 1 - \epsilon \frac{x_m^2 + y_m^2 + 1}{\epsilon + \sqrt{1 + (1 - \epsilon^2)(x_m^2 + y_m^2)}} \end{bmatrix}, \quad (6)$$

where \propto indicates that g is proportional to the quantity on the right-hand side. To obtain the normalization factor, it is sufficient to normalize $g(m)$ onto the unit sphere.

Equation (6) can be obtained by inverting (3) and imposing the constraint that P_s must lie on the unit sphere and, thus, $x_s^2 + y_s^2 + z_s^2 = 1$. From this constraint, we then get an expression for z_s as a function of ε , x_m , and y_m . More details can be found in [12].

Observe that Eq. (6) is the core of the projection model of central catadioptric cameras. It expresses the relation between the point m on the normalized image plane and the unit vector P_s in the mirror reference frame. Note that in the case of planar mirror, we have $\varepsilon = 0$ and (6) becomes the projection equation of perspective cameras $P_s \propto (x_m, y_m, 1)$.

This model has proved to be able to describe accurately all central catadioptric cameras (parabolic, hyperbolic, and elliptical mirror) and standard perspective cameras. An extension of this model for fisheye lenses was proposed in 2004 by Ying and Hu [9]. However, the approximation of a fisheye camera through a catadioptric one works only with limited accuracy. This is mainly because, while the three types of central catadioptric cameras can be represented through an exact parametric function (parabola, hyperbola, ellipse), the projective models of fisheye lenses vary from camera to

camera and depend on the lens field of view. To overcome this problem, a new unified model was proposed, which will be described in the next section.

Unified Model for Catadioptric and Fisheye Cameras

This unified model was proposed by Scaramuzza et al. in 2006 [10, 11]. The main difference with the previous model lies in the choice of the function g . To overcome the lack of knowledge of a parametric model for fisheye cameras, the authors proposed the use of a Taylor polynomial, whose coefficients and degree are found through the calibration process. Accordingly, the relation between the normalized image point $\tilde{m} = (x_m, y_m, 1)$ and the unit vector P_s in the fisheye (mirror) reference frame can be written as:

$$P_s = g(m) \propto \begin{bmatrix} x_m \\ y_m \\ a_0 + a_2\rho^2 + \dots + a_N\rho^N \end{bmatrix}, \quad (7)$$

where $\rho = \sqrt{x_m^2 + y_m^2}$. As the reader may observe, the first-order term (i.e., $a_1 \rho$) of the polynomial is missing. This follows from the observation that the first derivative of the polynomial calculated at $\rho = 0$ must be null for both catadioptric and fisheye cameras (this is straightforward to verify for catadioptric cameras by differentiating (6)). Also observe that because of its polynomial nature, this expression can encompass catadioptric, fisheye, and perspective cameras. This can be done by opportunely choosing the degree of the polynomial. As highlighted by the authors, polynomials of order 3 or 4 are able to model very accurately all catadioptric cameras and many types of fisheye cameras available on the market. The applicability of this model to a wide range of commercial cameras is at the origin of its success.

Omnidirectional Camera Calibration

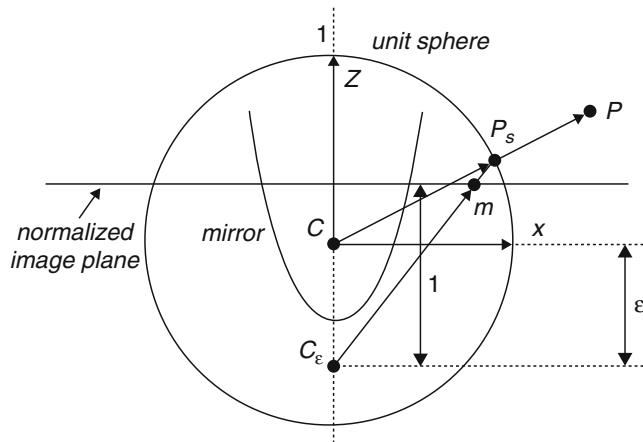

The calibration of omnidirectional cameras is similar to that for calibrating standard perspective cameras. Again, the most popular methods take advantage of planar grids that are shown by the

user at different positions and orientations. For omnidirectional cameras, it is very important that the calibration images are taken all around the camera and not on a single side only. This is in order to compensate for possible misalignments between the camera and mirror.

It is worth to mention three open-source calibration toolboxes currently available for Matlab, which differ mainly for the projection model adopted and the type of calibration pattern:

- The toolbox of Mei uses checkerboard-like images and takes advantage of the projection model of Geyer and Daniilidis discussed earlier. It is particularly suitable for catadioptric cameras using hyperbolic, parabolic, folded mirrors, and spherical mirrors. Mei's toolbox can be downloaded from [13], while the theoretical details can be found in [14].
- The toolbox of Barreto uses line images instead of checkerboards. Like the previous toolbox, it also uses the projection model of Geyer and Daniilidis. It is particularly suitable for parabolic mirrors. The toolbox can be downloaded from [12], while the theoretical details can be found in [15, 16].
- Finally, the toolbox of Scaramuzza uses checkerboard-like images. Contrary to the previous two, it takes advantage of the unified Taylor model for catadioptric and fisheye cameras developed by the same author. It works with catadioptric cameras using hyperbolic, parabolic, folded mirrors, spherical, and elliptical mirrors. Additionally, it works with a wide range of fisheye lenses available on the market – such as Nikon, Sigma, and Omnitech Robotics – with field of view up to 195°. The toolbox can be downloaded from [17], while the theoretical details can be found in [10, 11]. Contrary to the previous two toolboxes, this toolbox features an automatic calibration process. In fact, both the center of distortion and the calibration points are detected automatically without any user intervention. This toolbox became very popular and is currently used at several companies such as NASA, Philips, Bosch, Daimler, and XSens.

Omnidirectional Camera, Fig. 7 Unified projection model for central catadioptric cameras of Geyer and Daniilidis

Application

Thanks to the camera miniaturization, to the recent developments in optics manufacturing, and to the decreasing prices in the cameras^{if}; market, catadioptric and dioptric omnidirectional cameras are being more and more used in different research fields. Miniature dioptric and catadioptric cameras are now used by the automobile industry in addition to sonars for improving safety, by providing to the driver an omnidirectional view of the surrounding environment. Miniature fisheye cameras are used in endoscopes for surgical operations or onboard microaerial vehicles for pipeline inspection as well as rescue operations. Other examples involve meteorology for sky observation.

Roboticians have also been using omnidirectional cameras with very successful results on robot localization, mapping, and aerial and ground robot navigation [18–23]. Omnidirectional vision allows the robot to recognize places more easily than with standard perspective cameras [24]. Furthermore, landmarks can be tracked in all directions and over longer periods of time, making it possible to estimate motion and build maps of the environment with better accuracy than with standard cameras; see Fig. 2 for some of examples of miniature omnidirectional cameras used on state-of-the-art micro aerial vehicles. Several companies, like Google, are using omnidirectional cameras

to build photorealistic street views and three-dimensional reconstructions of cities along with texture. Two example omnidirectional images are shown in Fig. 7.

Definition

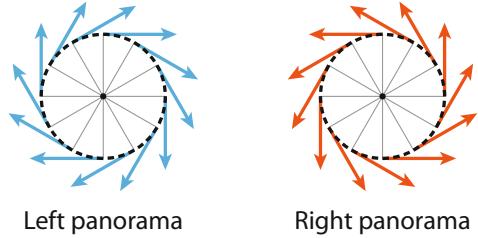

Omnidirectional stereo (ODS) is a type of multi-perspective projection that captures horizontal parallax tangential to a viewing circle. This data allows the creation of stereo panoramas that provide plausible stereo views in all viewing directions on the equatorial plane.

Background

The term “omnidirectional stereo” was first coined by Ishiguro et al. [1] in 1990, who used it in the context of autonomous mapping and exploration of an unknown environment. Their approach places a video camera on a rotating arm that is driven by a stepper motor (see Fig. 1). They then take vertical slit images from the sensor image for creating the left/right stereo panoramic views. As their primary goal is to map an environment, they use ODS images for depth estimation of scene points rather than display. They also present a binocular stereo method for depth estimation from two ODS images with a measure for direction-dependent uncertainty.

Omnidirectional Stereo, Fig. 1 Omnidirectional stereo images can be captured with a single camera mounted on an arm of length r that rotates about a point C . (Figure adapted from Ishiguro et al. [1])

Omnidirectional Stereo, Fig. 2 Omnidirectional stereo projection creates two panoramas, for the left and right views, using rays tangential to the viewing circle

Before the term “omnidirectional stereo” became established with its current meaning, it was used more broadly for any stereo imaging system, which captures stereo panoramas with disparity, regardless of direction. Gluckman et al. [2], for example, created a real-time system consisting of two catadioptric cameras that are vertically displaced. These cameras capture omnidirectional views of an environment that therefore primarily differ by vertical disparity. While this works just as well for depth estimation, these vertical stereo panoramas are unsuitable for being viewed by humans. This is because our eyes are horizontally displaced and the human visual system thus expects horizontal disparity, not vertical disparity. In the following, the focus therefore lies on stereo panoramas with horizontal disparity.

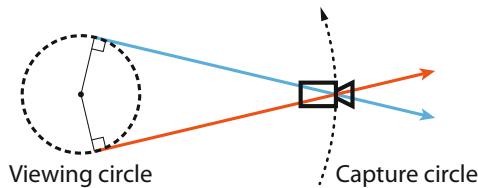

Since the early days of ODS for mapping and robotics, the main application has shifted toward display on monitors, projection screens, and head-mounted virtual reality displays: Peleg et al. [3] popularized “omnistereo” panoramas with automatic disparity control, Richardt et al. [4] proposed improvements for creating high-quality, high-resolution stereo panoramas, and Anderson et al. [5] and Schroers et al. [6] developed state-of-the-art systems for capture and display of real-world virtual reality video. The benefit of ODS video is that time-varying stereo panoramas can easily be packed into a traditional video, which can be processed, stored, and transmitted on existing video streaming platforms just like any other video. This has established omnidirectional stereo as a widely supported format

by video streaming pipelines and virtual reality displays.

Theory

Omnidirectional stereo is fundamentally a multi-perspective projection that is created from rays that are tangential to a *viewing circle* [3]. This projection can, for example, be captured by a slit camera that moves along a circular path and looks in the tangential direction. The slit images captured at different positions on the viewing circle are mosaicked into a panorama, producing the ODS projection. The two possible tangential directions give rise to the left and right panoramas, as illustrated in Fig. 2. The diameter of the viewing circle is usually chosen to be the average human interpupillary distance of 65 mm; however, other sizes are possible.

As we shall see, most ODS systems do not capture the ODS projection directly. The only implementation of a pair of rotating slit cameras is by Konrad et al. [7]. The key benefit of this approach is that the system directly captures the ODS projection without requiring computationally expensive processing. In addition, this system natively supports scenes containing nearby objects, occlusions, thin and repetitive textures, transparent and translucent surfaces, and specular and refractive objects, which remain challenging for other capture approaches. However, the prototype camera was limited to only five frames per second due to the fast rotation of the camera assembly that is required for operation.

Omnidirectional Stereo, Fig. 3 A single rotating camera can capture all rays tangential to the viewing circle, by rotating it on a larger *capture circle* that is concentric to the viewing circle. Note that this only works perfectly within the plane containing the viewing and capture circles; other rays are captured with vertical distortion. (Figure adapted from Anderson et al. [5])

Ishiguro et al. [1] first described and Peleg et al. [3] later popularized a single-camera approach that rotates a standard perspective camera on a larger *capture circle* that is concentric to the viewing circle. The camera needs to rotate a full 360 degrees to capture a complete ODS panorama, which assumes a static scene during the capture time. As illustrated in Fig. 3, the camera can simultaneously capture rays for both the left and the right stereo panorama. While this works perfectly in the 2D equatorial plane, out-of-plane rays introduce vertical distortion [5], and perspective cameras introduce perspective distortion. Richardt et al. [4] proposed techniques for correcting perspective distortion and for removing stitching artifacts using flow-based blending. Stabilization steps were also introduced that reduce drift from image alignment and enable handheld capture, where the camera's pose often deviates from the ideal position and orientation along the capture circle.

However, the rotating-camera approach is not practical for capturing ODS *videos*, as the camera needs to rotate a full 360 degrees for each video frame. For example, this would require very fast 30 revolutions per second for capturing ODS video with 30 frames per second. Peleg et al. [3] explored theoretical optical designs involving spiral mirrors and spiral lenses that would enable single-shot ODS capture and thus single-camera ODS video. However, these designs were never realized. The TORNADO system by Tanaka and Tachi [8] was the first practical implementation based on these designs. Elongated prism sheets deflect the light rays

entering the cylindrical camera system and emulate 32 slit cameras that rotate over time. Inside the cylinder, a hyperboloidal mirror reflects light rays into a stationary video camera. The projections of the slit cameras into the video camera are separated in two different ways: (1) based on their spatial location in images or (2) using linear/circular polarizers. Aggarwal et al. [9] proposed a different approach that uses a carefully designed mirror with a “coffee filter” shape and reflects multiple slit camera images into the video camera without any additional optical elements. High-resolution simulations validate this concept, but manufacturing inaccuracies severely reduce the visual quality of real-world captures. Low visual quality and image resolutions are problems shared by all current catadioptric single-camera approaches [8, 9].

Approaches with multiple omnidirectional cameras improve some of the quality problems caused by complex optical elements. Chapdelaine-Couture and Roy [10] presented an approach for three or more fisheye cameras that are arranged in a regular polygon, with parallel viewing directions toward the sky. They observed that the planes spanned by the optical axes of adjacent pairs of cameras can be used for cutting their omnidirectional images and stitching them together with minimal disparity mismatch. However, this approach can only capture the upper hemisphere of any scene. Matzen et al. [11] proposed a system that uses two consumer spherical cameras, which have two 180-degree fisheye lenses each. The cameras are mounted side by side with a distance of 64 mm, and the captured imagery is sliced by the plane going through the cameras (orthogonal to the optical axes) and recombined to create the necessary left/right panoramas for ODS imagery. Their approach cancels vertical disparity at the seams using warping in image space and uses this disparity to correct horizontal disparity. As horizontal disparity is maximal in front of the cameras but zero along the camera baseline, this correction depends on the azimuth angle. In both cases, the resolution of the resulting ODS video was not sufficient for high-quality virtual reality experiences due to limited sensor resolutions [10, 11].

The highest visual quality and image resolution of ODS video has been demonstrated by approaches that use multiple video cameras spaced evenly on a circle, like a discretized version of the continuously rotating camera of earlier approaches [1, 3, 4]. Anderson et al. [5] pack 16 GoPro cameras with fisheye optics into a tightly packed ring of 28 cm diameter, demonstrating that this is a sweet spot between more cameras and a smaller ring diameter that reduces vertical distortion. Their work comprises a detailed analysis of the sources of vertical parallax and distortion and presents a flow-based stitching pipeline that produces temporally coherent ODS video, as available on YouTube, for example. Schroers et al. [6] also use 16 video cameras, but formulate their video pipeline based on continuous light field reconstruction from sparse samples. This naturally leads to a panoramic image formation model that allows computer-generated imagery to be composited with captured real-world content. They also provide an analysis of the minimum visible depth that can be stitched or reconstructed, based on the number of cameras in the rig and their field of view.

Application

The initial application for omnidirectional stereo was for mapping and exploring environments using robots [1]. In this scenario, a single rotating camera provides a low-cost and effective solution for reconstructing a given static scene. Ishiguro et al. [1] demonstrate how to estimate the depth of points from a single ODS image but also from a binocular pair of ODS images. They further show that the accuracy of depth estimation depends on the direction relative to the camera baseline, with parallel directions having the highest uncertainty. This uncertainty can be decreased by integrating multiple observations in the form of local maps into a single global map.

Since then, omnidirectional stereo has become the de facto standard projection for stereo panoramas that are used for virtual reality photography and video. Google's Cardboard Camera app, for example, is based on the principles described

by Richardt et al. [4] for creating high-quality, high-resolution stereo panoramas. Multiple independently developed systems for VR videos – including Google Jump [5, 6], and Facebook Surround360 [12] – have arrived at remarkably similar hardware: multi-view camera rigs with 14–16 cameras that are packed into a tight ring to capture omnidirectional stereo video. As of 2019, this defined the state of the art in widely available virtual reality imagery and video.

Definition

Omnidirectional vision consists of the theoretical and practical computer vision approaches devised for images acquired by omnidirectional cameras, that is, cameras with a very large field of view, typically hemispherical or larger.

Background

Most regular cameras have a restricted field of view, typically up to several tens of degrees. Omnidirectional cameras, on the contrary, have hemispheric or even larger, up to complete spherical, fields of view. Computer vision theories and algorithms dedicated to omnidirectional images are subsumed under the expression omnidirectional vision. Researchers working on omnidirec-

tional vision have also proposed novel designs of omnidirectional cameras.

The interest of building omnidirectional cameras arose rather soon after the invention of photography, with the first known panoramic camera built in 1843 [1]. To be precise, this and other early panoramic cameras had a restricted vertical field of view and are thus not truly omnidirectional.

There exist several technologies to acquire omnidirectional images. The first to be used was based on rotating a regular camera about its optical center and optically or computationally stitching images together to a panoramic image. *Panoramic cameras* can be considered as a subset of omnidirectional ones, in that they usually deliver an extended field of view only in one direction. If the camera is rotated about different axes, acquired images may be stitched to form a complete omnidirectional mosaic.

Probably the second omnidirectional technology was based on multi-camera systems, where the rotating camera was replaced by several collocated cameras with overlapping fields of view. Such systems were built at least as early as in 1884 [2, 3].

The most common single-camera solutions that allow the acquisition of instantaneous omnidirectional images, that is, without having to acquire multiple images while rotating a camera, are *fisheye cameras* and *catadioptric cameras*. The latter achieve large fields of view by having one or more cameras look at a curved mirror or one or more planar or curved mirrors.

Theory

When working with images acquired by omnidirectional cameras, one usually first needs an *image formation model*. Many camera models have been proposed for omnidirectional systems. Some of them resemble classical models for radial and tangential distortion in that they are based on polynomial expressions. Others, typically models for fisheye lenses, use trigonometric functions and yet others are specific to catadioptric cameras. A recent overview of such

camera models can be found in [3]. Common to all models is that they allow to project 3D points onto image points and/or perform back projection, from image points to lines of sight in 3D.

Besides purely geometrical aspects of omnidirectional image formation, other aspects and properties have been examined such as focusing mechanisms, blur, and chromatic aberrations; see, for instance, [4]. Generally speaking, these issues all tend to be more complex than with regular cameras.

The *calibration* of an omnidirectional camera is in principle not different from that of a regular camera, in that it exploits images of reference objects with known shape or special properties, for example, showing straight lines on their surface. In practice, calibrating an omnidirectional camera is usually more complex, since usual calibration objects do not fill the field of view completely, thus requiring the acquisition of more images. Also, omnidirectional images are often less sharp and are by definition less resolved, thus making feature extraction and matching more challenging.

Besides modeling and calibrating omnidirectional cameras, other fundamental works in omnidirectional vision are dedicated to image processing. The goal of these works is to adapt image processing operations, for example, for edge or interest point extraction, to the image formation model which usually includes strong distortions, in order to enhance their performance [5, 6].

Application

Once an omnidirectional camera is calibrated, one can in principle use the same algorithms for tasks such as pose estimation, motion estimation, or 3D modeling as for regular cameras and the usual model thereof (pinhole model). There exist several differences though. For example, for motion estimation, results with omnidirectional cameras are often better than with cameras with a smaller field of view [7]. With a small field of view, a lateral translation and a lateral rotation give rise to similar optical flows, whereas

in an omnidirectional image, the optical flows in the “sideways” looking parts of the image will be very different for these two types of motion. This explains why motion estimation may be expected to be more stable when performed with omnidirectional images. For pose estimation, the converse is often the case, simply because the spatial resolution is lower than with a smaller field of view, decreasing the accuracy of the estimated object pose. Further, as mentioned above, processing of omnidirectional images may have to have recourse to specific approaches, in order to handle the strong distortions present in them.

Typical applications of omnidirectional vision are those where the extended field of view is directly beneficial. Among the first applications of omnidirectional images were the study of cloud formations in meteorology and the measurement of leaf coverage from fisheye images of forest canopies. A main application field for omnidirectional vision is the navigation of mobile robots, where obstacles can be detected instantaneously in all directions and where an omnidirectional camera allows for a more stable motion estimation and a more complete path planning than a narrow field of view camera. Other obvious usages are in video surveillance and tele-presence applications.

[Opaque](#)

Related Concepts

- ▶ [Transparency](#)

Definition

Opacity is the property of objects to not transmit light. This non-transmittance can be due to several factors: (1) absorption, (2) scattering, and (3) reflection.

The corresponding adjective is “opaque.” Opaque objects are neither transparent nor translucent. Sometimes the opposite property is referred to as *transmittance* (mostly in Physics).

In Computer Graphics, the opposite of opacity is typically referred to as *transparency*.

The word opaque is often used in conjunction with absorbing objects; however, it is important to note that reflecting objects like mirrors are also opaque.

Background

A common notion is that most computer vision algorithms, whether designed for 3D reconstruction, object detection, object classification, etc., require the scene and the objects it consists of to be opaque. However, with slightly more precision, objects are required to be diffusely opaque: in particular, specularly reflective objects are opaque by the above definition, but most vision techniques cannot handle them.

A multitude of research has gone into lifting the restriction on scene opacity. When going beyond opaque objects, images are typically enhanced by an *alpha channel* – a fractional measure of opacity or the amount by which an object obscures the background in an image.

In television and film production, the alpha channel is extensively used and usually estimated by *chroma keying* [5]. This technique uses a colored background in order to estimate the alpha channel.

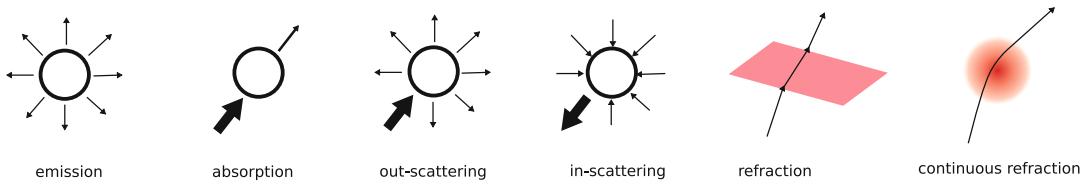

Theory

The following contains a discussion of the physical (optical) principles causing the perception of opacity.

The four main interactions of radiation with matter are absorption, scattering, reflection, and transmittance. Accordingly, the overall radiant energy, i.e., the energy carried by electromagnetic radiation, at a non-emissive point in space is, due to conservation of energy, given by [9]:

$$Q_{\text{tot}}(\lambda) = Q_a(\lambda) + Q_s(\lambda) + Q_r(\lambda) + Q_t(\lambda). \quad (1)$$

Here, Q_{tot} is the total amount of energy, whereas Q_a is the absorbed, Q_s the scattered,

Opacity, Fig. 1 The major effects of radiative transport (from left to right): emission, absorption, out-scattering, in-scattering, and two types of refraction

Q_r the reflected, Q_t the transmitted amount of energy, and λ the wavelength of light. Division by Q_{tot} results in a fractional formula:

$$1.0 = A + S + R + T, \quad (2)$$

where the terms, in order, correspond to the formula given above. Opaque objects are therefore those for which $T = 0$. An opaque object is neither transparent ($A = S = 0, R < 1$) nor translucent ($A + S + R < 1$).

In general, as indicated in Eq. 1, the values are wavelength dependent and therefore the source of color [9]. In some circumstances, the absorption and re-emission can change the wavelength (fluorescence/phosphorescence) and incur temporal delays (fluorescence $\approx 10^{-8}s$, phosphorescence up to several hours). A more refined version of Eq. 1 is therefore:

$$Q_{\text{tot}} = \int_{\Omega} \int_{\lambda_{\min}}^{\lambda_{\max}} \int_{t_0}^{\infty} Q_a(x, \lambda, t) + Q_s(x, \lambda, t) + Q_r(x, \lambda, t) + Q_t(x, \lambda, t) dt d\lambda dx. \quad (3)$$

As an example, consider a laser pulse with wavelength λ_0 hitting an object at position x_0 at time t_0 . If $Q_{\text{tot}}(x_{\text{BS}}, \lambda, t) = 0$ for a suitably chosen set of points x_{BS} defining the backside of the object (Typically, the points x_{BS} are in the geometrical shadow of the object with respect to the light source.) for all $t \geq t_0, \lambda \in [\lambda_{\min}, \lambda_{\max}]$, the object is said to be opaque to wavelength λ_0 .

In computer vision, we typically assume λ_0 to be in the visible part of the spectrum, i.e., between approximately 380 and 650 nm. The wavelength dependence is important since practically all materials are transparent in some wavelength range. As an example, common materials

are transparent to x-rays, but materials that are transparent in the visible can be opaque in other wavelength ranges, e.g., optical glass in the UV range.

Mechanisms

A look at the three main mechanisms that may render a material opaque further elucidates the property opacity. In general, the opacity depends on the thickness of material that an object consists of which is the reason to attribute opacity to objects rather than to materials.

Absorption Absorption occurs due to mainly two mechanisms: atomic and molecular absorption and absorption in solids.

(a) *atomic and molecular absorption* When a photon's energy is absorbed by the electronic orbitals of an atom or molecule, atomic or molecular absorption occurs. In this case, the photon's energy $Q_e = h\nu$ must match the energy difference between two atomic/molecular energy levels, the lower one of which is occupied by an electron. Here, ν is the photon frequency and h is Planck's constant. The electron takes up the photon's energy and occupies the upper energy level after the interaction, leaving the atom/molecule in an excited state. This effect gives rise to discrete absorption lines as, for example, seen in the solar spectrum (Fraunhofer lines). The exact energy levels are subject to many physical conditions such as the vibrational and rotational state of the atom, the presence of magnetic fields, the presence of nearby other atoms or molecules, etc. These conditions lead to discretely split or continuously broadened energy levels. Their prediction is in the domain of quantum mechanics.

Atomic and molecular absorption will explain the absorption seen in gases and liquids.

(b) *absorption in solids* The tight arrangement of atoms in a solid has a strong influence on the absorption properties of a material. One generally distinguishes *metals* or *conductors*, *semi-conductors*, and *insulators* or *dielectrics*. Conduction takes place when free electrons are present in the material. This is the case if the material's band (Bands replace the atomic orbitals in dense substances since the individual atoms' orbitals merge. The band structure is temperature dependent.) gap is negligible or non-existent. Since light is electromagnetic radiation, it acts on charged objects like the free electrons, exerting a force, the so-called Lorentz force, on them. The force results in an acceleration of the electrons, increasing their velocities, which results in increased heat. Conduction leads to very efficient absorption, i.e., a transmitted wave is only entering conducting materials up to a depth of small fractions of a wavelength (on the order of the *skin depth* [3], II-32-7). This effect is, e.g., exploited in optical thin film sensors.

In semi-conductors, the electrons are lifted across the band gap, which must be smaller than the absorbed photon's energy. This photo-electric effect, discovered by Hertz and Hallwachs and explained by Einstein, is used in photo-detectors like CCDs and CMOS.

Absorption in insulators is mainly caused by the interaction of the electromagnetic wave with the electron orbitals and nuclei. The orbitals and nuclei are put into vibration by the changing electromagnetic field, and energy is dissipated as heat within the materials. For a detailed discussion, see [3], II-32-3.

Scattering Scattering describes a broad range of physical processes, both particle and wave phenomena, upon interaction of light with a material. The term itself describes deviation of light from a straight path due to inhomogeneities in the material that is being traversed. As an example, scattering can be caused by small particles in paints, droplets in clouds and water spray, soot particles in smoke, and many more. If waves are

scattered by obstacles that are small in comparison to the wave length, the scattering is often termed *diffraction*. Properly speaking, reflection and refraction can also be considered as (very directed) scattering processes. However, the term scattering is most often employed to refer to microscopic light/material interactions. A formal description of energy transfer in scattering media, of which light transport is a special case, can be found in [8].

If a scattering process preserves energy, it is known as elastic scattering. The terminology stems from mechanics where a perfectly elastic collision is one that conserves kinetic energy and momentum. In this case, photons are effectively deviated. This may include the absorption and re-emission of photons, however, keeping their energy and thus the wavelength λ_0 constant.

If the photon energy changes in the process of absorption and re-emission, the scattering is known as inelastic. Examples are the already mentioned effects of fluorescence and phosphorescence.

Reflection The effect of reflection is a direct consequence of the electromagnetic nature of radiation. At material boundaries, where the electromagnetic material constants (They are not constant for different wavelengths of light.) (specific conductivity, magnetic permeability and electric permittivity) change abruptly, Maxwell's equations result in boundary conditions that necessitate a reflected and a transmitted part in response to an incident electromagnetic wave [1]. It is physically impossible to have only one of them. Therefore, reflection and transmission always occur when light interacts with a material surface. The reflected part may be minimized by anti-reflecting coatings. Similarly, the transmitted part may be absorbed very quickly, as in the case of metals (in the visible part of the spectrum).

Summary Opacity is a very broad term that covers a wide variety of different physical effects. Perfect opacity depends on the material thickness, the bulk material properties, possibly even the object shape, etc. It is a gradual process throughout the volume of an object (even of at

rather shallow depth beneath the surface) rather than a binary classification scheme. When the gradual effect is important, we speak of attenuation (see below).

Further Reading The classic textbook by Born and Wolf [1] and the informative book by Tilley [9] feature a detailed discussion of the physical effects pertaining to the concept of opacity. A classic intuitive explanation can be found in the Feynman Lectures on Physics [3], in particular lecture I-31 “The Origin of the Refractive Index,” lecture II-32 “Refractive Index of Dense Materials,” and lecture II-33 “Reflection from Surfaces.”

Modeling

As outlined above, there is no single physical process giving rise to what is known as opacity in computer vision. There can be a multitude of reasons for opacity to occur. The microscopic origins involved have been explained above. However, there are also macroscopic effects that may give rise to (partial) opacity.

An example is *sensor integration* over the area of a single pixel: If the scene consists of many tiny objects that are somehow interacting with the surrounding light, seen against a background, sensor integration averages over the light contribution from the objects and the background. This can often be seen when observing thin structures like hair or fur, or leaves on distant trees.

Correspondingly there is a wide variety of models of different complexity and applying to different scales of reality. Some of them are physical (to be outlined first), and some are purely phenomenological such as alpha blending in computer vision.

Attenuation The attenuation of light is due to the physical joint processes of absorption and scattering as outlined above. On the particle level, the absorption and scattering processes are statistical. Their net effect, however, is typically described in a continuous manner. In this description, the magnitude of absorption/scattering depends on the path length of light in the traversed medium. It is given by the *Beer-Lambert Law*:

$$\frac{L}{L_0} = \exp^{-\int_{s_0}^{s_1} \sigma_s \circ c(s) + \sigma_a \circ c(s) ds}. \quad (4)$$

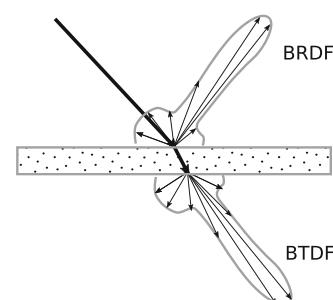

The ratio L/L_0 of outgoing over incident radiance is known as the *optical path length* in the interval $[s_0, s_1]$. Here, L_0 is the incident radiance and L is the radiance after attenuation. (Fresnel reflection (see below) is not included as a source of transmitted energy loss.) The path of the photon is described by the curve $c(s) : \mathbb{R} \mapsto \mathbb{R}^3$, σ_s is the *absorption coefficient* and σ_a the *scattering coefficient*. The scattering coefficient describes the loss of light due to out-scatter, while the absorption coefficient describes the loss due to absorption. Sometimes, the factor $\alpha = \sigma_s + \sigma_a$ is referred to as *attenuation coefficient*.

The linearized version of the Beer-Lambert law

$$\ln(L/L_0) = - \int_{s_0}^{s_1} \sigma_s \circ c(s) + \sigma_a \circ c(s) ds \quad (5)$$

is the basis for emission and absorption tomography.

The *Fresnel effect* is a natural source of attenuation and blending at interfaces of materials with different refractive index. A ray is usually split into a transmitted and a reflected part. While the geometry and the law of reflection, respective Snell's law, determine only the directions of the reflected and refracted ray, the radiance ratio can be computed with the Fresnel formulae. The transmittance and reflectance depend on the polarization state of the incident ray.

Scattering can occur both in transmission and in reflection. As mentioned, the effect is statistical

in nature. The prevalent modeling in the computer vision literature uses distribution functions that are essentially probabilities that a photon will be reflected/refracted or scattered in different directions.

We first discuss models for scattering at material interfaces. Reflection scattering is usually described by the (hemispherical) *bidirectional reflection distribution function* (BRDF), whereas transmissive scattering is described by the (hemispherical) *bidirectional transmission distribution function* (BTDF). These functions describe scattering at an interface or due to thin transmissive layers of material. Sometimes, the combined effect of reflection and transmission at an interface is described by a single (spherical) *bidirectional scattering distribution function* (BSDF).

In contrast, for volumetric phenomena, the redistribution of light is described by the *scattering phase function*. For light traversing a volume of participating media, the major effects are out-scattering, i.e., light being deflected from its original, unobstructed path, and in-scattering, i.e., light being deflected from elsewhere onto the unobstructed path of a photon. If only a single scattering event occurs, the process is called *single scattering*; otherwise it is referred to as *multiple scattering*. If both scattering and absorption occur, in-scattering can have an effect on the attenuation coefficient described above.

Standard physical models for scattering include *Rayleigh scattering* for scattering at microscopic particles much smaller than the wavelength of light and *Mie scattering* for scattering off spherical particles. For a detailed discussion, see e.g., [4].

Refraction

As previously discussed, a ray of light crossing an interface is typically both reflected and transmitted. The transmitted part is usually refracted as well, i.e., the ray changes direction upon being transmitted into the material. This results in a different background pixel to be seen if a refractive object is moved into a ray that previously hit the background. A single opacity value for a camera pixel is thus not sufficient to explain the complex change in light transport. Rather, the

opacity value must be associated with the ray in question. For opaque objects, the attenuation of the transmitted ray is very strong. They are thus perceived as not transmitting light. A special case of refraction occurs in unevenly heated media like gases or liquids or in mixtures of different gases. Here, *continuous refraction* is taking place, resulting in curved light paths. In wave optics, the *complex refractive index* is used as a mathematical tool to represent continuous refraction and attenuation in one number.

Application

Alpha Matting

Alpha matting is an extension to chroma keying discussed in the background section. Here, the more general problem where the background is arbitrary instead of consisting of a single color is considered. This problem comes in several flavors:

- dynamic scene, static known background,
- static scene, static unknown background, i.e., natural image matting,
- dynamic scene, static unknown background, and
- dynamic scene, dynamic background, i.e., video matting [2].

The corresponding process of synthetically overlaying an object image onto some background is known as *alpha blending*.

Apart from these two-dimensional applications, opacity has been used to three-dimensionally model transparent or translucent objects either phenomenologically as partially transparent view-dependent visual hulls [7] or for estimating the internal structure of volumetric light-emitting or absorbing objects and phenomena. The latter is usually performed using tomographic techniques [6].

Tomography

Tomography is the process of determining a function from its projections. In the tomographic sense, a projection is a line integral through some

volumetric function. A collection of line integrals, taken from many different directions, can be used to compute the inner structure of volumetric phenomena. The best known application is computed tomography (CT). In computer vision, attempts to reconstruct volumetric phenomena like fire, smoke, and plasmas using tomographic techniques, even dynamically, have shown good success.

Definition

For rotationally symmetric imaging systems, the optical axis is the (usually unique) axis of symmetry.

Background

The usual definition of optical axis in computer vision is tied to the pinhole camera model, where it is defined as the line passing through the center of projection and that is orthogonal to the image plane. For a perfectly aligned usual optical system and where the image plane is parallel to the lenses' principal planes, the optical axis is the line passing through the lenses' centers.

Theory

A more general definition is to consider the optical axis as the (unique) axis of rotational symmetry of an imaging system, if this symmetry exists. Here, it may be advisable to examine rotational symmetry of only the optical part of the image formation process and not the entire process from 3D to the pixel domain. This is meant to exclude

the way the photosensitive surface samples the incoming light.

Let us examine this with the aid of the pinhole camera model as example. Suppose that the aspect ratio equals 1, that is, pixel density is identical in vertical and horizontal directions on the image plane. Then, the projection function from the 3D scene to 2D pixel coordinates is rotationally symmetric relative to the pinhole camera's optical axis and the image plane's principal point. However, if the aspect ratio deviates from 1, the rotational symmetry is broken. If one looks at what happens before light rays hit the image plane, then the projection function is still rotationally symmetric though.

A similar example is a camera that exhibits distortions due to the image plane not being perfectly parallel to the lenses' principal planes. Again, the full mapping from 3D to 2D pixel coordinates is not rotationally symmetric here.

To consider rotational symmetry and thus the existence of an optical axis, one may thus consider the function that maps light rays coming into the camera, to rays leaving the optics towards the image plane. In that respect, rotational symmetry and the concept of optical axis are also defined for noncentral cameras, that is, cameras without a single center of projection, like some catadioptric cameras.

Definition

Optical flow is the vector field that describes the perceived motion of points in the image plane.

Background

When working with image sequences, analyzing the change of the image over time provides valuable information about the scene. The motion of points in the image, as described by the optical flow field, is an important cue in many computer vision tasks, such as tracking, motion segmentation, and structure-from-motion.

Estimating the optical flow from pairs of images is a classical computer vision task. The problem is approached by matching certain image structures, which are assumed to be more or less stable over time, between two successive images. While earlier estimation methods could only provide sparse optical flow fields, nowadays it is common to estimate a dense optical flow field that provides a displacement vector for each pixel in the first image, describing where this pixel went in the second image.

Optical flow estimation is closely related to the problem of nonrigid registration. The main difference is that the latter problem often assumes

a one-to-one mapping between two images. This assumption is not satisfied for optical flow due to occlusion.

Optical Flow Estimation

For estimating the optical flow field, a matching criterion is needed. In most cases this matching criterion is based on the pixel gray value or color, which leads to the so-called optical flow constraint:

$$\begin{aligned} I(x + u(x, y), y + v(x, y), t + 1) \\ - I(x, y, t) = 0, \end{aligned} \quad (1)$$

where I denotes the image sequence and $w = (u, v)^\top$ the optical flow field. As this constraint is nonlinear in u and v , it is usually linearized to yield

$$I_x u + I_y v + I_t = 0, \quad (2)$$

where subscripts denote partial derivatives.

For each pixel, the optical flow constraint yields one equation. Since we have two unknowns per pixel to estimate, the problem is underconstrained without additional assumptions. This is also known as the aperture problem.

There are two solutions to this problem. One is to assume a parametric flow model in a fixed neighborhood around each pixel. Choosing the neighborhood (the aperture) large enough, one collects enough information to estimate the model parameters, which determine the flow. This methodology was initially proposed by Lucas and Kanade [1].

The other solution imposes a regularity constraint on the resulting flow field. Rather than estimating flow vectors for each pixel independently, this leads to a global estimation of the whole flow field and is expressed as an energy minimization problem. The first such model has been introduced by Horn and Schunck [2] and reads:

$$\begin{aligned} E(u, v) = & \int (I_x u + I_y v + I_t)^2 \\ & + \alpha \left(|\nabla u|^2 + |\nabla v|^2 \right) dx dy. \end{aligned} \quad (3)$$

The energy is minimized via variational methods. Since it is a convex functional, the global minimizer $(u, v)^\top$ can be found with standard techniques such as gradient descent or by solving the linear system emerging from the Euler-Lagrange equations.

Numerous extensions of the basic Horn-Schunck model have been presented over the years to deal with several shortcomings of the original model. One important modification is to replace the quadratic penalizers in (3) by nonquadratic ones [3, 4]. This can be interpreted as replacing the inherent Gaussian distribution model in (3) by one based on robust statistics. Long-tailed distributions allow for outliers in both the optical flow constraint and the smoothness assumption, i.e., occlusion and motion discontinuities are integrated into the model. The most popular choice to date is the use of a regularized Laplace distribution, which leads to the l_1 -norm in the energy functional [5]. As the l_1 -norm is the limit between convex and nonconvex penalizers, it allows for the maximum number of outliers while still leading to a convex optimization problem.

The linearization of the optical flow constraint in (2) helps solving for the optical flow field, but it includes the assumption that the image is locally linear. In practice this is only true for very small neighborhoods with a few pixels radius and restricts the magnitude of the displacement vectors that can be estimated. In [6] it was suggested to work with the original, nonlinearized optical flow constraint and to postpone the linearization to the numerical scheme. As due to the nonlinearized optical flow constraint the energy becomes nonconvex, local minima are an issue and need to be approached by appropriate heuristics. In [5] this was shown to coincide with the ideas of earlier multiresolution approaches [1, 4]. The numerical scheme in [5] can be regarded

as a Gauss-Newton method combined with a continuation strategy to avoid local minima.

Contemporary variational methods for optical flow estimation are based on the following energy functional:

$$\begin{aligned} E(u, v) = & \int \Psi(I(x+u, y+v, t+1) \\ & - I(x, y, t))^2 \\ & + \alpha \Psi(|\nabla u|^2 + |\nabla v|^2) dx dy, \end{aligned} \quad (4)$$

where $\Psi(s^2)$ denotes a robust function, which is often chosen as the regularized l_1 -norm $\Psi(s^2) = \sqrt{s^2 + \epsilon^2}$ with a reasonably small regularization constant ϵ .

Other improvements include extended matching criteria that are invariant to brightness changes [7] and orientation-specific, anisotropic, or nonlocal regularizers [8, 9]. Multigrid solvers and efficient GPU implementations have pushed even advanced optical flow estimation techniques towards real-time performance [10, 11].

Instead of these variational techniques, one can approach optical flow estimation also with combinatorial methods. The most straightforward version of this is simple block matching, which leads to unsatisfactory results though. More enhanced combinatorial methods, e.g., based on belief propagation, perform much better [12, 13].

Nonetheless, variational techniques are currently the dominating way to estimate optical flow. This is very much in contrast to the related task of disparity estimation, where combinatorial methods are much more powerful. This is mainly because disparity estimation is a search problem among an ordered set of labels, which allows for efficient, globally optimal algorithms. In contrast, the two-dimensional nature of optical flow estimation leads to combinatorial problems that are NP-hard. Without the advantage of global optimality, pure combinatorial techniques are inferior to variational techniques due to discretization artifacts and missing subpixel accuracy. Most combinatorial approaches alleviate these problems by running a variational approach as a post-

processing step. Combinatorial techniques are promising in the sense that they can potentially better deal with large motion as well as occlusion. Brox and Malik [14] is an example of combining a combinatorial search (simple block matching) with variational methods to estimate faster motion.

Application

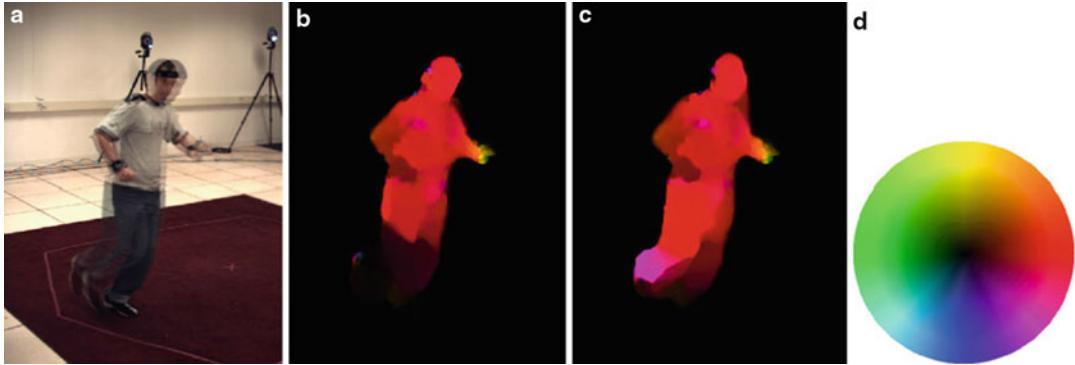

Typical applications of optical flow are tracking, motion segmentation, and action recognition. Tracking has again many applications in fields like structure-from-motion and surveillance. The most widely spread tracker, the KLT tracker [15], is based on the Lucas-Kanade technique described above. Trackers based on variational optical flow have been proposed as well [16, 17]. In motion segmentation, one can directly cluster the optical flow vectors, as done in the motion layer framework by Wang and Adelson [18]. A joint estimation of optical flow and corresponding motion segments has been proposed in [19, 20]. Histograms of the optical flow can be used for action recognition [21].

Open Problems

The main remaining problems in optical flow estimation are concerned with occlusion and precise motion boundary estimation, especially in homogenous image areas. While both are implicitly covered by state-of-the-art techniques in areas with rich structure, homogenous image areas yield the data term to be irrelevant and the estimation results are solely driven by the smoothness assumption, which is a relatively weak prior for such situations.

Experimental Results

A quantitative comparison of a large number of optical flow estimation methods is available

Optical Flow: Traditional Approaches, Fig. 1 From left to right: (a) Two-frame overlay showing large motion especially at the foot of the person. (b) Optical flow estimated with [5]. The motion of the upper body part is estimated well, but the motion of the leg is missed.

(c) Optical flow estimated with large displacement optical flow [14]. The fast motion can be captured. (d) *Color code* used to represent the optical flow. For instance, red stands for motion to the right

at [22]. However, the numbers must be treated with care. As they are computed on the basis of only eight image pairs, overfitting is an issue. More complex methods with many partially hidden parameters have a clear advantage, as more parameters can be specifically adapted to the needs of the benchmark. For this reason, the top-performing methods in the benchmark are not necessarily the best performing ones on a more diverse set of natural videos. Nevertheless, the benchmark allows to coarsely separate techniques that lack certain qualities in the lower part of the table. The computation times, even though they are not directly comparable due to the usage of different hardware, also give hints on the applicability of techniques in practice.

Measuring the quality of optical flow estimation methods is generally hard, because deriving ground truth flow in real videos comes with a very big effort. With the improved rendering quality in computer graphics, large sets of realistic, synthetic test sequences could be a possible way out of this dilemma and will ideally lead to larger benchmark datasets that better cover the space of scenes faced in optical flow applications.

Special properties of certain optical flow estimation techniques can be observed also qualitatively. Figure 1 compares a method that can

explicitly deal with larger motion to one that does not have this specific capability.

Definition

Optimal estimation in the computer vision context refers to estimating the parameters that describe the underlying problem from noisy observation. The estimation is done according to a given criterion of optimality, for which maximum likelihood is widely accepted. If Gaussian noise is assumed, it reduces to minimizing the Mahalanobis distance. If furthermore the Gaussian noise has a homogeneous and isotropic distribution, the procedure reduces to minimizing what is called the reprojection error.

Background

One of the central tasks of computer vision is the extraction of 2D/3D geometric information from noisy image data. Here, the term *image data* refers to values extracted from images by image processing operations such as edge filters and interest point detectors. Image data are said to be *noisy* in the sense that image processing operations for detecting them entail uncertainty to some extent.

For optimal estimation, a statistical model of observation needs to be introduced. Let $\mathbf{x}_1, \dots, \mathbf{x}_N$ be the observed image data. The standard model is to view each datum \mathbf{x}_α as perturbed from its true value $\bar{\mathbf{x}}_\alpha$ by $\Delta\mathbf{x}_\alpha$, which is assumed to be independent Gaussian noise of mean $\mathbf{0}$ and covariance matrix $V[\mathbf{x}_\alpha]$. Then, maximum likelihood is equivalent to the minimization of the *Mahalanobis distance*

$$I = \sum_{\alpha=1}^N \langle \bar{\mathbf{x}}_\alpha - \mathbf{x}_\alpha, V[\mathbf{x}_\alpha]^{-1}(\bar{\mathbf{x}}_\alpha - \mathbf{x}_\alpha) \rangle, \quad (1)$$

with respect to the true values $\bar{\mathbf{x}}_\alpha$ subject to given knowledge about them. Hereafter, $\langle \mathbf{a}, \mathbf{b} \rangle$ denotes the inner product of vectors \mathbf{a} and \mathbf{b} .

If the noise is homogeneous and isotropic, in which case $V[\mathbf{x}_\alpha] = c\mathbf{I}$ for all α for some constant c and the identity matrix \mathbf{I} , the Mahalanobis distance I is equivalent to the sum of the squares of the geometric distances between the observations \mathbf{x}_α and their true values $\bar{\mathbf{x}}_\alpha$. In this case, I is often referred to as the *reprojection error*. That name originates from the following intuition: In inferring the 3D structure of the scene from its projected images, maximum likelihood under homogeneous and isotropic Gaussian noise means *reprojecting* the inferred 3D structure onto the images and minimizing the square distance between the *reprojection* of the solution and the projection of the scene. Reprojection error minimization is also referred to as *geometric fitting*.

Theory

The estimation procedure depends on the way the knowledge about true values $\bar{\mathbf{x}}_\alpha$ is represented. A typical approach is to introduce some function $\mathbf{g}(t, \theta)$ to express $\bar{\mathbf{x}}_\alpha$ in a parametric form

$$\bar{\mathbf{x}}_\alpha = \mathbf{g}(t_\alpha, \theta), \quad (2)$$

where t_α is a control variable that specifies the identity of the α th datum and θ is an unknown parameter that specifies the underlying structure.

After (2) is substituted, the Mahalanobis distance I becomes a function of θ alone, which is then minimized with respect to θ . This is the standard approach in the traditional statistic estimation framework and also known as *regression*.

This parametric approach, however, is quite limited in computer vision applications. Often, no such knowledge as (2) is available about the true values $\bar{\mathbf{x}}_\alpha$ except that they satisfy some implicit equations of the form

$$F^{(k)}(\mathbf{x}, \theta) = 0, \quad k = 1, \dots, L. \quad (3)$$

The unknown parameter θ allows one to infer the 2D/3D shape and motion of the objects observed in the images.

This type of estimation leads to some theoretical problems. Usually, no restriction is imposed on the true values $\bar{\mathbf{x}}_\alpha$ except that they should satisfy (3). This is called the *functional model*. One could alternatively introduce some statistical model according to which the true values $\bar{\mathbf{x}}_\alpha$ are “sampled.” This model is called *structural*. The distinction is crucial when one considers limiting processes in the following sense. Traditional statistical analysis mainly focuses on the asymptotic behavior as the number of observations increases to ∞ . This is based on the reasoning that the mechanism underlying noisy observations would better reveal itself as the number of observations increases (*the law of large numbers*) while the number of available data is limited in practice. So, the estimation accuracy vs. the number of data is a major concern. In this light, efforts have been made to obtain a consistent estimator in the sense that the solution approaches its true value in the limit $N \rightarrow \infty$ of the number N of the data.

In computer vision applications, in contrast, one cannot *repeat* observations. One makes an inference given a single set of images, and how many times one applies image processing operations, the result is always the same, because standard image processing algorithms are deterministic and no randomness is involved. This is in a stark contrast to conventional statistical problems where observations are viewed as “samples” from potentially infinitely many possibilities; we

could obtain, by repeating observations, different values originating from unknown, uncontrollable, or unmodeled causes, which is called *noise* as a whole.

In vision problems, the accuracy of inference deteriorates as the uncertainty of image processing operations increases. Thus, the inference accuracy vs. the uncertainty of image operations, which is called *noise* for simplicity, is a major concern. Usually, the noise is very small, often subpixel levels. In light of this observation, it has been pointed out that in image domains the *consistency* of estimators should more appropriately be defined by the behavior in the limit $\sigma \rightarrow 0$ of the noise level σ [1, 2]. The functional model suits this purpose. If the error behavior in the limit of $N \rightarrow \infty$ were to be analyzed, one needs to assume some structural model that specifies how the statistical characteristics of the data depend on N . However, it is difficult to predict the noise characteristics for different N . Image processing filters usually output a list of points or lines or their correspondences along with their confidence values, from which only those with high confidence are used. If a lot of data are to be collected, those with low confidence need to be included, but their statistical properties are hard to estimate, since such data are possibly misdetections. This is the most different aspect of image processing from laboratory experiments, in which any number of data can be collected by repeated trials.

Maximum Likelihood with Implicit Constraints

Maximum likelihood based on the functional model is to minimize the Mahalanobis distance (1) subject to implicit constraints in the form of (3). In statistics, maximum likelihood is criticized for its lack of consistency. In fact, estimation of the true values \bar{x}_α , called *nuisance parameters* when viewed as parameters, is not consistent as $N \rightarrow \infty$ in the maximum likelihood framework [3]. However, the lack of consistency has no realistic meaning in vision applications as explained above. On the contrary, maximum likelihood has very desirable properties in the limit $\sigma \rightarrow 0$ of the noise level σ : the solution is *consistent*

in the sense that it converges to the true value as $\sigma \rightarrow 0$ and *efficient* in the sense that its covariance matrix approaches a theoretical lower bound as $\sigma \rightarrow 0$ [1, 2].

According to the experience of many vision researchers, maximum likelihood is known to produce highly accurate solutions. A major concern is its computational burden, because maximum likelihood usually requires complicated nonlinear optimization. The standard approach is to express each of \bar{x}_α explicitly in terms of θ by introducing some auxiliary parameters, or nuisance parameters. After all the expressions are substituted back into (1), the Mahalanobis distance I becomes a function of θ and the nuisance parameters. Then, this joint parameter space, which usually has very high dimensions, is searched for the minimum. This approach is called *bundle adjustment*, a term originally used by photogrammetrists. This is very time-consuming, in particular if one seeks a globally optimal solution by searching the entire parameter space exhaustively.

Linear Reparameterization

In many important vision applications, the problem can be reparameterized to make the functions $F^{(k)}(\mathbf{x}, \theta)$ linear in θ (but generally nonlinear in \mathbf{x}), allowing one to write (3) as

$$\langle \xi^{(k)}(\mathbf{x}), \theta \rangle = 0, \quad k = 1, \dots, L, \quad (4)$$

where $\xi^{(k)}(\mathbf{x})$ represents a nonlinear mapping of \mathbf{x} . This formalism covers many fundamental problems of computer vision including fitting a parametric curve such as a line, an ellipse, and a polynomial curve to a noisy 2D point sequence or a parametric surface such as a plane, an ellipsoid, and a polynomial surface to a noisy 3D point sets and computing the fundamental matrix or the homography from noisy point correspondences over two images [4, 5]. For this type of problem, a popular alternative to bundle adjustment is minimization of a function of θ alone, called the *Sampson error*. Let us abbreviate $\xi^{(k)}(\mathbf{x}_\alpha)$ to $\xi_\alpha^{(k)}$. The first order variation of $\xi_\alpha^{(k)}$ by noise is

$$\Delta \xi_{\alpha}^{(k)} = T_{\alpha}^{(k)} \Delta x_{\alpha}, \quad T_{\alpha}^{(k)} \equiv \left. \frac{\partial \xi^{(k)}(\mathbf{x})}{\partial \mathbf{x}} \right|_{\mathbf{x}=\bar{x}_{\alpha}}. \quad (5)$$

Define the covariance matrices of $\xi_{\alpha}^{(k)}$, $k = 1, \dots, L$, by

$$\begin{aligned} V^{(kl)}[\xi_{\alpha}] &= E[\Delta \xi_{\alpha}^{(k)} \Delta \xi_{\alpha}^{(l)\top}] \\ &= T_{\alpha}^{(k)} E[\Delta x_{\alpha} \Delta x_{\alpha}^{\top}] T_{\alpha}^{(l)\top} \\ &= T_{\alpha}^{(k)} V[x_{\alpha}] T_{\alpha}^{(l)\top}, \end{aligned} \quad (6)$$

where $E[\cdot]$ denotes expectation. The Sampson error that approximates the minimum of the Mahalanobis distance I subject to the constraints in (4) has the form

$$K = \sum_{\alpha=1}^N \sum_{k,l=1}^L W_{\alpha}^{(kl)} \langle \xi_{\alpha}^{(k)}, \theta \rangle \langle \xi_{\alpha}^{(l)}, \theta \rangle, \quad (7)$$

where $W_{\alpha}^{(kl)}$ is the (kl) element of $(V_{\alpha})_r^-$. Here, V_{α} is the matrix whose (kl) element is

$$V_{\alpha} = (\langle \theta, V^{(kl)}[\xi_{\alpha}] \theta \rangle), \quad (8)$$

where the true data values \bar{x}_{α} in the definition of $V^{(kl)}[\xi_{\alpha}]$ are replaced by their observations x_{α} . The operation $(\cdot)_r^-$ denotes the pseudoinverse of truncated rank r , (i.e., with all eigenvalues except the largest r replaced by 0 in the spectral decomposition), and r is the rank of V_{α} , which is equal to the number of independent equations of (4). The name Sampson error stems from the classical ellipse fitting scheme [6].

The Sampson error (7) can be minimized by various means including the *FNS* (*Fundamental Numerical Scheme*) [7] and the *HEIV* (*Heteroscedastic Errors-in-Variable*) [8]. It can be shown that the exact maximum likelihood solution can be obtained by repeating Sampson error minimization, each time modifying the Sampson error so that in the end the modified Sampson error coincides with the Mahalanobis distance [5, 9]. It turns out that in many practical applications, the solution that minimizes the Sampson error coincides with the exact maximum likelihood solution up to several significant digits;

usually, two or three rounds of Sampson error modification are sufficient.

It can be shown that the covariance matrix $V[\hat{\theta}]$ of any unbiased estimator $\hat{\theta}$ of θ satisfies under some general conditions the inequality

$$V[\hat{\theta}] \succ \left(\sum_{\alpha=1}^N \sum_{k,l=1}^L \bar{W}_{\alpha}^{(kl)} \bar{\xi}_{\alpha}^{(k)} \bar{\xi}_{\alpha}^{(l)\top} \right)_r^-, \quad (9)$$

where $\bar{\xi}_{\alpha}^{(k)}$ are the true values of $\xi_{\alpha}^{(k)}$ and $\bar{W}_{\alpha}^{(kl)}$ is the value of $W_{\alpha}^{(kl)}$ defined earlier evaluated for the true values of $\xi_{\alpha}^{(k)}$ and θ . The symbol \succ means that the left-hand side minus the right-hand side is positive semidefinite. The right-hand side of (9) is called the *KCR (Kanatani-Cramer-Rao) lower bound* [1, 2, 5]. It can be shown that the covariance matrix of Sampson error minimization solution coincides with this bound in the leading order in the noise level [1, 2].

Algebraic Methods

Recently, there has been a remarkable progress in the study of algebraic methods. By “algebraic methods,” we mean we solve some “algebraic equations” (directly or iteratively), rather than minimizing some cost function such as the reprojection error. Originally, algebraic methods were thought of as an auxiliary to maximum likelihood and used for initialization of maximum likelihood iterations. In the last decade, however, it has been found that some algebraic methods outperform maximum likelihood in accuracy [5].

Algebraic methods solve a nonlinear equation in the form

$$M\theta = \lambda N\theta, \quad (10)$$

with

$$M = \sum_{\alpha=1}^N \sum_{k=1}^L W_{\alpha}^{(kl)} \xi_{\alpha}^{(k)} \xi_{\alpha}^{(k)\top}, \quad (11)$$

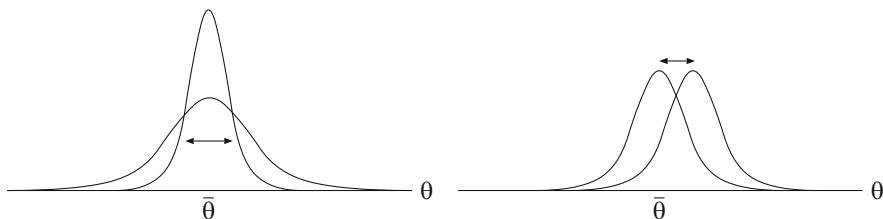

where $W_{\alpha}^{(kl)}$ are some weights that depend on θ . Various methods with different names arise according to the choice of the weights $W_{\alpha}^{(kl)}$ and the matrix N in (10). This scheme was originally motivated to minimize $\langle \theta, M\theta \rangle$, which is called the (weighted) *algebraic distance*, hence the name “algebraic method,” subject to the con-

straint $\langle \theta, N\theta \rangle = \text{constant}$. The solution of (10) is obtained by iteration: we first regard $W_\alpha^{(kl)}$ and N as given and solve the generalized eigenvalue problem (10), then update $W_\alpha^{(kl)}$ and N using the resulting θ , and repeat this process.

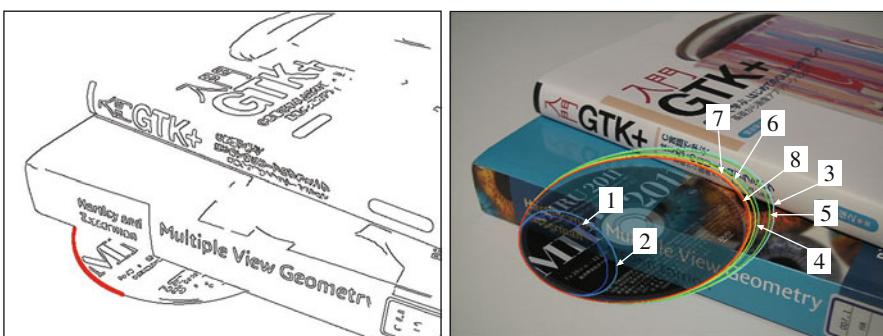

If we choose $W_\alpha^{(kl)} = 1$ and $N = I$ (hence no iterations are necessary), this method is nothing but the standard *least squares*. If we choose $W_\alpha^{(kl)} = 1$ and $N = V_0[x_\alpha]$ (the covariance matrix of x_α up to scale), this reduces the method of Taubin [10], which is known to produce a fairly accurate solution. Efforts were made to improve the accuracy of the Taubin method by choosing optimal N , resulting in a scheme called *HyperLS* [11], which is non-iterative. If we use the same N as in the Taubin method but use the weights $W_\alpha^{(kl)}$ that appear in (7) and (8), we obtain the iterative scheme of *renormalization* [12]. Like for HyperLS, we can optimize the matrix N of renormalization to obtain *hyper-renormalization* [13], which exhibits higher accuracy than maximum likelihood [5].

The superiority of hyper-renormalization is confirmed by statistical analysis. If we regard the input x_α as random variables, the computed solution θ of (10) is also a random variable. It can be shown that the matrices M and N of (10) control, respectively, the covariance and the bias of θ (Fig. 1) and that the matrices M and N of hyper-renormalization are such that the covariance of θ reaches the KCR lower bound up to $O(\sigma^4)$ and the bias of θ is $\mathbf{0}$ up to $O(\sigma^4)$.

On the other hand, efforts have been made to improve the accuracy of maximum likelihood by correcting the solution a posteriori, called *hyperaccurate correction* [14]. It can be shown that maximum likelihood followed by hyperaccurate correction can achieve equivalent accuracy to hyper-renormalization [5] (Fig. 2). However, iterations for computing maximum likelihood solution sometimes fail to converge in the presence of large noise, compared to which hyper-renormalization iterations are rather robust.

Oren-Nayar Reflectance Model

Ping Tan

School of Computing Science, Simon Fraser University, Vancouver, BC, Canada

Related Concepts

- Bidirectional Reflectance Distribution Function
- Diffuse Reflectance
- Radiance
- Reflectance Models

Definition

The Oren-Nayar model computes the amount of reflected radiance at a surface point according to the lighting, viewing, and surface normal directions at that point. It is characterized by its high accuracy in modeling diffuse reflection for rough surfaces. It was introduced by Michael Oren and Shree K. Nayar [1] in 1994.

Background

When light arrives at surfaces, it can be reflected, refracted, scattered, or absorbed. Reflectance models are mathematical functions that describe the interactions between light and surfaces. Usually, they are functions of lighting, viewing, and surface normal directions. There are various reflectance models at different levels of precision and complexity. Most reflectance models include components describing diffuse and specular reflection, respectively.

The Oren-Nayar model is a reflectance model that accurately represents the diffuse reflection of rough surfaces. In the field of computer vision, diffuse reflection is often modeled by Lambert's model [2] which assumes the light is uniformly reflected in all directions. However, many real surfaces, especially rough surfaces such as clay or concrete, exhibit significant non-Lambertian

diffuse reflection. For example, the reflection is often stronger when the viewing direction is close to the lighting direction, which is called *backscattering*. Oren and Nayar designed a more accurate model to describe diffuse reflection of rough surfaces. This model can be applied to generate realistic computer graphic images or to accurately infer scene properties such as shape and material from observed image intensities.

Theory

Light reflected by a surface can be roughly divided into specular and diffuse reflection. The specular reflection accounts for the light reflected directly at the surface without entering it. Specular reflection typically is concentrated within a small angle in space. In comparison, diffuse reflection accounts for the light that enters the surface and is distributed more uniformly in all directions.

In computer vision, Lambert's reflectance model is often used to describe diffuse reflection, which assumes that the diffuse reflection is equally distributed on a hemisphere indicating all the reflected directions. However, real surfaces, especially rough surfaces like clay and concrete, often exhibit non-Lambertian reflection. A common non-Lambertian phenomenon is the *backscattering* where more light is reflected toward the incident direction and the surface appears brighter when the viewing direction is closer to the lighting direction. For example, this phenomenon is observed in lunar photometry and is modeled by Opik [3] and Minnaert [4].

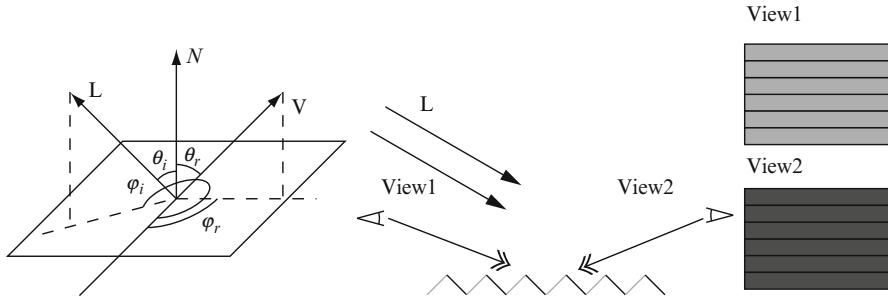

Backscattering can be well explained by studying the surface microstructures. As shown on the right of Fig. 1, when the polar angle of the incident light θ_i is large, some of the microstructures are in shadows. When the surface is viewed from a direction *View1* that is similar to the incident direction *L*, all visible microstructures are illuminated and the surface appears brighter. However, when the surface is viewed from the direction *View2*, all visible microstructures are shadowed and the surface appears darker.

Oren and Nayar adopted a microfacet surface model to derive the diffuse reflection of rough surfaces, where surfaces consist of many infinitely long V-cavities and each cavity facet is Lambertian. The reflectance model of a surface is derived by integrating the reflection of all facets. A similar microfacet model is used by the Cook-Torrance reflectance model [5] to study specular reflection, where each microfacet acts as a mirror. The Oren-Nayar model is derived in three steps in the original paper [1]. Firstly, a reflectance model $I^{(1)}$ is derived for anisotropic surfaces consisting of V-cavities of the same slope and the same direction. This model includes two components, one for direct illumination and the other for interreflection between microfacets. Secondly, a reflectance model $I^{(2)}$ is derived for isotropic surfaces consisting of V-cavities with the same slope but all kinds of directions in a plane. This model $I^{(2)}$ is derived by integrating $I^{(1)}$ over different cavity directions. Thirdly, the final Oren-Nayar model is derived for general isotropic surfaces that consist of V-cavities whose slopes follow a Gaussian distribution with mean μ and variance σ^2 and whose directions follow a uniform distribution. The Oren-Nayar reflectance model $I^{(3)}$ can be derived by integrating $I^{(2)}$ over different cavity slopes. This model includes a component $I_1^{(3)}$ for direct illumination and a component $I_2^{(3)}$ for microfacet interreflection. These two components are defined as the following, respectively,

$$\begin{aligned} I_1^{(3)}(\theta_r, \theta_i, \phi_r - \phi_i; \sigma) = & \frac{\rho}{\pi} E_0 \cos \theta_i \left[C_1(\sigma) + \right. \\ & \cos(\phi_r - \phi_i) C_2(\alpha; \beta; \phi_r - \phi_i; \sigma) \tan \beta + \\ & \left. (1 - |\cos(\phi_r - \phi_i)|) C_3(\alpha; \beta; \sigma) \tan \left(\frac{\alpha + \beta}{2} \right) \right] \end{aligned} \quad (1)$$

and

$$\begin{aligned} I_2^{(3)}(\theta_r, \theta_i, \phi_r - \phi_i; \sigma) = & 0.17 \frac{\rho^2}{\pi} \\ & E_0 \cos \theta_i \frac{\sigma^2}{\sigma^2 + 0.13} \left[1 - \cos(\phi_r - \phi_i) \left(\frac{2\beta}{\pi} \right)^2 \right]. \end{aligned} \quad (2)$$

Oren-Nayar Reflectance Model, Fig. 1 *Left:* directions involved in the definition of the Oren-Nayar model. N is the surface normal direction, and L and V are the lighting and viewing direction, respectively. *Right:* a rough surface consists of many microfacets. When the polar angle of the incident light θ_i is large, some of the microfacets are in

Here, (θ_i, ϕ_i) and (θ_r, ϕ_r) are the polar and azimuth angles of the lighting and viewing directions, respectively, as illustrated on the left of Fig. 1, $\alpha = \max(\theta_r, \theta_i)$, $\beta = \min(\theta_r, \theta_i)$, E_0 indicates the illumination intensity, and ρ is the albedo in Lambert's reflectance model of microfacet. C_1 , C_2 , and C_3 are evaluated according to the following equations:

$$C_1 = 1 - 0.5 \frac{\sigma^2}{\sigma^2 + 0.33}$$

$$C_2 = \begin{cases} 0.45 \frac{\sigma^2}{\sigma^2 + 0.09} \sin \alpha & \text{if } \cos(\phi_r - \phi_i) \geq 0 \\ 0.45 \frac{\sigma^2}{\sigma^2 + 0.09} \left(\sin \alpha - \left(\frac{2\beta}{\pi} \right)^3 \right) & \text{otherwise} \end{cases}$$

$$C_3 = 0.125 \left(\frac{\sigma^2}{\sigma^2 + 0.09} \right) \left(\frac{4\alpha\beta}{\pi^2} \right)^2.$$

Experiments reported in [1] show that the Oren-Nayar reflectance model matches the measured reflectance data from rough surfaces well and captures the *backscattering* effect. An interesting fact about this model is that it degenerates to Lambert's model when $\sigma^2 = 0$. In applications, to reduce computation and simplify analysis, a simplified version of the Oren-Nayar model is often desired. The term C_3 and the interreflection are found to be relatively small during simulation. Hence, a simplified model can be obtained by discarding C_3 and ignoring interreflection:

shadow and some of them are illuminated, as illustrated by darker and brighter segments. The surface appears brighter in the view 1 than in the view 2, because most of the visible microfacets in view 1 are illuminated and those in view 2 are shadowed

$$I(\theta_r, \theta_i, \phi_r - \phi_i; \sigma) = \frac{\rho}{\pi} E_0 \cos \theta_i (A + B \max[0, \cos(\phi_r - \phi_i)] \sin \alpha \tan \beta) \quad (3)$$

Here, $A = 1.0 - 0.5 \frac{\sigma^2}{\sigma^2 + 0.33}$ and $B = 0.45 \frac{\sigma^2}{\sigma^2 + 0.09}$.

Application

The Oren-Nayar reflectance model computes reflected radiance according to the 3D shape, viewing, and lighting configurations. Like many other reflectance models, it can be used to create computer graphic images. It is shown in [1] that the Oren-Nayar reflectance model can generate images of rough surfaces more realistically than Lambert's model. This reflectance model was also applied for photometric stereo in [6] and generated better results than the Lambertian photometric stereo algorithm.

Although the standard taxonomy of quadrics in Euclidean space is familiar to most, what is missing is the geometrical structure of the manifold of all osculating paraboloids, inclusive a metric. Here the two-parameter case (important in many applications) is discussed in a little detail.

Theory

“Osculating paraboloids” are second-order Monge patches:

$$\begin{aligned} x\mathbf{e}_x + y\mathbf{e}_y + z(x, y)\mathbf{e}_z \\ = x\mathbf{e}_x + y\mathbf{e}_y + \frac{1}{2}(a_{20}x^2 + 2a_{11}xy + a_{02}y^2)\mathbf{e}_z, \end{aligned} \quad (1)$$

that occur in many contexts. Apparently they inhabit a three-dimensional quadric shape space that may be parameterized by the coefficient triple $\{a_{20}, a_{11}, a_{02}\}$.

Typically the z -domain will be some physical parameter with a physical dimension different from that of the xy -domain. The appropriate setting then is not Euclidean. In most applications one treats the z -dimension as isotropic, then the space is a “singly isotropic space,” or “graph space.”

Scaling and addition in this space correspond to point-wise addition of heights, thus is well defined and makes geometrical sense. The quadric shape space is a linear space under addition and multiplications with real numbers. Thus it is of some interest to find a basis that makes intuitive, and/or pragmatic sense.

One lead is that all such surfaces that differ only by a rotation about the z -axis (\mathbf{e}_z) are geometrically congruent and may often be grouped as a single “shape.” This leads one to consider the isotropic paraboloid:

$$\frac{x^2 + y^2}{2}, \quad (2)$$

to be “special,” since it is invariant under such rotations. Moreover, the pair:

Osculating Paraboloids

Definition

Osculating paraboloids commonly occur in second-order approximations where the first order is irrelevant or can be transformed away.

Background

Despite the common occurrence of osculating paraboloids in many settings, there appears to be no literature dedicated to their shape space.

$$xy, \frac{x^2 - y^2}{2}, \quad (3)$$

is likewise “special” because they are the same under a rotation over $\frac{\pi}{4}$ (notice that all quadrics transform into themselves under rotations over π). These shapes transform into their “negatives” under rotations of $\frac{\pi}{2}$, thus, in a sense, they are their own negatives. This is not the case in general, for instance, $x^2 + y^2$ cannot be transformed into its negative (i.e., $-(x^2 + y^2)$) under any rotation.

Thus the basis of quadrics contains only two distinct shapes (Fig. 1), rather than three as one might naively expect. Using this basis one evidently has:

$$\begin{aligned} & \frac{1}{2} (a_{20}x^2 + 2a_{11}xy + a_{02}y^2) \\ &= r \frac{x^2 - y^2}{2} + sxy + t \frac{x^2 + y^2}{2}, \end{aligned} \quad (4)$$

with:

$$r = \frac{a_{20} - a_{02}}{2}, s = a_{11}, t = \frac{a_{20} + a_{02}}{2}. \quad (5)$$

By a suitable rotation any quadric may be written in the canonical form

$$\frac{1}{2} (k_1 u^2 + k_2 v^2), \text{ with } k_1 \geq k_2. \quad (6)$$

Such a canonical form is convenient because it abstracts away from the orientation about the z-axis (Fig. 2). The general quadric is rotated by angle φ with respect to the u-axis (the first principal direction), where $-\frac{\pi}{2} < \varphi < \frac{\pi}{2}$. One has:

$$a_{20} = \frac{k_1 + k_2}{2} + \frac{k_1 - k_2}{2} \cos 2\varphi, \quad (7)$$

$$a_{11} = \frac{k_1 - k_2}{2} \sin 2\varphi, \quad (8)$$

$$a_{02} = \frac{k_1 + k_2}{2} - \frac{k_1 - k_2}{2} \cos 2\varphi, \quad (9)$$

and, equivalently:

$$r = \frac{k_1 - k_2}{2} \cos 2\varphi, \quad (10)$$

$$s = \frac{k_1 - k_2}{2} \sin 2\varphi, \quad (11)$$

$$t = \frac{k_1 + k_2}{2}. \quad (12)$$

Introduce the Casorati curvature (see Fig. 3) as:

$$k = \sqrt{\frac{k_1^2 + k_2^2}{2}}, \quad (13)$$

and the shape parameter (see Fig. 4) as:

$$\sigma = \arctan \frac{k_1 + k_2}{k_1 - k_2}. \quad (14)$$

These differential invariants can be written into various forms, e.g.,

$$k = \sqrt{\frac{a_{20}^2 + 2a_{11}^2 + a_{02}^2}{2}} = \sqrt{r^2 + s^2 + t^2}, \quad (15)$$

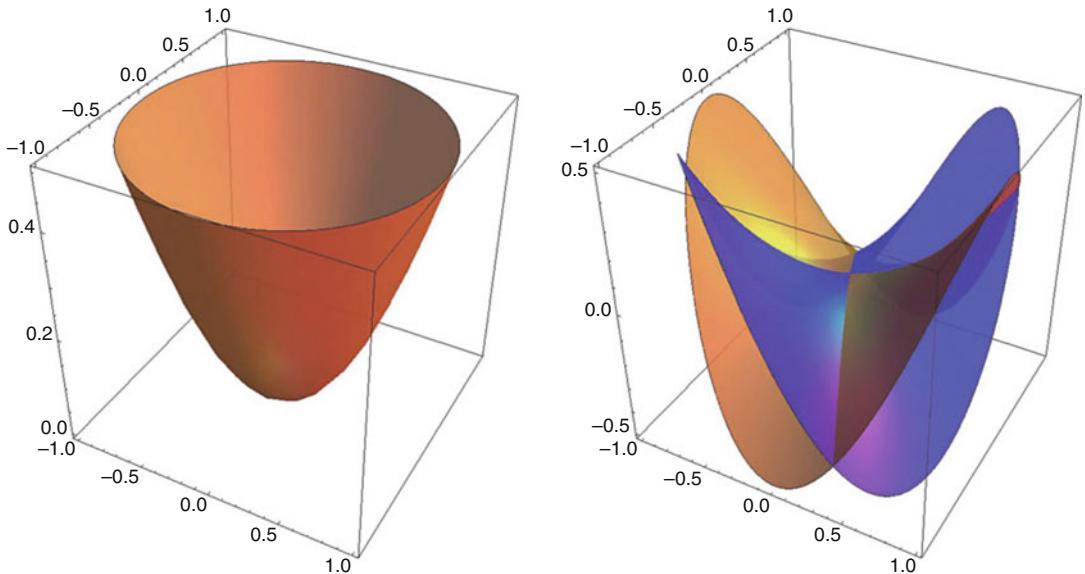

and

$$\tan \sigma = \frac{a_{20} + a_{02}}{\sqrt{(a_{20} - a_{02})^2 + 4a_{11}^2}} = \frac{t}{\sqrt{r^2 + s^2}}. \quad (16)$$

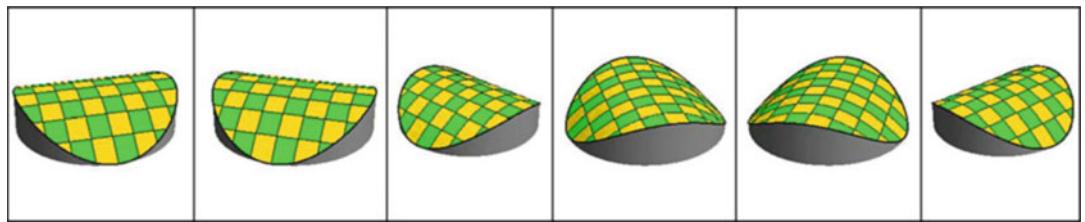

This can be further simplified by identifying the mean curvature $2H = \kappa_1 + \kappa_2 = a_{20} + a_{02}$, the Gaussian curvature $K = \kappa_1 \kappa_2 = a_{20}a_{02} - a_{11}^2$, and the “bending energy” $E = k_1^2 + k_2^2 = a_{20}^2 + 2a_{11}^2 + a_{02}^2$. (Notice that H and K should be distinguished from the invariants of the same name in Euclidean differential geometry. They correspond to the case of infinitesimal height, or to isotropic geometry.) The expression $\frac{1}{2}\sqrt{r^2 + s^2}$ captures the anisotropy of the quadric and may well be denoted its “non-umbilicity.”

The Casorati curvature is perhaps less well known, and it may be motivated as follows. One has:

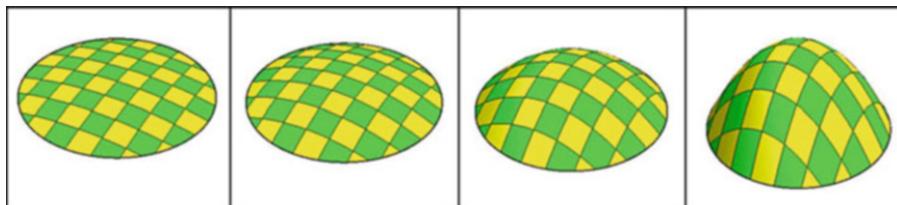

$$k = \sqrt{\frac{k_1^2 + k_2^2}{2}}, \quad (17)$$

Osculating Paraboloids, Fig. 1 The basis of osculating quadrics. At left the isotropic paraboloid $(x^2 + y^2)/2$, at right the anisotropic paraboloids xy and $(x^2 - y^2)/2$, these are mutually congruent

Osculating Paraboloids, Fig. 2 A suite of surfaces of the same Casorati curvature and shape parameter but different orientations. The orientation domain is periodic with period π

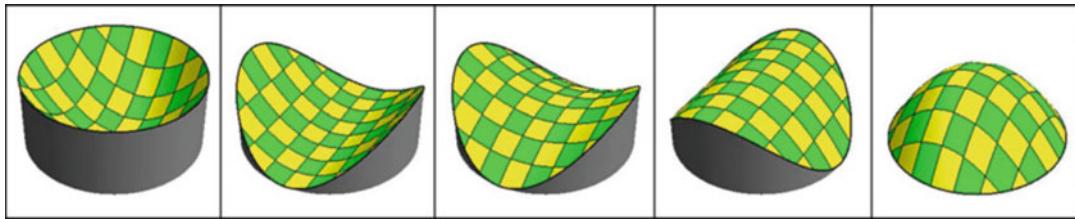

Osculating Paraboloids, Fig. 3 A scale of surfaces of the same shape, the Casorati curvature varying by factors of two

and thus κ vanishes only for the planar case. This is different for the mean curvature $2H = \kappa_1 + \kappa_2$, which vanishes for minimal surfaces ($t = 0$), or the Gaussian curvature $K = \kappa_1 \kappa_2$, which vanishes for cylindrical surfaces. This is often confusing to the beginner, for whom minimal surfaces and cylinders are evidently “curved.” Moreover, one easily verifies that when the “spatial average”

and “standard deviation” of a function $F(x, y)$ are defined as:

$$\langle F(x, y) \rangle_\mu = \int_{\mathbb{R}^2} F(x, y) \left(\frac{e^{-\frac{x^2+y^2}{2\mu^2}}}{2\pi\mu^2} \right) dx dy,$$

$$\text{and } [F]_\mu = \sqrt{\langle F^2 \rangle_\mu - \langle F \rangle_\mu^2}. \quad (18)$$

Osculating Paraboloids, Fig. 4 A suite of surfaces of the same Casorati curvature, the shape parameter taking values of $+\pi/2$, $+\pi/4$, 0 , $-\pi/4$, and $-\pi/2$

one has:

$$k = \frac{[k_1 x^2 + k_2 y^2]}{[x^2 + y^2]} \quad (19)$$

(where $\mu > 0$ has fallen out of the equation). Thus the Casorati curvature is essentially *the root mean square deviation from planarity*.

The shape parameter σ is best understood as a measure of the ratio of umbilicity (isotropy) to non-umbilicity (anisotropy) of the shape. Shapes that differ only in the sign of the shape parameters stand in the relation as a cast to its mold. The minimal shapes ($\sigma = 0$) “are their own molds” as they can be fitted into their negatives after a rotation over $\frac{\pi}{2}$.

Now consider polar coordinates in shape space, defined as:

$$\varrho = \sqrt{r^2 + s^2 + t^2} = k \quad (20)$$

$$\vartheta = \arctan \frac{t}{\sqrt{r^2 + s^2}} = \sigma, \quad (21)$$

$$\phi = \arctan \frac{s}{r} = 2\varphi. \quad (22)$$

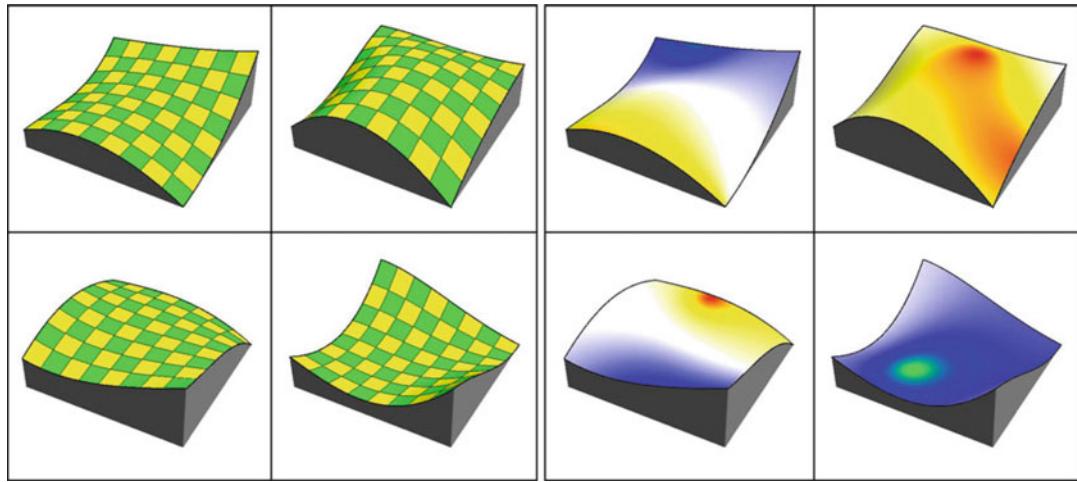

The spheres concentric with the origin are loci of constant Casorati curvature, and the origin represents the planar case. A “shape” is a right circular cone with the t -axis as its axis. The t -axis itself is such a (degenerated) cone, it represents the umbilics. The rs -plane is also such a (again, degenerated) cone, it represents the minimal surfaces, which are the surfaces of zero mean curvature. The cone with semi-top angle of

$\frac{\pi}{2}$ is the locus of parabolic (cylindrical) surfaces. Each half-plane on the t -axis houses the complete zoo of shapes up to orientation. A meridian contains all shapes of the same curvature, a latitude circle a single shape in all orientations. Thus one obtains a complete overview of all quadric shapes in a very natural parameterization (Figs. 5, 6, 7, and 8).

On a general curved surface the shape of the local osculating paraboloids will change from point to point (see Figs. 5, 6, and 7). Since the change will be smooth, the surface can be mapped on a surface in shape space, a surface that may well be expected to have self-intersections and perhaps not everywhere smooth (e.g., have edges of regression or swallowtails), but will be continuous. This allows one to draw a number of useful conclusions concerning generic surfaces, e.g.:

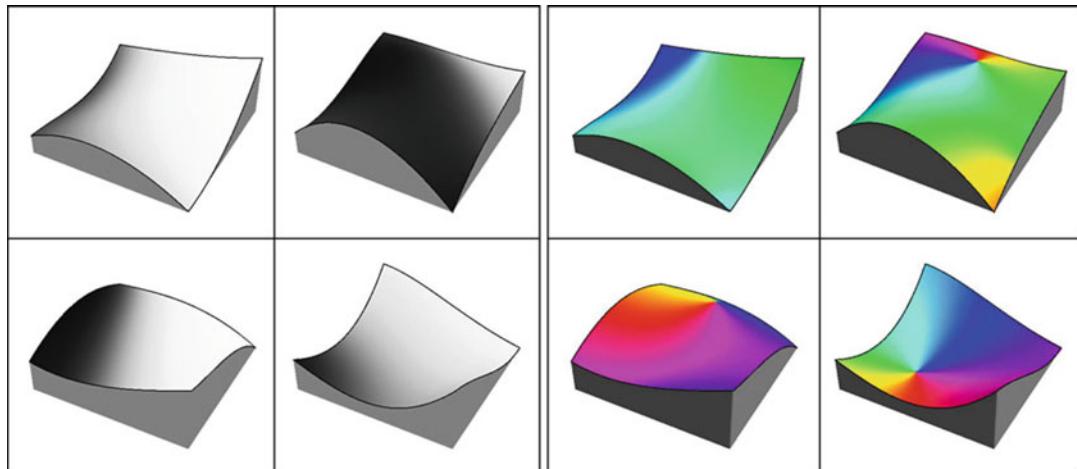

- Planar points do not occur.
- Umbilics are isolated points.
- As a surface is deformed umbilics come and go in pairs.
- Parabolic curves occur on curves; on a closed surface they are closed curves.
- Minimal points occur on curves in hyperbolic areas; on a closed surface they are closed curves.
- Convex and concave regions are mutually isolated through hyperbolic areas.

The local structure of these surfaces naturally involves the osculating cubics, which can be written as follows:

Osculating Paraboloids, Fig. 5 At left plots of four random surfaces. At right the surfaces have been color coded with the shape parameter. The color scale uses Hering's "opposite colors" (G: *Gegenfarben*). The umbilics are red

(convex) and green (concave), the parabolic points yellow (ridge) and blue (rut), whereas the minimal points (zero mean curvature, symmetric saddles) are white

Osculating Paraboloids, Fig. 6 At left the surfaces of Fig. 5 left have been shaded with the Casorati curvature. The gray scale represents a nonlinear monotonic function of the logarithm of the curvature. At right the surfaces

have been colored with the orientation of the direction of largest principal curvature. Notice the singularities at umbilical points

$$\begin{aligned} C(x, y) = & \frac{1}{2!} (a_{20}x^2 + 2a_{11}xy + a_{02}y^2) \\ & + \frac{1}{3!} (a_{30}x^3 + 3a_{21}x^2y + 3a_{12}xy^2 \\ & + a_{03}y^3). \end{aligned} \quad (23)$$

In an infinitesimal neighborhood of the origin one finds:

$$a'_{20}(x, y) = a_{20} + a_{30}x + a_{21}y, \quad (24)$$

$$a'_{11}(x, y) = a_{11} + a_{21}x + a_{12}y, \quad (25)$$

Osculating Paraboloids,

Fig. 7 Scales used to indicate the parameters of osculating quadrics; these scales are used in Figs. 5 and 6

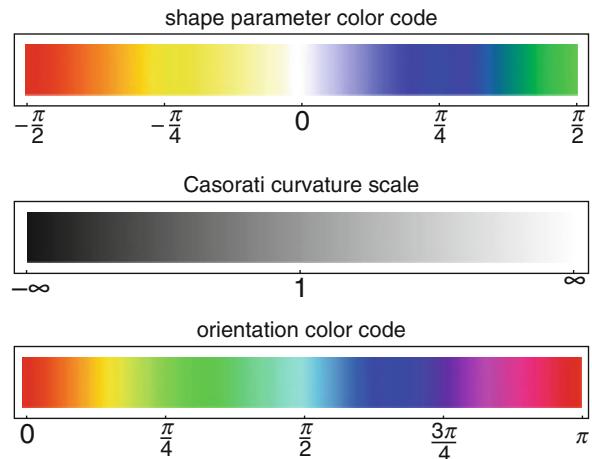

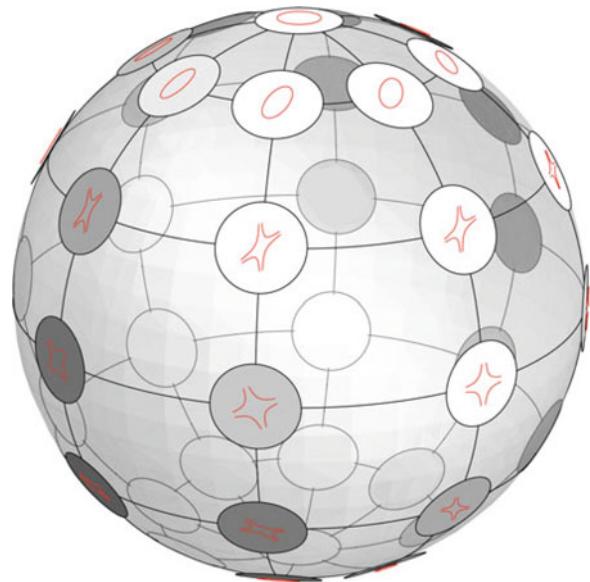

**Osculating Paraboloids,**

Fig. 8 A sphere of constant Casorati curvature. The shapes have been indicated by their Dupin indicatrices. The equator has all orientations of the symmetric saddle, and each meridian has all shape indices with the umbilics at the poles. Each latitude circle repeats a shape at all orientations

$$a'_{02}(x, y) = a_{02} + a_{12}x + a_{03}y. \quad (26)$$

Thus the quadric is perturbed by a linear combination of the two vectors in $\{r, s, t\}$ -space:

$$\frac{\partial}{\partial x} \{r, s, t\} = \frac{1}{2} \{a_{30} - a_{12}, 2a_{21}, a_{30} + a_{12}\} \quad (27)$$

$$\frac{\partial}{\partial y} \{r, s, t\} = \frac{1}{2} \{a_{21} - a_{30}, 2a_{12}, a_{03} + a_{21}\} \quad (28)$$

with weights x and y . These tangent vectors span a planar element in $\{r, s, t\}$ -space. The planar element will in general be nondegenerate, the condition being that the two tangent vectors are independent, implying the cubic indicatrix of Dupin to have a single branch. Thus a neighborhood of a generic surface point maps on a surface in shape space. This allows one to infer various generic properties in a most simple manner, for instance that generic umbilics will be isolated points, the locus of parabolic points will be a curve on the surface, and so forth.

The osculating quadrics shape space may also be used to measure shape differences, a likely metric being:

$$d\ell^2 = \frac{dr^2 + ds^2 + dt^2}{r^2 + s^2 + t^2}, \quad (29)$$

which is invariant with respect to rotations and homotheties about the origin. The metric can be rewritten as:

$$d\ell^2 = (d \log k)^2 + d\sigma^2 + \sin^2 \sigma d\phi^2, \quad (30)$$

from which one sees that the geodesics are planar logarithmic spirals in planes through the origin. Lines through the origin and circles with the center at the origin are degenerated cases. For shapes of the same Casorati curvature the distance is simply a spherical arc length; in case the shapes have the same orientation this becomes the shape parameter, and for minimal surfaces it is the orientation difference. For shapes of the same shape parameter and orientation the distance is the logarithm of the ratio of Casorati curvatures, thus independent of the unit of length (or absolute size).

The osculating paraboloids shape space has numerous applications in very diverse contexts.

Open problem

The shape space concept described here appears to be little known and there is a decided lack of useful literature. The Casorati curvature and shape parameter appear in the literature as “curvedness” and (in a scaled version) as “shape index.”

Definition

A pan-tilt-zoom (PTZ) camera typically refers to an active camera which has some degree of pan, tilt, and zoom control. They are commonly used to monitor large areas for visual surveillance applications. The pan, tilt, and zoom controls of most off-the-shelf PTZ cameras are often programmable, enabling the camera to be remotely controlled over a network. Some variants of PTZ cameras are called *network* cameras when they come equipped with a real-time operation system which makes it possible to stream video over a network in real time. An example of such a camera is the Sony

SRG-300SE PTZ camera (https://pro.sony/ue_US/products/robotic-cameras/srg-300se).

Background

Active PTZ cameras serve as a practical alternative to high-resolution omnidirectional cameras in wide-area surveillance systems. On the one hand, flexible pan and tilt ranges provide most PTZ cameras a large *effective* field of view (FOV) similar to an omnidirectional sensor, but in addition to that, these cameras can also zoom in on a small region of interest and capture it in high resolution. However, unlike omnidirectional sensors, PTZ cameras cannot simultaneously observe the complete scene. Since activities of interest in a visual surveillance scenario typically occur in small regions within a large area, simultaneous imaging is not always required. The inability to simultaneously observe the complete scene is often compensated by deploying a network of static and PTZ cameras.

In order to utilize a programmable PTZ camera, many systems require the knowledge of a camera model that explains how 3D points in the world project to the image plane of a PTZ camera given a specific pan, tilt, and zoom configuration. Analyzing images from PTZ cameras may also require backprojecting a pixel on the image plane to obtain its corresponding 3D viewing ray (parameterized by the pan-tilt angles) on the camera's viewing sphere or the corresponding 3D ray in the world coordinate frame, provided the camera position is also known. For example, consider a calibrated PTZ camera monitoring a car parking area. For a calibrated camera, pixels can be mapped to precise locations on the ground plane. The model also makes it possible to actively track a person in the scene while ensuring that the PTZ camera is able to center its view on the individual. When a scene is monitored by a network of PTZ cameras, a calibrated camera model makes it possible to infer associations between objects or events detected in video captured from different viewpoints.

Conventional offline camera calibration methods such as [1] cannot easily be used to calibrate

PTZ cameras since both the observed scene as well as the inter-camera baselines can be quite large. This precludes the use of conventional calibration objects which are typically too small for such large scenes [2,3]. Also an active camera's calibration parameters must be continually estimated online by refining the pan-tilt angle and focal length estimates using a closed-loop mechanism [4] instead of relying on a set of precomputed pan-tilt control settings computed offline. This is due to the fact that the pan-tilt controllers present in most off-the-shelf PTZ cameras can be imprecise during operation.

Theory

PTZ Camera Model In many cases, PTZ cameras can be modeled using a simple motion model where the pan and tilt rotation axes are assumed to pass through the center of projection of the camera. However, depending on the camera's mechanical assembly and design, the pan and tilt rotation axes may need to be modeled as arbitrary axes not passing through the projection center [5]. In either case, the 2D projection of a 3D point onto the image plane can be computed using a few matrix operations. For indoor scenes, the intrinsic and extrinsic parameters of a network of pan-tilt cameras can be estimated offline by tracking a single moving LED over time within the working volume [5].

In outdoor scenes, the simple model works fine since the deviation of the rotation axes from the projection center is negligible compared to the average depth in the scene. This allows the PTZ camera to be modeled as a purely rotating and zooming camera for which self-calibration algorithms are well-known [6]. A PTZ camera is then treated like a pinhole camera with a fixed projection center, but the camera intrinsics are modeled as a function of zoom, and the camera's orientation obviously depends on the camera's pan and tilt settings.

Using homogeneous coordinates to represent a 3D world point and the corresponding image point denoted as \mathbf{X} and \mathbf{x} , respectively, the imaging process can then be linearly modeled

as follows:

$$\mathbf{x} = \mathbf{K}_z \mathbf{R}_{pt} [\mathbf{I}] - \mathbf{C} \mathbf{X} \quad (1)$$

where \mathbf{K}_z denotes the 3×3 camera *intrinsic* matrix, \mathbf{R}_{pt} denotes the 3×3 rotation matrix, and \mathbf{C} denotes the fixed projection center of the camera in world coordinates. The subscripts z , p , and t refer to the zoom, pan, and tilt settings of the active camera. The rigid transformation from world coordinates to camera coordinates is defined by the rotation matrix \mathbf{R}_{pt} and translation vector $\mathbf{t}_{pt} = -\mathbf{R}_{pt} \mathbf{C}$ which are often referred to as the camera's *extrinsic* parameters. \mathbf{K}_z depends on the zoom setting z and is defined in terms of five intrinsic parameters – α , s , f_z , u_z , and v_z . α is the pixel aspect ratio (an unknown constant), s is a skew parameter (typically set to 0), f_z is the focal length measured in pixel, and (u_z, v_z) is the principal point in the image plane:

$$\mathbf{K}_z = \begin{pmatrix} \alpha f_z & s & u_z \\ 0 & f_z & v_z \\ 0 & 0 & 1 \end{pmatrix} \quad (2)$$

Rotating and Zooming Cameras Let \mathbf{x} and \mathbf{x}' be the 2D projections of a 3D point \mathbf{X} for two different PTZ configurations (see Fig. 1). Based on (1), $\mathbf{x} = \mathbf{K}[\mathbf{R} \mathbf{t}]\mathbf{X}$ and $\mathbf{x}' = \mathbf{K}'[\mathbf{R}' \mathbf{t}]\mathbf{X}$. Selecting \mathbf{C} as the world origin results in $\mathbf{t} = \mathbf{0}$, and then eliminating \mathbf{X} leads to the following:

$$\mathbf{x}' = \mathbf{K}'\mathbf{R}'\mathbf{R}^{-1}\mathbf{K}^{-1}\mathbf{x}$$

For rotation at constant zoom, the intrinsics are constant. Therefore,

$$\mathbf{x}' = \mathbf{K}\mathbf{R}_{rel}\mathbf{K}^{-1}\mathbf{x} \quad (3)$$

where $\mathbf{R}_{rel} = \mathbf{R}'\mathbf{R}^{-1}$ denotes the relative 3D rotation about \mathbf{C} between the two views and \mathbf{K} denotes the intrinsic for the fixed zoom level. Similarly for a zooming camera with fixed orientation,

$$\mathbf{x}' = \mathbf{K}'\mathbf{K}^{-1}\mathbf{x} \quad (4)$$

These 2D homographies $\mathbf{H}_{rot} = \mathbf{K}\mathbf{R}_{rel}\mathbf{K}^{-1}$ and $\mathbf{H}_{zoom} = \mathbf{K}'\mathbf{K}^{-1}$ are used for automatic calibration of PTZ cameras [7, 8].

Radial Distortion Correction PTZ cameras deviate from an ideal pinhole model due to radial distortion. This can be corrected using a standard model [9, 10]. The effect of radial distortion is more pronounced for smaller focal lengths, i.e., for lower zoom settings. The coefficients of radial distortion for a PTZ camera are therefore functions of zoom. The center of distortion is often assumed to coincide with the principal point (u_z, v_z) which is also dependent on zoom [11].

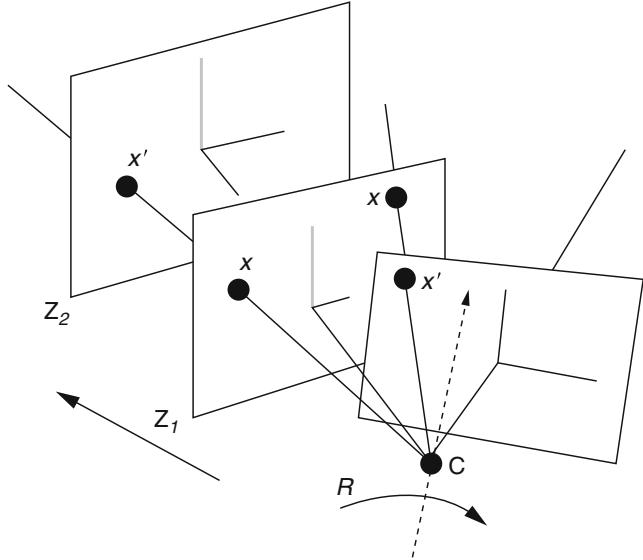

PTZ Camera Calibration For a PTZ camera, the camera calibration process involves estimating the camera intrinsics \mathbf{K}_z and coefficients of radial distortion for all zoom settings within the admissible range. Some other methods only model the variation of focal length with zoom [8]. In practice, the intrinsics are computed at a discrete set of zoom values, and during online operation the intrinsics for any zoom setting can be obtained by piecewise interpolation after looking up values in a precomputed table [7, 8]. The extrinsic parameters of a PTZ camera can be computed using image observations of 3D points with known coordinates [2, 10]. Alternatively, structure from motion techniques may also be used to calibrate a PTZ camera network where a common area is visible to all the cameras. The process is similar to the calibration of conventional camera networks [12, 13] but requires handling dynamic network topologies due to changing visibility relations between active cameras in the network [14].

To maintain precise calibration of an active PTZ camera in deployment, one must also address the fact that most PTZ cameras lack precise and repeatable pan-tilt controllers. This implies that even if the motorized controllers are precalibrated, the true 3D rotation of the camera for a particular pan-tilt setting of the camera may differ from the orientation predicted based on the precalibration. Systems where a precise calibration must be maintained may require a closed-loop calibration system depending on

Pan-Tilt-Zoom (PTZ)

Camera, Fig. 1 2D

feature point
correspondences under
camera rotation and zoom

the accuracy of the PTZ controllers [7]. For closed-loop calibration, a calibrated panoramic mosaic must be computed offline. During online operation, this image serves as a calibration reference for all video frames captured online. Every video frame can then be aligned to the calibrated mosaic using a homography computed online with an image registration method. This provides a way to estimate the 3D directions on the camera's viewing sphere for all pixels in the video stream of the active camera.

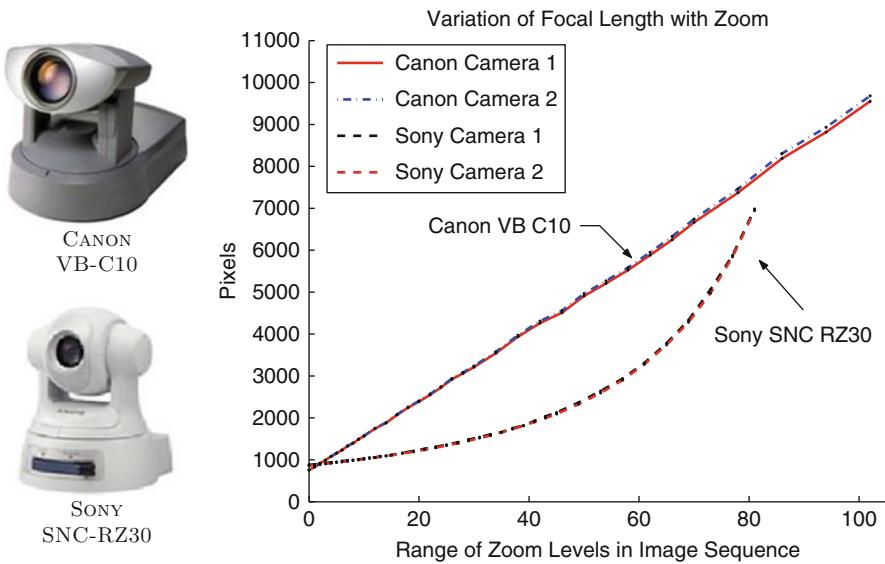

In [7], both camera intrinsics and the calibrated mosaic are computed automatically using the motion of natural scene features induced by actively panning, tilting, and zooming the camera. The 2D feature correspondences are robustly computed using the 2D homography-based motion model for rotating and zooming cameras. Figure 2 shows parameters estimated using this method for two common off-the-shelf PTZ cameras. This method makes it possible to automatically recalibrate PTZ cameras after they are deployed on site.

PTZ Camera Control When a network of PTZ cameras are used to monitor a large space, the task of controlling the camera network and reconfiguring the cameras becomes more challenging. In this situation, a controller must determine

where each camera should focus in its field of view given all the other cameras' configurations with the goal of improving the overall coverage of an event from multiple viewpoints. Recently, provably correct greedy algorithms have been proposed to optimize the camera orientations and zoom levels to maximize the coverage. The concept of conic Voronoi diagrams is introduced to solve the underlying sensor allocation problem for camera networks [15].

Application

Capturing High-Resolution Images of Humans Surveillance cameras monitoring large scenes cannot capture images of human faces at a sufficient resolution for identifying the individual when they are at a distance. PTZ cameras have been used to automatically zoom in on the face and capture a series of high-resolution face images once a pedestrian is detected (see Fig. 3a) [16]. This has applications in forensic video analysis. A multi-view video acquisition system utilizing a network of controllable PTZ cameras was also described in [17]. It was designed to track a person within an indoor

Pan-Tilt-Zoom (PTZ) Camera, Fig. 2 The variation of the focal length parameter with the zoom control for two common PTZ cameras. These parameters were estimated using an automatic method for PTZ camera calibration

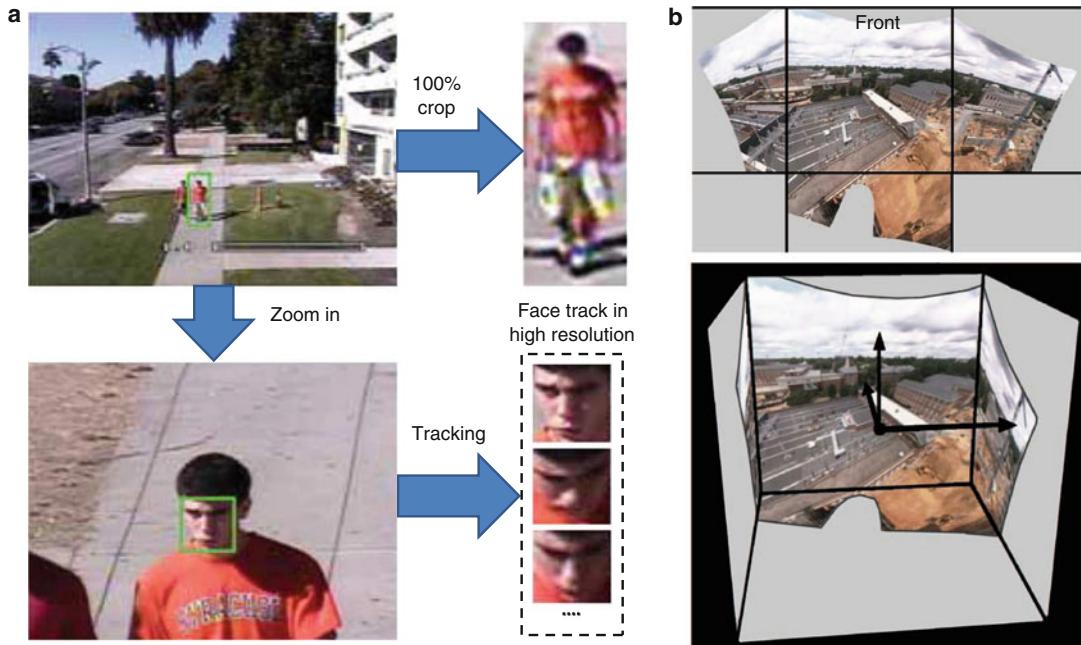

scene while automatically adapting the pan-tilt camera controls to keep the individual centered in all the views. Their system is used for video conferencing [18] and event broadcasting.

Detection and Tracking PTZ cameras are often deployed as part of a network of cameras for visual surveillance. In certain cases, static cameras provide a global view of the environment and are used primarily for detection and for actively steering the PTZ camera to regions of interest or to actively track moving targets. Such systems find applications in traffic monitoring, tracking pedestrians, security systems, or automatic event detection. To monitor more complex environments, smart surveillance systems can use multiple calibrated PTZ cameras working in cooperation to track multiple targets [19, 20]. Accurate calibration is required to correctly match targets tracked by different PTZ cameras and for handing off a moving target from one camera to another [21].

PTZ Closed-Loop Calibration An open-loop calibration system for PTZ cameras that rely only on precomputed calibration of the PTZ controls

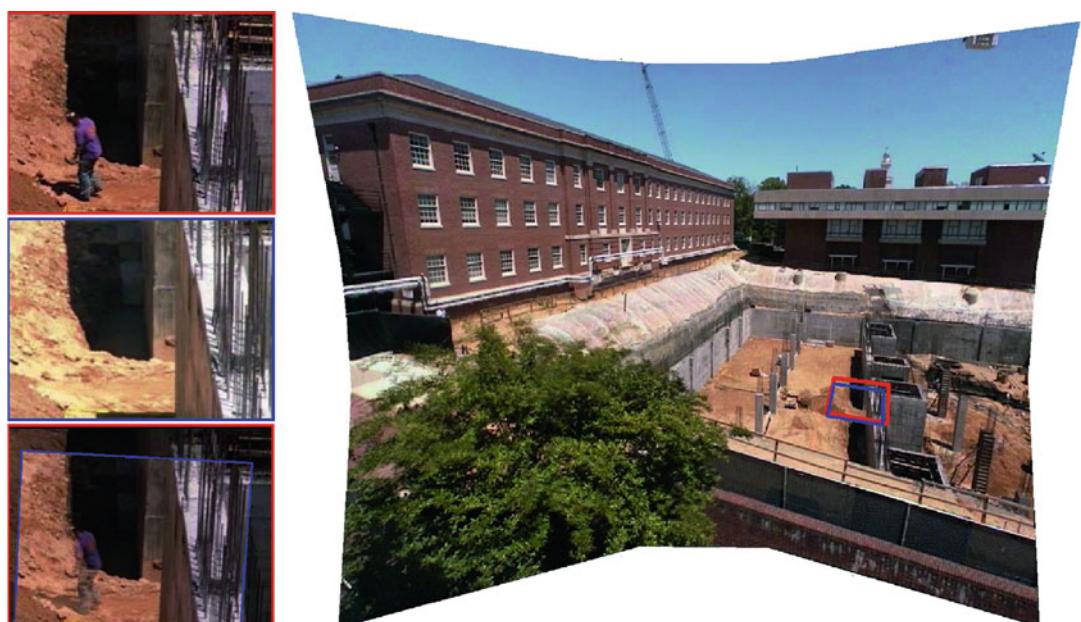

will tend to be inaccurate during operation due to the imprecise nature of the PTZ controllers or due to vibrations or other sources of instability. To deal with this, a closed-loop calibration system should be used which is based on a calibrated panorama constructed offline (see Fig. 3b for an example). Figure 4 shows an outdoor panorama used for closed-loop control in [7]. Using feature-based image alignment, the video frames are robustly aligned to the calibrated panorama which allows pixels in the video stream to be precisely mapped to 3D directions on the camera's viewing sphere. When extrinsic camera calibration is known, 3D scene reasoning can be performed more effectively.

PTZ Cameras for Sports Video Analysis PTZ cameras are frequently used to record and stream sports, and the analysis of such sports videos such as in soccer requires detecting, tracking, and localizing the players and other objects such as the ball on the soccer field. Performing these tasks accurately requires the knowledge of the camera pose during the operation of the PTZ camera. The line markings on a soccer field provide ground control points for recovering

- ▶ [Parametric Surface](#)
- ▶ [Splines](#)

Definition

A *parametric curve* S in 2-dimensional Euclidean space has the following form:

$$\begin{aligned} S(\cdot) : \mathbb{R} &\rightarrow \mathbb{R}^2 \\ t &\mapsto (x(t), y(t)), t \in [a, b] \end{aligned} \quad (1)$$

where t is the parameter and varies in the domain $[a, b]$. In practice, the domain $[a, b]$ is often normalized as a specific region, such as $[0, 1]$. And $x(t), y(t)$ are real-valued functions continuously mapping to a 2D point on a curve.

Similarly, a parametric curve S in 3-dimensional space has the following form:

$$\begin{aligned} S(\cdot) : \mathbb{R} &\rightarrow \mathbb{R}^3 \\ t &\mapsto (x(t), y(t), z(t)), t \in [a, b] \end{aligned} \quad (2)$$

For example, an ellipse can be represented in a parametric form as: $x = a \cos t$, $y = b \sin t$, with $t \in [0, 2\pi]$, in contrast with its implicit representation: $\frac{x^2}{a^2} + \frac{y^2}{b^2} - 1 = 0$.

Background

Since parametric functions are easy to construct and analyze, parametric curves are one of the most popular representations of general curves in computer graphics and computer vision. There are many types of parametric curves because of

the flexibility in choosing the underlying analytic function. Spline curves are one of the most widely used parametric curves. Some popular spline curves are cubic curves, Hermite curves, Bézier curves, and B-spline curves (see ▶ [Splines](#) for further details).

Compared to nonparametric representations of curves, such as the implicit representation of *algebraic curves* and other explicit representation, parametric curves are easier to control the local geometry and thus attractive for interactive curve design or representing the nonrigid deformation; parametric curves are capable of approximating complex shapes with desired smoothness; parametric curves are independent of the choice of coordinate system and lend themselves well to geometric transformations.

Application

In computer vision, parametric curves are generally used in modeling image edges, contours, and 2D object boundaries. It is shown as a powerful tool for shape fitting and manipulating. There are numerous applications, such as image segmentation, rigid/nonrigid object registration, motion estimation, object tracking, that benefit from parametric curve representations. For example, in the Snake-based image segmentation designed by Kass et al. [6] and modified by Brigger et al. [2], splines are used to model the image contours which converge to object shapes by minimizing the energy guided by external and internal forces. For image motion estimation, Szeliski and Coughlan [11] proposed to represent the local motion flow field using multi-resolution splines. And grid-based splines, such as Thin-Plate spline (TPS) [3] and Free Form Deformation (B-spline) proposed by Sederberg [9], can be effectively applied to nonrigid image registration. Other types of parametric curves are proposed for specific vision problems. For instance, Rational Gaussian curves [5] does not require a regular grid of control points and is suitable for shape recovery. And elastic strings [8] have metrics which are invariant under reparametrizations of curves and are useful for modeling elastic objects.

Definition

A parametric surface is a surface in the Euclidean space \mathbb{R}^3 which is defined by a parametric equation with two parameters,

$$\begin{aligned} \mathbb{S}(\cdot) : \mathbb{R}^2 &\rightarrow \mathbb{R}^3 \\ (u, v) &\mapsto (x(u, v), y(u, v), z(u, v)), \end{aligned} \quad (1)$$

where u, v are the parameters and vary within a certain 2D domain in the parametric uv -plane. $x(u, v), y(u, v), z(u, v)$ are the real-valued functions continuously mapping to the points on a surface.

For example, Bézier surface is one of the most commonly used parametric surfaces (patch) defined as

$$P(u, v) = \sum_{i=0}^m \sum_{j=0}^n B_i^m(u) B_j^n(v) \mathbf{p}_{ij}, \quad (2)$$

where \mathbf{p}_{ij} ($\in \mathbb{R}^3$) are the control points of Bézier spline surface. $B_i^n(\cdot) : \mathbb{R} \rightarrow \mathbb{R}$ are the basis functions determined by *Bernstein polynomials* of degree n (see the detail in contribution *splines*).

Parameterization is an important process of deciding and defining the parameters necessary for modeling a parametric surface. For example, through a spherical parameterization, a unit sphere can be described as

$$\begin{aligned} x &= \cos \theta \cos \varphi \\ y &= \cos \theta \sin \varphi \\ z &= \sin \theta \\ -\frac{\pi}{2} &\leq \theta < \frac{\pi}{2}, 0 \leq \varphi < \pi. \end{aligned} \quad (3)$$

Background

Parametric representation is the most general method to represent a surface, because it is capable of modeling a complex shape in a compact set of parameters and with desired smoothness. Surfaces that occur in two of the main theorems of vector calculus, Stokes' theorem and the divergence theorem, are frequently given in a parametric form. Parametric surfaces also provide a convenient way for

computing the curvature and arc length of curves on the surface, surface area, differential geometric invariants such as the first and second fundamental forms, Gaussian, mean, and principal curvatures. Compared to implicit representation, parametric representation is more convenient for image rendering, due to the local points on a surface that can be fast and precisely determined. In addition, they may provide the potential for feature retrieving and surface modifying. Some typical parametric surfaces (patches) are spline-based parametric surfaces, such as bicubic patches, Bézier patches, and B-spline patches (see the contribution *splines*).

Application

Parametric surface attracts attention in computer vision, because of its convenience in handling 3D image segmentation, nonrigid registration, and recognition. For example, a classic method for image segmentation, the level set method introduced by Osher and Fedkiw [8], employs parametric curve/surface to represent image contours (level sets) for tracking shapes. The parametric curve/surface makes it easy to handle shapes that change topology, e.g., shape splits in two, develops holes, or the reverse of these operations. The snake-based image segmentation designed by Kass et al. [7] and modified by Brigger et al. [2] employs splines to model the image contours and serving for an energy minimization guided by external and internal forces. Spherical harmonics represented in spherical parameterized coordinates play a special role in a wide variety of topics including indirect lighting and in recognition of 3D shapes [5]. And grid-based parametric surface, such as Thin-Plate spline (TPS) [3] and Free-Form Deformation (B-spline) proposed by Sederberg [9], can be effectively applied for nonrigid object registration.

Definition

A partial differential equation (PDE) is an equation involving functions of multiple independent variables and their partial derivatives.

Background

Images can be thought of as functions on a two-dimensional image domain, i.e., of two variables. Output entities or objects that are sought in (especially low-level) computer vision are also often described as functions or some aspect thereof. Thus, the desired property of the output is often described using a PDE involving the input image and the output entity, often derived as a solution to a variational problem. Such a PDE is then solved, usually numerically, to obtain the output with the desired property.

Application

Here, some basic and historical applications of PDE used in computer vision and image processing are illustrated. See the articles on the Related Concepts for more examples.

Diffusion

Diffusion equation is the PDE that describes the process of diffusion, which is the movement of a substance from regions with high concentration to those of low concentration. The PDE is usually written as:

$$\frac{\partial u}{\partial t} = \operatorname{div}(D \nabla u), \quad (1)$$

where u is the density of the substance as a function of space and time, t is the time, and D is a symmetric positive definite matrix that characterizes the propagation of the density. When D

is the identity matrix, it describes a homogeneous diffusion, just as the heat is dispersed in a material. The equation is called the heat equation in this case.

In image processing, the intensity at each point in the image can be considered as the density, and by diffusing it, i.e., numerically solving the PDE with a given image as the initial condition, the image can be smoothed. The simplest case, where D is the identity matrix, is blurring (with, in fact, a Gaussian kernel). By choosing different D 's, the smoothing can be controlled in more sophisticated ways than the simple blurring. For instance, by using a scalar times the identity as D , and decreasing the scalar as the function of the image gradient, more diffusion occurs where there is no edge, leading to an edge-preserving smoothing. More general D would lead to anisotropic diffusion, where the diffusion can also depend on the direction.

For more details, see the article ▶ [“Diffusion Filtering”](#)

Geodesics

The shortest path between two points, which is a line in the ordinary case, is in general a curve called a *geodesic*. In computer vision and image processing, various problems can be solved by finding the shortest paths, where “short” is defined to suit the purpose at hand. For instance, edges are the points in the image where the change in the image function is steep. If the distance is defined to be inversely related to the magnitude of the gradient along the path, the shortest path according to this distance would be more likely to go through edge points.

Let us represent a curve between points \mathbf{a} and \mathbf{b} by a map \mathbf{v} from a unit interval to the image domain $R \subset \mathbb{R}^2$:

$$\mathbf{v} : [0, 1] \rightarrow R, \quad \mathbf{v}(s) = (x(s), y(s)), \quad (2)$$

$$\mathbf{v}(0) = \mathbf{a}, \quad \mathbf{v}(1) = \mathbf{b}.$$

We usually assume that $\mathbf{v}(s)$ (i.e., $x(s)$ and $y(s)$) is continuously differentiable. Then, the “length” of the curve is defined by

$$\int_0^1 g(\mathbf{v}(s))ds, \quad (3)$$

where $g : R \rightarrow \mathbb{R}^+$ is a positive function on the image domain that defines the local length ratio. Note that the parametrization of $\mathbf{v}(s)$ has a freedom that affects the integral, that is, by replacing s with another parameter, the curve on the image domain stays unchanged, while the length as defined above changes. Thus it is usually the practice to fix the parametrization so that the speed $|\dot{\mathbf{v}}|$ of the curve point measured with respect to the ordinary (Euclidean) distance is constant, where

$$\dot{\mathbf{v}} = \frac{d\mathbf{v}}{ds} = \left(\frac{dx}{ds}, \frac{dy}{ds} \right), |\dot{\mathbf{v}}| = \sqrt{\left(\frac{dx}{ds} \right)^2 + \left(\frac{dy}{ds} \right)^2}.$$

By changing the function g , different distances to suit the purpose can be defined. To find edges for instance, we may define g by

$$g(\mathbf{v}) = \frac{1}{|\nabla I(\mathbf{v})| + \varepsilon}, \quad (4)$$

where $\mathbf{v} \in R$ is a point on the image domain and $\nabla I(\mathbf{v})$ is the gradient of the image function $I(\mathbf{v})$. We add ε , a small positive constant, to the denominator so that $g(\mathbf{v})$ does not go to infinity. The length of the curve (2) with this function g is, substituting (4) to (3),

$$\int_0^1 \frac{1}{|\nabla I(\mathbf{v}(s))| + \varepsilon} ds. \quad (5)$$

Then a shortest curve according to this length would be more likely to go through edge points.

This can be generalized beyond length. For instance, since the image gradient is a vector field, the relative direction of the path and the gradient can be also taken into account by defining

$$g(\mathbf{v}, \dot{\mathbf{v}}) = \frac{1}{|\nabla I(\mathbf{v}) \times \dot{\mathbf{v}}| + \varepsilon} \quad (6)$$

that also takes the tangent vector $\dot{\mathbf{v}}$, where \times is the exterior product of 2D vectors. The length is now defined by

$$\begin{aligned} & \int_0^1 g(\mathbf{v}(s), \dot{\mathbf{v}}(s))ds \\ &= \int_0^1 \frac{1}{|\nabla I(\mathbf{v}(s)) \times \dot{\mathbf{v}}(s)| + \varepsilon} ds. \end{aligned} \quad (7)$$

In this case, when the tangent vector $\dot{\mathbf{v}}$ is perpendicular to the gradient vector ∇I , the $|\nabla I \times \dot{\mathbf{v}}|$ becomes maximum, which makes it more likely that the curve goes through edge points perpendicular to the gradient direction, when its length is minimized.

For more details and examples, see the articles ▶ “Geodesics, Distance Maps, and Curve Evolution” ▶ “Numerical Methods in Curve Evolution Theory” and ▶ “Parametric Surface”

Variational Methods

Finding the minimum length curve is an example of variational problem. In computer vision, many problems are successfully solved by the variational methods, where the object to be found is defined as a function. Then, the object’s desired property is characterized as a functional, so that the problem of finding the object with the property becomes the variational problem of finding the function that achieves the extremum of the functional, which is then solved, usually numerically, to obtain the object with the desired property.

In the above example, the object to be found is the curve, which is defined as the map \mathbf{v} . The curve’s desired property is characterized as the length, which is a functional. Finding the minimum-length curve is then the variational problem.

Early examples of the vision problems solved using the variational methods include Shape from Shading [1] and Optical Flow [2].

Variational problems are sometimes solved dynamically, i.e., by moving the function from some initial solution to find the extremum of the functional. Other times it is solved by deriving an accompanying PDE called the Euler-Lagrange equation and then solving it [3]. Yet other times, it can be algorithmically solved by discretizing the problem [4].

For more details, see the article ▶ “[Variational Method](#)”

Active Contours

An active contour, also known as a snake [3], is a particularly successful example of the methods that represent curves as the map (2) and uses the variational method. The curve is subject to various constraints:

- Internal forces give the contour a tendency to be smooth.
- Image forces push the active contour toward salient image features such as edges.
- External constraint forces represent task-specific influences such as user-specified preferred region for the contour to be attracted.

These forces are expressed by an energy functional:

$$E(\mathbf{v}) = \int_0^1 \{ E_{\text{int}}(\mathbf{v}(s)) + E_{\text{image}}(\mathbf{v}(s)) \\ + E_{\text{ext}}(\mathbf{v}(s)) \} ds, \quad (8)$$

where E_{int} , E_{image} , and E_{ext} represent the internal, image, and external forces, respectively. This energy is then minimized as a variational problem, by solving its Euler-Lagrange equation numerically.

For more details, see the article ▶ “[Numerical Methods in Curve Evolution Theory](#).”

Level Sets

When a curve is explicitly parametrized as in (2), it can only be represented as a single open curve. Topological changes such as detachment into multiple curves and closing the curve cannot be handled very well in this way. Curves can be alternatively represented implicitly as a *level set*, which is the cross section C of the graph of a function $z = f(x, y)$ on the image domain by the plane $z = c$ for some constant c , i.e., $C = \{(x, y) \in R | f(x, y) = c\}$. In such a representation, the topology of the curve can change naturally, e.g., closing, opening, or break-

ing a curve. Motion of curves represented this way can then be described by a PDE involving the function $f(x, y)$. For instance, curves and surfaces propagating with speed at each point that is an arbitrary function of curvature at that point is described in [5]. The formulation can also be used for surfaces or sets of even higher dimension.

Penumbra and Umbra,

Fig. 1 (a) Shadows cast in the case of an object on a surface and (b) shadows cast in the case of an object in free-space

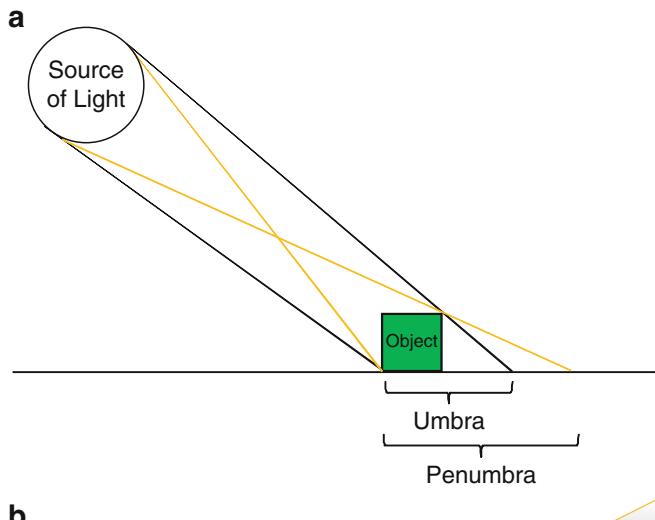

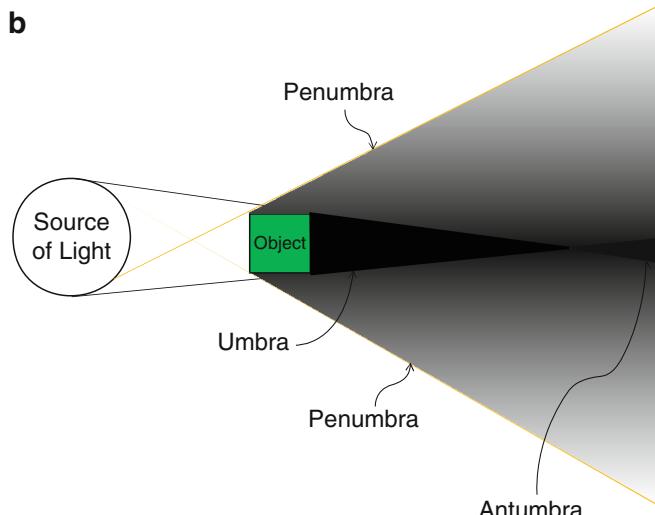

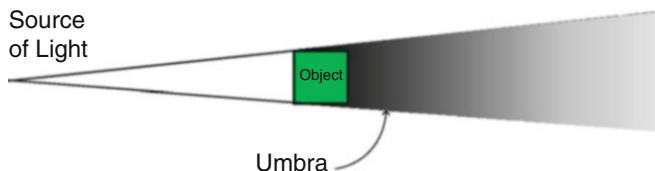

**b****Penumbra and Umbra,**

Fig. 2 Shadows cast in the case of an object in free space with a point source of light

**Definition**

Umbra is the Latin name for “shadow” and is typically used to refer to the shadow cast by an object when illuminated by a light source [2]. In the umbra region of the shadow, the entire light source is occluded by the object. The region around the umbra where only a portion of the light is obscured is called the penumbra [1].

Considering a simplistic arrangement of a light source and an object, Fig. 1a shows the regions denoted as the umbra and penumbra. As well, Fig. 1b shows the antumbra, the region where the light source actually appears bigger than the object; an antumbra is typically formed only when the object is in free-space, as opposed to resting on a surface.

The above considerations are for an area light source. In contrast, it is straightforward to see that

for a point source of light, only an umbra is cast (see Fig. 2).

In astronomical setups – similar to when objects are in free space – observers who see partial eclipses (of the sun or the moon) are located in the penumbra.

Synonyms

Multi-camera scene understanding; Multi-camera tracking; Person Re-identification

Definition

The objective of person re-identification (re-id) is to associate targets across cameras with non-overlapping fields of view. Specifically, a person re-identification algorithm takes two images from two non-overlapping cameras and provides a decision whether those two images are of the same person or not.

Background

In the last few years, the problem of re-identifying persons across multiple non-overlapping cameras has received increasing attention. A thorough recent survey on person re-identification (re-id) can be found at [1]. Most existing person re-id techniques are based on supervised learning. These methods either seek the best feature representation [2,3] or learn discriminant metrics [4,5] that yield an optimal matching score between two cameras or between a gallery and a probe image. Recently, deep learning methods have shown significant performance improvement on image classification and have been applied to person re-id [6,7]. Considering that a modest-sized camera network can easily have hundreds of cameras, these supervised re-id models will require huge amount of labeled data which are difficult to collect in real-world settings. In an effort to bypass tedious labeling of training data in supervised re-id models, there has been recent interest in using active learning for labeling examples in an interactive manner. In [8], an entropy-based selection approach is proposed for reducing manual annotation. In [9], the authors uses a dominant clustering-based approach for probe relevant set selection and utilize it for pair selection in a dynamic setting.

Unsupervised learning has received little attention in person re-identification because of their weak performance on benchmarking datasets compared to supervised methods. Representative methods along this direction use either hand-crafted appearance features [10] or saliency statistics [11] for matching persons without requiring huge amount of labeled data. Recently, sparse dictionary learning-based methods have also been utilized in an unsupervised setting [12].

Domain adaptation [13, 14], which aims to adapt a source domain to a target domain, has been successfully used in many areas of computer vision and machine learning, e.g., object classification, and action recognition and speech processing. Despite its applicability in classical computer vision tasks, domain adaptation for person re-identification still remains as a challenging and under-addressed problem. Only very recently, domain adaptation for re-id has begun to be considered [15]. However, these studies consider only improving the re-id performance in a static camera network with fixed number of cameras. Furthermore, most of these approaches learn supervised models using labeled data from the target domain.

Main Text

With the advancement of imaging sensor technology, surveillance systems have seen remarkable increase in various applications ranging from law enforcement to large retail applications, from facility access and environment monitoring. Even though the sensing devices are becoming cheaper, monitoring a wide area by deploying a large number of cameras is still not feasible due to the amount of human supervision, privacy concerns, and maintenance costs involved. As a result, only a small part of the whole area is covered by a number of cameras with non-overlapping fields of view (FoVs). The non-overlapping camera FoVs leave blind gaps which are critical in the sense that no information can be obtained from these areas. This raises the need for automated methods able to extract and access high-level

semantic information carried by the extremely high volume of recorded video data. As a result of losing a person when he/she leaves a camera FoV, it is extremely challenging to reassociate the same person at a different location and time among multiple persons. This inter-camera person association problem is known as the person re-identification problem.

In spite of a surge of effort put in by the research community in recent years, re-identification has remained quite an open issue due to a number of hard challenges. First, footages are recorded in an uncontrolled environment by cameras with large FoVs, generating low-resolution images of the targets. This makes the acquisition of discriminating biometric features (e.g., face and gait features) hard as well as unreliable. Due to the poor quality of the acquired biometric features, methods relying on such features perform unsatisfactorily. As a result, visual appearance features are, still, the first choice in re-identification problems. As a target's appearance often undergoes large variations across non-overlapping camera views due to significant changes in viewing angle, lighting, background clutter, and occlusion, the appearance features for the target can be very different from camera to camera.

The computer vision community has tried to address the person re-identification problem by designing discriminative signatures for each target or by finding a non-Euclidean metric which minimizes the distance between features of the same target across cameras. Similar to the most other visual recognition problems, the most successful approaches have been based on supervised training phases. Labeled data across pairs of cameras are used to learn models that define the transformation between the views in two cameras, and these learned models are used to associate between images during the testing phase. However, this level of supervision hampers scalability of the problem because of the need to label quantities of data, which grows with the size of the camera network and the variety of conditions that may be encountered.

Below we discuss future research directions in person re-identification, especially the possibility

of significantly reducing the level of supervision without any sacrifice in performance. This will ensure that it is possible to scale person re-identification problems to larger and larger networks of cameras without compromising accuracy of the association task. We specifically focus on two problems. The first problem relates to scalability of person re-identification as the number of people grows. The second relates to scalability as the size of the camera network grows.

Optimal Subset Selection for Labeling

Given unlabeled training data across a network of cameras and a similarity measure, can we select a minimal subset of images that should be labeled and from which the person re-identification models can be learned? The intuition here is that if we choose this minimal subset judiciously, the labels can be propagated using the similarity measure to the rest of the dataset. Thus, most of the labels would be obtained automatically with only a small subset of images being labeled.

Building on preliminary result on network consistent re-id [16, 17], we now ask whether *consistency can be used to reduce the labeling effort*. However, in order to take advantage of consistency relations for reducing the labeling effort, we have to choose image pairs in a judicious manner. Toward this objective, we can represent a camera network as an edge-weighted k -partite graph. Nodes on the graph are observations of the targets, and edge weights are computed based on similarities in the observations. We formulate the pair subset selection as the following combinatorial optimization problem: given a complete k -partite graph $G_k = (V, E)$ with nonnegative edge weights and an integer B , choose a maximum-weight set S of edges from E such that $G' = (V, S)$ is triangle-free and $|S| \leq B$, where B is labeling budget. Once the subset for labeling is selected, the remaining labels can be obtained by label propagation on the graph, and existing methods for learning re-identification models can be used. Note that this subset selection is a NP-hard problem as it

requires searching over every subset of image pairs. Polynomial time sub-optimal algorithms with linear or quasilinear time complexity can be adopted to solve this problem in an efficient way. Preliminary experiments in [18] have shown that we are able to achieve same recognition performance as the state of the art, with only 8% manual labels on the challenging Market-1501 dataset with six fixed cameras [19].

On-Boarding New Cameras Through Transfer Learning

We now address a very practical problem in camera networks, which has received little attention in the person re-identification literature. *Given a camera network where the inter-camera transformations/distance metrics have been learned in an intensive training phase, how can we onboard new cameras into the installed system with minimal additional effort?* To illustrate such a problem, let us consider a scenario with \mathcal{N} cameras for which we have learned the optimal pair-wise distance metrics, so providing high re-id accuracy for all camera pairs. However, during a particular event, a new camera may be temporarily on-boarded to cover a certain related area that is not well-covered by the existing network of \mathcal{N} cameras. Despite the dynamic and open nature of the world, almost all work in re-identification assume a *static* and *closed* world model of the re-id problem where the number of cameras is fixed in a network. Given newly introduced camera(s), traditional re-id methods will try to relearn the inter-camera transformations/distance metrics using a costly training phase. This is impractical since labeling data in the new camera and then learning transformations with the others is time-consuming and defeats the entire purpose of temporarily introducing the additional camera.

In [20], the authors have shown that it is possible to add a new camera to an existing network using transfer learning. First, they propose an unsupervised method based on geodesic flow kernel that can effectively find the best source camera to adapt with a target camera. Given camera pairs, each consisting of 1 (out of \mathcal{N}) source camera and a target camera, they first compute a kernel over the subspaces representing

the data of both cameras and then use it to find the kernel distance across the source and target camera. Then, they rank the source cameras based on the average distance and choose the one with lowest distance as the best source camera to pair with the target camera. This is intuitive since a camera which is closest to the newly introduced camera will give the best performance on the target camera and hence is more likely to adapt better than others. Second, they introduce a transitive inference algorithm to exploit information from best source camera to improve accuracy across other camera pairs. Extensive experiments on multiple benchmarks show that the proposed method significantly outperforms the state-of-the-art unsupervised alternatives while being extremely efficient to compute.

Open Problems

We now discuss two open research problems in re-identification, such as network-level knowledge transfer and learning in mobile networks.

Knowledge Transfer Across Networks

Above, we explained how it is possible to add a new target camera to an existing network of cameras using transfer learning with no additional supervision for the new camera. However, transfer learning across networks is still a largely under-addressed problem with many challenges. Given multiple existing source networks and a newly installed target network with limited labeled data, we first need to find the relevance/similarity of each source network, or parts thereof, in terms of amount of knowledge that it can transfer to a target network. Developing efficient statistical measures for finding relevance in a multi-camera network with significant changes in viewing angle, lighting, background clutter, and occlusion can be a very interesting future work. Furthermore, labeled data from source networks are often a subject of legal, technical, and contractual constraints between data owners and customers. Thus, existing transfer learning approaches may not be directly applicable in such scenarios where the source data is absent. The

question we want to ask here is whether learned source models, instead of source data, can be used as a proxy for knowledge transfer across networks. Compared to the source data, the well-trained source model(s) are usually freely accessible in many applications and contain equivalent source knowledge as well. Knowledge distillation [21] along with attention transfer techniques can be adopted to transfer knowledge from a number of existing labeled networks to an unlabeled target network containing targets which never appeared in the source network.

Learning in Mobile Camera Networks

Despite the success of existing person re-identification works in static platforms, considering mobile cameras (e.g., network of robots) opens up exciting new research problems in terms of learning such data association models. It is not possible to learn transformation models between every possible pair of views in two mobile cameras due to the constantly changing nature of the videos being captured. Thus, in order to efficiently learn data association models, we need the data to represent the variety of scenarios that will be encountered by the mobile cameras. A semi-supervised pipeline that uses limited manual training data along with newly generated data through a generative adversarial network (GAN) could be a possibility. One initial approach could be to use the unlabeled samples produced by a Multi-view Generative Adversarial Network in conjunction with the labeled training data to learn view-invariant features in a mobile network. Moreover, apart from generating samples, we may need to evolve the learned models over time based on the observed features.

Definition

A *perspective camera* is a mathematical model of an ideal pinhole camera that follows perspective projection.

Background

P

A modern camera generally consists of an enclosed hollow with an opening (aperture) at one end for light to enter, a lens positioned in front of the opening, and a recording surface on the other end. In an ideal pinhole camera, the camera aperture is described as a point and no lenses are used to focus light. In that case, the camera can be modeled by a perspective transformation, thus also called *perspective camera*.

This model does not consider many effects of a real camera such as geometric distortions or blurring of unfocused objects caused by lenses and finite-sized apertures. Therefore, the pinhole camera model (perspective camera) can only be used as a first-order approximation of the transformation from a 3D scene to a 2D image. Its validity depends on the quality of the camera and the camera calibration process.

Lens distortion might be the major effect that the pinhole camera model does not take into account. It is sufficiently small if a high-quality camera is used and thus can be neglected. Otherwise, less distortion can be modeled through camera calibration and can be compensated for by applying suitable coordinate transformations on the image coordinates (lens distortion correction). Because of that, the pinhole camera model (perspective camera) has been the most popularly used camera model in computer vision and computer graphics to describe the relationship between a 3D scene and an image.

Theory

Figure 1 shows a pinhole camera model. There is a plane \mathcal{F} at a fixed distance f in front of an *image plane* \mathcal{I} . The image plane is also called the *retinal plane*. An ideal pinhole C is found in the plane \mathcal{F} . Assume that an enclosure is provided so that only light coming through the pinhole can reach the image plane. The rays of light emitted or reflected by an object pass through the pinhole and form an inverted image of that object on the image plane. Each point in the object, its corresponding image point, and the pinhole constitute a straight line. This kind of projection from 3D space to a plane is called *perspective projection*.

The geometric model of a pinhole camera thus consists of an image plane \mathcal{I} and a point C on the plane \mathcal{F} . The point C is called the *optical center*, or the *focus*. The plane \mathcal{F} going through C and parallel to \mathcal{I} is called the *focal plane*. The distance between the optical center and the image plane is the *focal length* of the optical system. The line going through the optical center C and perpendicular to the image plane \mathcal{I} is called the *optical axis*, and it intersects \mathcal{I} at a point c , called the *principal point*. It is clear that the focal plane is also perpendicular to the optical axis. Experiences have shown that such a simple system can accurately model the geometry and optics of most of the modern Vidicon and CCD cameras [1].

Now let us derive the equations for the perspective projection. The coordinate system

(c, x, y) for the image plane is defined such that the origin is at the point c (intersection of the optical axis with the image plane) and that the axes are determined by the camera scanning and sampling system. We choose the coordinate system (C, X, Y, Z) for the three-dimensional space as indicated in Fig. 1, where the origin is at the optical center and the Z -axis coincides the optical axis of the camera. The X - and Y -axes are parallel, but opposite in direction, to the image x - and y -axes. The coordinate system (C, X, Y, Z) is called the *standard coordinate system* of the camera, or simply *camera coordinate system*. From the above definition of the camera and image coordinate system, it is clear that the relationship between 2D image coordinates and 3D space coordinates can be written as

$$\frac{x}{X} = \frac{y}{Y} = \frac{f}{Z}. \quad (1)$$

It should be noted that, from the geometric viewpoint, there is no difference to replace the image plane by a virtual image plane located on the other side of the focal plane (Fig. 2). Actually this new system is what people usually use. In the new coordinate system, an image point (x, y) has 3D coordinates (x, y, f) , if the scale of the image coordinate system is the same as that of the 3D coordinate system.

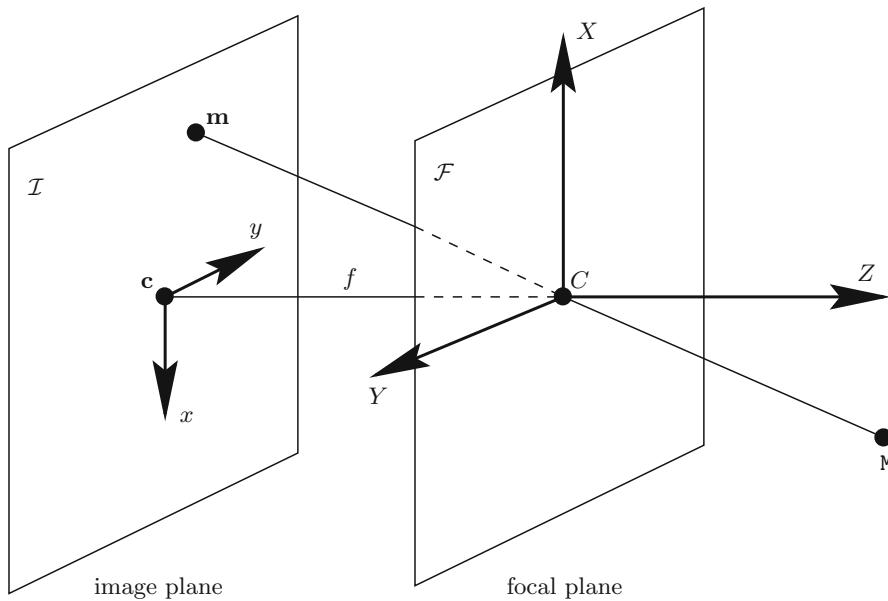

Perspective Projection Matrix

The relationship between 3D coordinates and image coordinates, Eq. (1), can be rewritten linearly as

$$\begin{bmatrix} U \\ V \\ S \end{bmatrix} = \begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix}, \quad (2)$$

where $x = U/S$ and $y = V/S$ if $S \neq 0$.

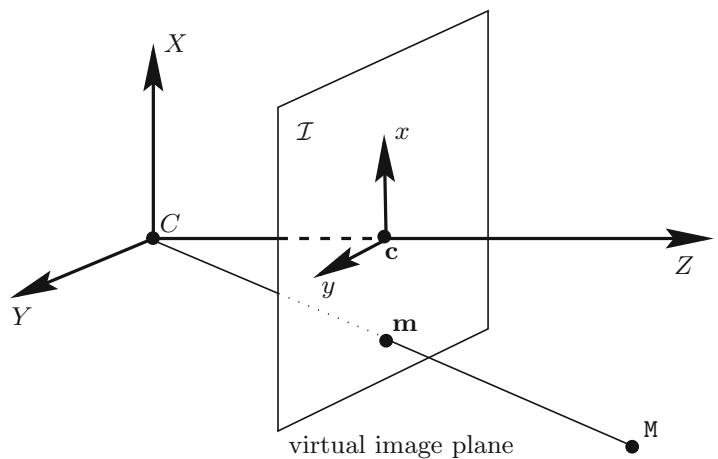

Given a vector $\mathbf{x} = [x, y, \dots]^T$, we use $\tilde{\mathbf{x}}$ to denote its augmented vector by adding 1 as the last element. Let \mathbf{P} be the 3×4 matrix

Perspective Camera, Fig. 1 The pinhole camera model

Perspective Camera,

Fig. 2 The pinhole camera model with a virtual image plane

$$\mathbf{P} = \begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix},$$

which is called the camera *perspective projection matrix*. Given a 3D point $\mathbf{M} = [X, Y, Z]^T$ and its image $\mathbf{m} = [x, y]^T$, the formula (Eq. 2) can be written in matrix form as

$$s\tilde{\mathbf{m}} = \mathbf{P}\tilde{\mathbf{M}}, \quad (3)$$

where $s = S$ is an arbitrary nonzero scalar.

For a real image point, S should not be 0. We now make an extension to include the case $S = 0$. If $S = 0$, then $Z = 0$, i.e., the 3D point is in the focal plane of the camera, and the image coordinates x and y are not defined. For all points in the focal plane but the optical center, their corresponding points in the image plane are at infinity. For the optical center C , we have $U = V = S = 0$ (i.e., $s = 0$) since $X = Y = Z = 0$.

Definition

The Phong reflectance model calculates the amount of reflected radiance at a surface point according to the lighting, viewing, and surface normal directions at that point. It is characterized by modeling specular reflection as an exponential function of a cosine function, which provides moderate accuracy in a simple formulation. It was introduced by Bui Tuong Phong in 1973 in his PhD thesis and later published in [1].

Background

When light arrives at surfaces, it can be reflected, refracted, scattered, or absorbed. Reflectance models are mathematical functions that describe the interactions between light and surfaces. Usually, they are functions of lighting, viewing, and surface normal directions. There are various

reflectance models at different levels of precision and complexity. Most reflectance models include components describing diffuse and specular reflection, respectively.

The Phong model is a reflectance model widely used for its simplicity and moderate accuracy. It represents reflected light as a linear combination of ambient, diffuse, and specular components. This model is characterized by its treatment of the specular component, which is designed based on the empirical observation that glossy surfaces have focused highlight that falls off quickly and matt surfaces have extended highlight that falls off slowly. Like many other reflectance models, this model can be applied to create computer graphic images or to infer scene properties such as shape and material from observed image intensities.

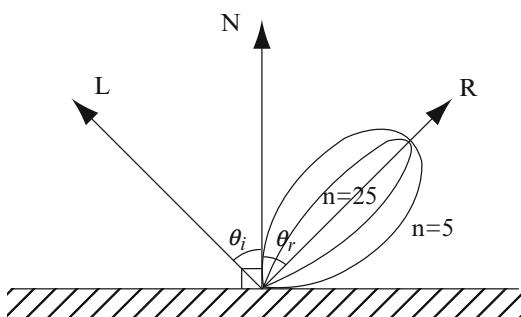

Phong Reflectance Model, Fig. 1 Directions involved in the definition of Phong model. N is the surface normal direction. L and V are the lighting and viewing direction, respectively. H is the bisector of L and V . R is L mirrored about N

Theory

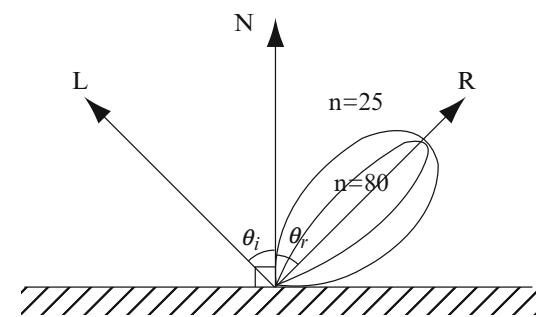

Light reflected by a surface can be roughly divided into specular and diffuse reflection. The specular reflection, or highlight, accounts for the light reflected directly at the surface without entering it. Specular reflection typically is concentrated within a small angle in space. In comparison, diffuse reflection accounts for the light that enters the surface and is distributed more uniformly in all reflected directions.

The observed intensity of specular reflection depends on the viewing direction. For example, an ideal reflector like a mirror reflects light toward a direction R that is the incident direction L reflected about the surface normal direction N . Hence, the reflectance is zero except when the viewing direction V is coincident with R . Here, R is within the same plane as L and N , and the angle between R and N is the same as that between L and N . Mathematically, R can be computed as $R = 2N(N \cdot L) - L$. All these directions are represented by unit vectors. The geometric relations of these unit vectors are shown in Fig. 1.

Most real surfaces are not ideal reflectors. The Phong model can be used to describe their specular reflection. According to this model, the specular reflection is centered at the direction R and falls off as an exponential function of cosine of the angle between R and V . In other words, the specular reflection is proportional to $(V \cdot R)^n$. The parameter $n > 0$ is known as shininess, which determines the spread of the specular reflection. It

Phong Reflectance Model, Fig. 2 Left: the specular reflection of Phong model. Right: the specular reflection of Blinn-Phong model

is larger for glossy surfaces and smaller for matt surfaces. Specular reflections with different shininess are illustrated on the left of Fig. 2. When $n = \infty$, it represents reflection of ideal reflectors. It should be noticed that Phong model is designed based on empirical observations rather than physics. There are other physically based reflectance models for specular reflection such as Cook-Torrance model [2], Ward's model [3], and Ashikhmin's model [4] that are more complicated and accurate than the Phong model.

The complete Phong reflectance model represents reflected light as a linear combination of ambient, diffuse, and specular components. The ambient component is a small constant accounting for weak scattered light in the scene. The diffuse component is represented by Lambert's model. Hence, the reflected radiance is computed as

$$\begin{aligned} I = & k_a I_a + k_d I_d \max(N \cdot L, 0) \\ & + k_s I_s (\max(V \cdot R, 0))^n. \end{aligned} \quad (1)$$

Here, I_a , I_d , and I_s are parameters to indicate the illumination power for the ambient, diffuse, and specular components. k_a , k_d , and k_s are scalars that determine the relative strength of these three components. In color images, these parameters are vectors with different values at different wavelengths.

Variations There is a well-known variation of the Phong model, the Blinn-Phong model, which is proposed by Jim Blinn [5]. In the Blinn-Phong model, the term $V \cdot R$ is replaced by $N \cdot H$. Hence, the reflected radiance is

$$\begin{aligned} I = & k_a I_a + k_d I_d \max(N \cdot L, 0) \\ & + k_s I_s (\max(N \cdot H, 0))^{n'}, \end{aligned} \quad (2)$$

where $H = \frac{L+V}{\|L+V\|}$ is the bisector of L and V , which is often called “halfway vector.” When V is in the same plane as N and L , the angle between N and H is half of that between V and R . Hence, it is a close approximation to the original Phong model. This model is illustrated on the right of Fig. 2. The Blinn-Phong model is originally

proposed to speed up the computation of the Phong model. It is the default shading model in OpenGL [6] for its efficiency. According to an experimental evaluation [7] with measured reflectance data from real surfaces, the Blinn-Phong model can represent real data more accurately than the original Phong model.

Application

The Phong reflectance model computes reflected radiance according to the 3D shape, viewing, and lighting configurations. Like many other reflectance models, it is widely used to create computer graphic images. It also provides an analytical tool for radiometric image analysis to understand scene properties such as shape and material from measured image intensities.

Photometric consistency function

Related Concepts

- ▶ Camera Calibration
- ▶ Multi-baseline Stereo

Definition

Photo-consistency is a scalar function that measures the visual compatibility of a 3D reconstruction with a set of calibrated images.

Background

Automated 3D reconstruction from images has been a core computer vision problem for years. Multi-view stereo (MVS) is a process of reconstructing 3D structure of an object or a scene from multiple images [1]. MVS assumes calibrated photographs, where camera calibration is often achieved by a calibration chart (e.g., checkerboard patterns) or a Structure from Motion algorithm [2].

In principle, how MVS algorithms recover 3D information is the same as how humans perceive depths with their two eyes, that is, triangulation from correspondences. Therefore, the critical first step of MVS is to establish feature correspondences across multiple input images, where a robust mechanism is necessary to evaluate the goodness of such feature correspondences, which

is the role of a photo-consistency function. In a sense, an MVS reconstruction process is to carve out a 2D surface in a 3D space, where photo-consistency scores are high.

Theory and Examples

Photo-consistency $f(p, V)$ is a scalar function, which measures the visual compatibility of a given 3D reconstruction p with a set of images V . Typically, p is a 3D point ($p \in \mathbb{R}^3$), while more sophisticated methods use an oriented point (a 3D point with a surface normal) [3, 4] or a bounded surface region such as a triangle in a polygonal mesh model [5, 6]. For the moment, the visibility information V is assumed to be given for p , where details about visibility estimation are referred to a later section.

A simple photo-consistency function at a 3D point p is defined as follows: p is projected into each visible image in V , and the similarity of image textures near their projections is computed as photo-consistency. Instead of comparing a single pixel color in each image, a set of pixel colors in each local image region is compared for robustness. More concretely, let A_{uv}^i be the $\tau \times \tau$ rectangular grid of pixel intensities centered at the image projection of p in image $I_i \in V$ (see Fig. 1). Note that u and v are indexes of the rectangular grid, and $\tau = 5, 7$ is typically used. Photo-consistency $f(p, V)$ can be defined as

$$f(p, V) = \sum_{I_i, I_j \in V} \sum_{u, v} \left(A_{uv}^i - A_{uv}^j \right)^2, \quad (1)$$

which evaluates a sum of squared differences (SSD) of intensities for every pair of images. SSD score is often used for binocular stereo problems, where a pair of images have a narrow baseline and are acquired under the same or similar lighting conditions. The main reasoning is that the SSD score is sensitive to illumination changes and non-Lambertian effects, which is often the case of MVS problems. Instead of SSD, many MVS algorithms employ the Normalized Cross Correlation measure, which has shown to be more robust:

$$f(p, V) = \sum_{I_i, I_j \in V} \frac{\sum_{u,v} (A_{uv}^i - \bar{A}_{uv}^i) (A_{uv}^j - \bar{A}_{uv}^j)}{\sqrt{\left(\sum_{u,v} (A_{uv}^i - \bar{A}_{uv}^i)^2\right) \left(\sum_{u,v} (A_{uv}^j - \bar{A}_{uv}^j)^2\right)}}. \quad (2)$$

\bar{A}_{uv}^i is the average intensity of $\{A_{uv}^i\}$. Another advantage of the NCC score is that the value is guaranteed to be in a range $[-1.0, 1.0]$, where 0.6 or 0.7 is usually a good photo-consistency score,

$$f(p, V) = \sum_{I_i, I_j \in V} \frac{\sum_{u,v} (A_{uv}^i - \bar{A}_{uv}^i)^T \cdot (A_{uv}^j - \bar{A}_{uv}^j)}{\sqrt{\left(\sum_{u,v} |A_{uv}^i - \bar{A}_{uv}^i|^2\right) \left(\sum_{u,v} |A_{uv}^j - \bar{A}_{uv}^j|^2\right)}},$$

where the average intensity \bar{A}_{uv}^i is computed for each color channel independently.

This photo-consistency function works well for a simple scene, where images in V have similar resolutions, distances to the point p , and rotational parameters. For more complicated scenes, more appropriate evaluation is necessary, which is to first sample a rectangular grid of 3D points $\{p_{ij}\}$ around p in the 3D space, project all the points into each image, and sample pixel colors at their projections (see Fig. 2). Typically, 3D points are sampled on a plane that is front parallel to one of the images in V (I_i in Fig. 2), so that image distances between the adjacent projected points are roughly one pixel. Sampled pixel colors are used in exactly the same way as before (Eq. 1)–(3) to compute photo-consistency scores. Figure 2 illustrates that this photo-consistency function takes into account camera rotation (I_2) and resolution (I_3) differences to sample colors at the correct pixel locations.

Advanced Photo-Consistency Functions

For robustness, photo-consistency functions often measure the similarity of image textures over a local region instead of at a single point. In this sense, a natural input to the function should be a 3D point plus some spatial support. One example is an oriented point, which is a combination of a 3D location (\mathbb{R}^3) and a surface normal (\mathbb{S}^2), which essentially uses a tangent plane approxi-

mation of a surface to sample 3D points [3, 4]. Pons and Vu et al. initialize their reconstruction as a polygonal mesh model, and in the process of iterative mesh deformation, photo-consistency is evaluated on the polygonal mesh model directly [5, 6].

Visibility Estimation

Photo-consistency requires visibility information V as an input. However, it is not easy to obtain good visibility without a 3D model, simply because occlusion information is unknown. Similarly, without visibility, it becomes difficult to obtain accurate 3D reconstructions – chicken-and-egg problem. Furthermore, visibility should reflect certain photometric factors such as specular highlights – images with specular highlights should be excluded from V . Fortunately, researchers found out that accurate visibility is not necessary to obtain a successful 3D reconstruction. Instead, a “robust” photo-consistency function can be used to ignore outlier images in V , while overestimating V . There are several approaches in robustifying photo-consistency functions. One approach is to ignore images whose photo-consistency function scores are worse than a predetermined threshold, which is simple but has proven to work well [3]. Vogiatzis and Hernández et al. proposed more sophisticated approach that handles outliers systematically, which boosted their reconstruction accuracy [7].

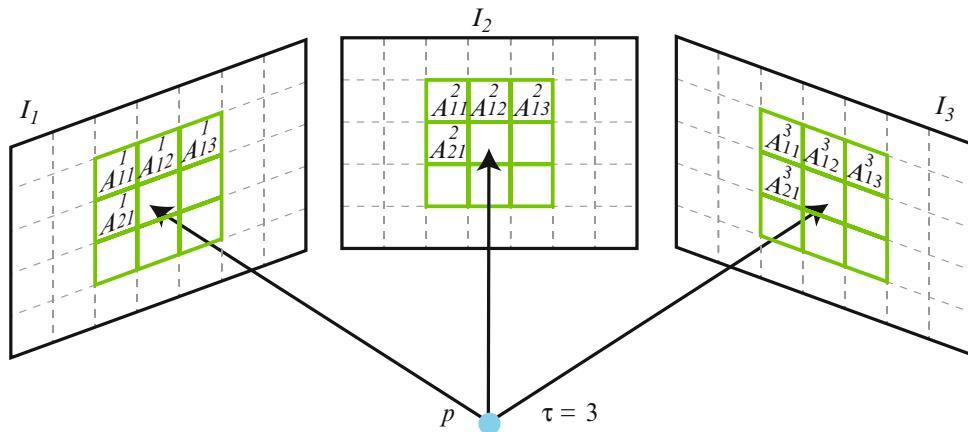

Photo-Consistency, Fig. 1 A simple photo-consistency evaluation starts by projecting a 3D point p into each visible image and collecting pixel colors $\{A_{uv}^i\}$ in each local image region

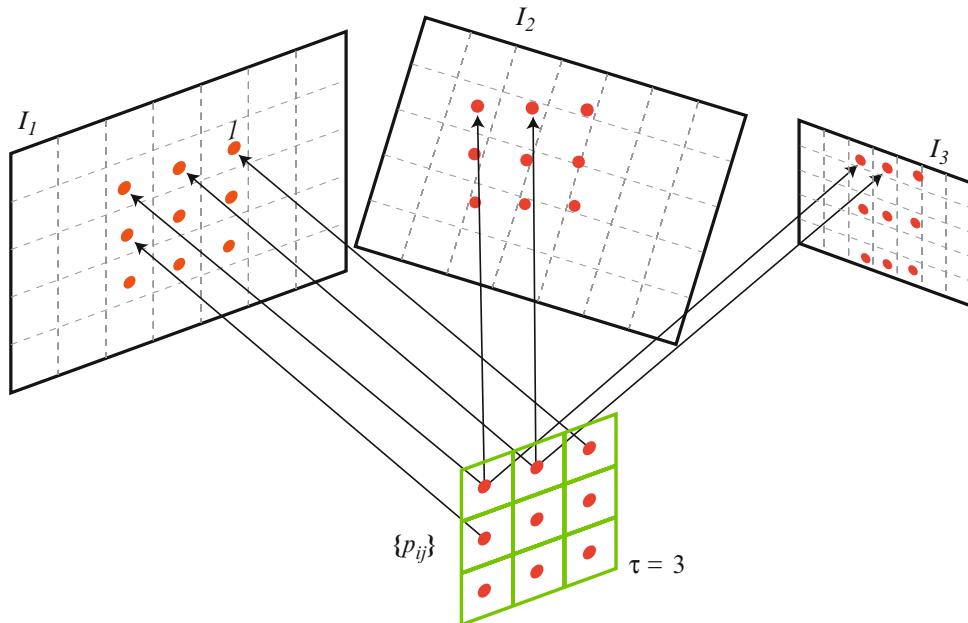

Photo-Consistency, Fig. 2 More appropriate and accurate photo-consistency evaluation is to sample points in 3D, then project them into each image, which handles differences in camera rotations (I_2) and resolutions (I_3) properly

Photogrammetry

Konrad Schindler¹ and Wolfgang Förstner²

¹ETH Zürich, Zürich, Switzerland

²Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany

Definition

Photogrammetry is the science and technology of obtaining information about the physical environment from images, with a focus on applications in surveying, mapping, and high-precision metrology. The aim of photogrammetry is to provide automated or semiautomated procedures for these engineering tasks, with emphasis on a specified accuracy, reliability, and completeness of the information.

Background

Photogrammetry is a long-established engineering discipline, which dates back to the middle of the nineteenth century, shortly after the invention of the photographic process. It has its roots in surveying, predominantly for aerial mapping of the earth's surface, although terrestrial “close-range” photogrammetry has always been an integral part of the discipline. Traditionally photogrammetry has emphasized 3D *geometric* modeling of the environment, since in an interactive setting this implicitly encompassed the semantic interpreta-

tion of the image content. The use of geospatial imagery with the primary purpose to infer semantic object properties from radiometric intensities is often referred to as “remote sensing.” Today these two fields overlap in terms both of methodology and of applications.

Methods

The goal of photogrammetry is to extract geometric and semantic information from imagery.

In terms of *geometric* processing methods, the photogrammetric measurement process is essentially an application of structure-from-motion theory [1], mostly (but not exclusively) with calibrated camera intrinsics. In fact a large part of the theory of camera calibration and camera orientation was first developed and applied in photogrammetry, including camera orientation from 2D-to-3D correspondences [2, 3], relative camera orientation from 2D-to-2D correspondences [4], and bundle adjustment [5].

The methods for *semantic* interpretation comprise the entire armamentarium of image understanding, from early rule-based systems [6] through model-based object recognition [7] to statistical learning with modern Bayesian techniques [8]. For an overview on classical techniques, see [9].

Deep learning is used for geometric and interpretation tasks with remote sensing data for land cover classification [10, 11], with aerial images [12] for building extraction or with laser data [13–15] for interpreting terrestrial environments.

Due to the complexity of the task, only semi-automatic methods have so far found their way into commercial software and operational production pipelines.

Relation to Computer Vision

Since the advent of digital images in the 1970s, a main goal has been to automate the photogrammetric process, and photogrammetrists have developed or adopted pattern recognition methods for tasks such as interest point extraction [16], feature matching and dense stereo reconstruction [17, 18], semantic

segmentation [19], and object category detection [20]. Thus, the science of photogrammetry is increasingly converging with computer vision and image understanding. Still photogrammetry, being a practical engineering discipline, tends to put greater emphasis on a defined (usually high) accuracy, reliability, and completeness than on total automation.

Recent Developments in Sensor Technology

Since the 1990s, range images captured directly with airborne and terrestrial laser scanners have gained popularity with both practitioners and researchers in geo-information and have become a second main data source of photogrammetry [21].

Hand in hand with that development, it has become a standard routine to determine approximate or even final sensor orientations directly, rather than indirectly from observed points. The practice of observing the position and attitude of the camera during flight missions directly with a highly accurate GNSS (global navigation satellite system) receiver and IMU (inertial measurement unit) is known as *direct georeferencing*.

With the advent of high-resolution satellite sensors, spaceborne images from both optical and microwave sensors nowadays also serve as input data for the photogrammetric process. Mobile mapping systems mounted on vehicles have led to a growing interest in large-scale photogrammetric mapping from the ground.

Classical photogrammetric textbooks are [22], [23], and most recently [24].

Application

The most important application field of photogrammetry is topographic mapping of the earth's surface at different scales. The overwhelming majority of all existing maps have been created through photogrammetric processing of airborne or spaceborne imagery. However, photogrammetry is also prominent for

small-scale mapping down to single villages, mines, etc. A related endeavor has been the mapping of other planets in the solar system from images taken by spacecraft.

Non-topographic applications for a long time occupied only a small fraction of the market. They used to be subsumed under the term "close-range photogrammetry," the main application fields being industrial metrology (e.g., aircraft, ships, vehicle parts), construction, cultural heritage documentation, forensics, and the medical domain.

Although mapping remains the dominant application area, the boundary between photogrammetry and 3D computer vision is dissolving more and more. Today tasks like visual driver assistance and robot navigation, motion capture, virtual and augmented reality, object tracking, etc. are by many also considered applications of photogrammetry.

Technology transfer between academia and industry has always been well established in photogrammetry, via the International Society for Photogrammetry and Remote Sensing (ISPRS, <http://www.isprs.org>) and the long-running biennial Photogrammetric Week (<http://www.ifp.uni-stuttgart.de/publications/phowo.html>).

Photometric Consistency Function

► Photo-Consistency

Photometric Invariants

Todd Zickler

School of Engineering and Applied Science,
Harvard University, Cambridge, MA, USA

Definition

A photometric invariant is a function of an image, or a function of a set of images, that is discriminative with respect to some scene properties and independent of others.

Background

J. J. Gibson was the first to write extensively about computing useful “invariants” from visual observations. According to Gibson, an

invariant represents the extraction of persistent scene properties despite changing environmental conditions and therefore enables the concurrent awareness of both persistence and change within a scene. While he does not use the term “photometric invariant,” he describes the concept quite well [10]:

... the illumination can change in amount, in direction, and in spectral composition. Some features of any optic array in the medium will change accordingly. There must be invariants for perceiving surfaces, their relative layout, and their relative reflectances. They are not yet known, but they almost certainly involve ratios of intensity and color among parts of the array.

The notion of a photometric invariant is different from, but related to, the mathematical definition of an invariant. In mathematics, an invariant is a property that remains unchanged when certain transformations are applied, whereas a photometric invariant is a function of an image (or set of images) that persists despite changes in certain scene properties and conditions.

Photometric invariants are also related to, but distinct from, image decompositions based on the explicit separation of an image according to scene characteristics, such as shading and lightness [11], diffuse and specular reflectance [12], or illuminant and spectral reflectance [1]. Computing such explicit decompositions is ill-posed, whereas photometric invariants can be computed directly from image intensities, often in closed form. In fact, it is not uncommon for photometric invariants to be used as initialization for iterative image decomposition techniques.

Photometric invariants are used to discriminate among the scene properties of interest while eliminating dependence on other “distractors.” Insensitivity and discriminability are usually in conflict, and in general one cannot obtain one without sacrificing some of the other. For example, it can be shown that there is no photometric invariant computed from grayscale imagery that can exactly discriminate between surface shapes under variable lighting, because given any two images, one can always find a single surface to

explain them [2]. A high-performing invariant, therefore, is one that provides a *balance* between insensitivity and discriminability and does so in a way that is appropriate for the desired visual task and operating environment. For this reason, performance of photometric invariants should be conducted empirically, preferably using imagery that is representative of the end goal.

Theory

An early discovery of a photometric invariant was made by Koenderink and van Doorn [13], who considered matte (Lambertian) surfaces under directional lighting. Under these conditions, certain stationary points of image isophotes cling to parabolic surface points and therefore provide information about surface shape that does not depend on the locations of light sources.

Since then, the community has discovered a diverse collection of photometric invariants, usually written as simple functions of intensity and color at the image projection of one or more scene points. Each of these invariants is derived by assuming models for lighting, reflectance, and spectral sensors and by doing so in the context of an imaging model that expresses the measurements in the k th channel as

$$I_k(x, L) = \int_{\Lambda} \int_{S^2} c_k(\lambda) L(\lambda, \omega) f(x, \lambda, n, \omega, \omega') \max(0, \langle \omega, n \rangle) d\omega d\lambda. \quad (1)$$

Here, $\{c_k(\lambda)\}_{k=1\dots K}$ are the spectral responses of a camera with K channels; $f(x, \lambda, n, \omega, \omega')$ is the spatially varying, spectral bidirectional reflectance distribution function (BRDF) at the back projection of image point x evaluated with surface normal $n \in S^2$, light direction $\omega \in S^2$, and view direction $\omega' \in S^2$; and $L(\lambda, \omega)$ is the (spatially uniform) spectral radiance distribution that illuminates the scene.

The photometric invariants differ in their assumptions about the sensors $\{c_k(\lambda)\}$ as well as their assumptions regarding reflectance and lighting. In all cases, reflectance and lighting models are based on factored representations that separate the variation with respect to spatial position, wavelength, and angular geometry:

$$f(x, \lambda, \theta) = \sum_{n=1}^N m_n(x, \lambda) g_n(\theta), \quad (2)$$

with $\theta \triangleq \{n, \omega, \omega'\}$ defined to simplify notation and

$$L(\lambda, \omega) = \sum_{m=1}^M e_m(\lambda) \ell_m(\omega). \quad (3)$$

The assumptions that underlie each derivation provide some intuition for when each invariant might be usefully employed. These assumptions are categorized below; the resulting invariants are listed in Tables 1 and 2; and visualizations for some of them appear in Fig. 1. Note that empirical evaluations of many of these invariants reveal them to be useful when the underlying assumptions are only approximately satisfied.

Reflectance model. Common factored models are the Lambertian model ($N = 1$, $g_1(\theta) = \text{constant}$ in Eq. 2) and the dichromatic model with a neutral interface ($N = 2$, $g_1(\theta) = \text{constant}$, $m_2(x, \lambda) = m_2(x)$). Invariants for both of these cases are listed separated in Tables 1 and 2.

Lighting model. The most common instance of the factored lighting model has the same spectrum in every direction ($M = 1$ in Eq. 3), with the associated spectrum $e_1(\lambda)$ being either arbitrary, “even” ($e_1(\lambda) = \text{constant}$, so that $L(\lambda, \omega) = \ell(\omega)$), or Planckian and thus completely defined by its color temperature T : $e_1(\lambda; T)$.

Color or grayscale. Invariants can be computed from multiple spectral measurements (usually three), which are denoted by $\{I_k(x)\}_{k=1,2,3}$ in Tables 1 and 2. In some cases, they are computed from a single spectral measurement (a “grayscale” image), which is denoted by $I(x)$.

Sensor model. For invariants based on color, the three sensors $\{c_k(\lambda)\}_{k=1,2,3}$ may be arbitrary,

or they may be delta functions (*i.e.*, “narrow-band” sensors): $c_k(\lambda) = \delta(\lambda - \lambda_k)$. In between these two extremes are possibly overlapping sensors that nonetheless support spectral relighting by independent per-channel gain factors. Such sensors are said to support *von Kries adaptation*, and, as described in [3], they must satisfy a tensor rank constraint when integrated against all pairs of material spectral ($m_n(\cdot, \lambda)$) and lighting spectra ($e_m(\lambda)$) that could possibly exist in the operating environment.

Single point or multiple points. Invariants can be computed independently at each pixel, or they may be computed by combining measurements at distinct image points (denoted by $I(x_i)$ in the tables).

Single image or multiple images. Similarly, invariants can be computed from measurements in a single image or by combining measurements from multiple images captured under distinct lighting environments (denoted by $I(x, L_j)$ in the tables).

Application

Photometric invariants can be viewed as an alternative to learning-based approaches that attempt to model the appearance of persistent scene properties (shape, reflectance patterns, *etc.*) over all configurations of lighting, viewpoint, and other distractors. Instead of modeling this appearance variation, they “hard-code” an invariance, perhaps at the expense of discriminability. When applicable, the main advantages of invariant-based approaches are their computational efficiency and reduced requirement for training data. Whether a learning-based approach or an invariant-based approach (or a combination of the two) is more desirable depends on the visual task and the operating environment.

Multiple-point photometric invariants that are independent of geometry θ and light intensity $\ell(\omega)$ isolate surface reflectance information, and since they do not depend on light and viewing conditions, they may improve performance on object recognition and image indexing tasks [7, 15]. In some cases, performance may be further

Photometric Invariants, Fig. 1 Visualization of photometric invariants (*bottom row*) computed from one or two input images (*top row*). From left to right that based on

normalized RGB, Planckian lighting [5], ratio of determinants [14], and color subspaces [18]

improved by using an invariant that is also independent of illuminant spectrum [9].

Invariants that are computed at a single point and are independent of geometry can also improve material-based segmentation and boundary detection by reducing the occurrence of false boundaries due to shading and specular highlights. In some cases, this can be achieved from a single image [8, 18], and additional images can be used to handle more complex BRDFs [14].

The Planckian invariant [5] has the unique property of being independent of illuminant spectrum while also being computed at a single point. For this reason, it can be used for detecting and removing shadows in images that contain mixtures of distinct illuminant spectra [6].

Photometric invariants that are computed at a single point and are independent of material properties can be used to extract surface shape information. For diffuse surfaces, photometric ratios [17] can provide access to surface curvature information independent of surface albedo, and for surfaces described by the dichromatic model, color subspaces [18] can isolate the diffuse component and therefore improve the performance of shape-from-shading, photometric stereo, and a variety of other Lambertian-based vision algorithms.

Finally, as mentioned above, photometric invariants may be used as initialization for explicit image decompositions. The color subspace invariant [18] (and one closely related to it [16]) can be useful when decomposing an image into its diffuse and specular components, and the reflectance ratio [7, 15] is closely related to retinex-like algorithms for decomposing an image into shading and lightness [11].

Definition

Photometric stereo is the problem of recovering the three-dimensional shape of a stationary scene

given a collection of images of the scene taken under variable lighting conditions.

Background

The amount of light reflected by an object is a function of the incoming light, the shape of the object, and its material properties. As a function of shape, the light reflected by each surface point depends on the inclination of the surface (the surface normal) at that point relative to the light sources. Early work in photometric stereo [1] assumes that the lighting conditions are given and that the material properties of the object are known. A collection of images of an object taken under varying lighting conditions (with both the object and camera stationary) can then be used to compute the normals to the surface of the object and subsequently its three-dimensional shape. More recent photometric stereo methods can additionally recover the lighting conditions and material properties as part of the process.

Photometric stereo (PS) can be contrasted with shape from shading (SFS), the problem of recovering the shape of an object from a *single* image [2]. The problem of SFS is generally ill posed, and its solution typically requires complete knowledge of lighting and material properties. In addition, SFS is often cast as a partial differential equation (PDE), and so its solution relies on boundary conditions. These boundary conditions generally require knowledge of the 3D coordinates of a subset of the points on the sought shape. In contrast, by using a collection of images, PS generally leads to more robust solutions; it can often be solved also in the absence of knowledge of lighting conditions or material properties requires no boundary conditions, and its solution is generally algebraic.

Theory

Let $I_1(x, y), I_2(x, y), \dots, I_k(x, y), (x, y) \in \Omega \subset \mathbb{R}^2$, be a collection of k images depicting a stationary scene pictured by a stationary camera.

Suppose further that each image I_i is taken under different lighting, which is denoted by L_i . The objective of photometric stereo is to recover the 3D shape of the scene, represented by $z(x, y)$, which depicts the depth value z at each point (x, y) .

In general terms, let $\hat{\mathbf{n}}(x, y) \in \mathbf{S}^2$ denote the normal to the surface at $(x, y, z(x, y))$ ($\|\hat{\mathbf{n}}(x, y)\| = 1$), and let $\rho(x, y)$ denote the reflectance properties of each scene point. The light reflected by a scene point $(x, y, z(x, y))$ is determined by the surface normal $\hat{\mathbf{n}}(x, y)$, the reflectance properties $\rho(x, y)$, and the lighting conditions L_i and can thus be expressed as a function $R(\hat{\mathbf{n}}, \rho, L_i)$. (Note that this expression does not model the effects of cast shadows and interreflections, as these effects depend more globally on the shape of the observed object.) Each image then provides a constraint on the surface normal of the form $I_i(x, y) = R(\hat{\mathbf{n}}, \rho, L_i)$. With sufficiently many images, these constraints can be used to recover the surface normal at each point, $\hat{\mathbf{n}}$, and, subsequently, the surface $z(x, y)$.

For a concrete example, due to the pioneering work of Woodham [1], consider a scene composed of a matte surface whose reflectance is described by the Lambertian model, and suppose that in each image, the scene is illuminated by a single directional source. Specifically, a *directional* source (also referred to as a *point source at infinity*) is expressed by a vector $\mathbf{l}_i \in \mathbb{R}^3$ in the direction of the source whose magnitude represents the light intensity. According to the Lambertian law, the light reflected by a point $(x, y, z(x, y))$ with normal $\hat{\mathbf{n}}(x, y)$ and albedo $\rho(x, y)$ (the *albedo* of a scene point is a material property representing the fraction of incident light that is reflected by the surface at that point), is given by the following:

$$I_i(x, y) = \rho(x, y) \mathbf{l}_i^T \hat{\mathbf{n}}(x, y) \quad (1)$$

where the superscript T denotes the transpose operator. This law is applicable as long as $\mathbf{l}_i^T \hat{\mathbf{n}}(x, y) \geq 0$; otherwise, the point is in shadow (commonly referred to as *attached shadow*). Note that for this equation, it is assumed that the

camera is calibrated so that the amount of light recorded by the camera is identical to the amount of light reflected by the surface.

Suppose now that k such images I_1, \dots, I_k are obtained, in which the scene is illuminated by directional light sources $\mathbf{l}_1, \dots, \mathbf{l}_k$, respectively. Let $\mathbf{I}_i \in \mathbb{R}^p$ be a vector arrangement of the pixel intensities in $I_i(x, y)$, $\mathbf{I}_i = (I_i(x_1, y_1), \dots, I_i(x_p, y_p))^T$, where p denotes the number of discrete pixels in Ω . Let $M = [\mathbf{I}_1, \dots, \mathbf{I}_k]^T$ be a $k \times p$ matrix whose rows include the intensity measurements in all images. Let $L = [\mathbf{l}_1, \dots, \mathbf{l}_k]^T$ be a $k \times 3$ matrix containing all k light sources. Finally, let $S = [\rho(x_1, y_1) \hat{\mathbf{n}}(x_1, y_1), \dots, \rho(x_p, y_p) \hat{\mathbf{n}}(x_p, y_p)]$ be a $3 \times p$ matrix whose columns contain the surface normals of the scene points scaled by the corresponding albedo (with the columns of M and S organized in correspondence). M is referred to as the measurement matrix, L as the lighting matrix, and S as the shape matrix. Then, the Lambertian law for all the input images can be summarized by the following matrix equation:

$$M = LS. \quad (2)$$

Assuming that all the lighting directions and intensities are known (so L is known) and that L includes three linearly independent rows, then S can be determined by solving the linear, possibly overdetermined equation system above. In particular, if $k = 3$ and L is invertible, then

$$S = L^{-1}M. \quad (3)$$

Once S is recovered, the surface normals of the scene can be recovered by normalizing each column of S , i.e., let \mathbf{s}^i denote the i 'th column of S and then

$$\hat{\mathbf{n}}(x_i, y_i) = \frac{\mathbf{s}^i}{\|\mathbf{s}^i\|} \quad (4)$$

$$\rho(x_i, y_i) = \|\mathbf{s}^i\|. \quad (5)$$

Note that the collection of surface normals of a differentiable shape uniquely determines the depth values of its bounding surface up to an additive constant.

Integrability

To further obtain an explicit recovery of the depth values $z(x, y)$, *integrability* (or *consistency*) of the recovered normals can be imposed. For integrability, the surface $z(x, y)$ is assumed to be differentiable, and the normals can be expressed in terms of its derivatives. Under these conditions, it can be readily shown that the normal at a point $(x, y, z(x, y))$ is given by the following:

$$\hat{\mathbf{n}}(x, y) = \frac{(z_x, z_y, -1)}{\sqrt{z_x^2 + z_y^2 + 1}} \quad (6)$$

where z_x and z_y represent the two partial derivatives of z , $z_x = \partial z / \partial x$ and $z_y = \partial z / \partial y$. An estimate of these partial derivatives can be obtained from the recovered shape matrix S using the ratios $z_x = -s_1/s_3$ and $z_y = -s_2/s_3$, where $s = (s_1, s_2, s_3)^T$ is the column of S corresponding to point (x, y) . Finally, a forward discretization of the partial derivatives is used to obtain the following first-order difference equations:

$$z(x+h, y) - z(x, y) = h z_x(x, y) \quad (7)$$

$$z(x, y+h) - z(x, y) = h z_y(x, y) \quad (8)$$

where h is the (known) mesh size (often $h = 1$). This is an overdetermined system of linear equations in $z(x, y)$ and can be solved to least squares up to an additive constant which can be determined, e.g., by setting $z(x_0, y_0) = 0$ for some point (x_0, y_0) .

Simultaneous Recovery of Shape and Light

The method above assumes that the intensity and direction of the light sources are known and uses this information to recover the shape and albedo of the object. However, these derivations can still be used even when the lighting conditions are unknown. The main observation is that in the absence of noise, the measurement matrix M has rank 3, and so it can be factored to recover the lighting and shape up to a certain ambiguity [3]. In addition, when $\text{rank}(M)$ exceeds 3, replacing it by its rank 3 approximation can eliminate at least some of the noise in the image.

To see that $\text{rank}(M)$ is (at most) 3, note that it is a product of the $k \times 3$ lighting matrix L with the $3 \times p$ shape matrix S (Eq. 2). Hence, M can be factored using singular value decomposition (SVD) as follows. Let \hat{M} be the best rank 3 approximation to M , i.e., $\hat{M} = \operatorname{argmin}_{\tilde{M}} \|\tilde{M} - M\|_F$, where $\|\cdot\|_F$ denotes the Frobenius norm of a matrix. \hat{M} can be readily computed using the SVD decomposition of M . Next, let $\hat{M} = U \Sigma V^T$ be the SVD decomposition of \hat{M} and define $\hat{L} = U \sqrt{\Sigma}$ and $\hat{S} = \sqrt{\Sigma} V^T$. Evidently, this decomposition is nonunique, as any 3×3 non-singular matrix A can be used to obtain another valid decomposition, i.e.,

$$\hat{M} = (\hat{L} A^{-1})(A \hat{S}). \quad (9)$$

Equation (9) therefore defines a nine-parameter ambiguity – the entries of A . This ambiguity can be reduced by imposing integrability [4], as is explained below.

To impose integrability, the following equation can be used:

$$z_{xy} = z_{yx} \quad (10)$$

which holds when z is twice differentiable, $z_{xy} = \partial^2 z / (\partial x \partial y)$, and $z_{yx} = \partial^2 z / (\partial y \partial x)$. Let A denote the ambiguity matrix, so that $S = A \hat{S}$. Then

$$z_x = -\frac{s_1}{s_3} = -\frac{\mathbf{a}_1^T \hat{\mathbf{s}}}{\mathbf{a}_3^T \hat{\mathbf{s}}} \quad (11)$$

$$z_y = -\frac{s_2}{s_3} = -\frac{\mathbf{a}_2^T \hat{\mathbf{s}}}{\mathbf{a}_3^T \hat{\mathbf{s}}}, \quad (12)$$

where $(s_1, s_2, s_3)^T$ is a column in the unknown shape matrix S , $\hat{\mathbf{s}}$ is the corresponding column in the recovered matrix \hat{S} , and \mathbf{a}_i^T denotes the i 'th rows of A ($1 \leq i \leq 3$). Plugging these into (10),

$$\frac{\partial}{\partial y} \left(\frac{\mathbf{a}_1^T \hat{\mathbf{s}}}{\mathbf{a}_3^T \hat{\mathbf{s}}} \right) = \frac{\partial}{\partial x} \left(\frac{\mathbf{a}_2^T \hat{\mathbf{s}}}{\mathbf{a}_3^T \hat{\mathbf{s}}} \right), \quad (13)$$

a linear equation in the components of $A^T A$ is obtained for every column in \tilde{S} :

$$\mathbf{a}_1^T \hat{s}_y \mathbf{a}_3^T \hat{s} - \mathbf{a}_1^T \hat{s} \mathbf{a}_3^T \hat{s}_y = \mathbf{a}_2^T \hat{s}_x \mathbf{a}_3^T \hat{s} - \mathbf{a}_2^T \hat{s} \mathbf{a}_3^T \hat{s}_x \quad (14)$$

with $\hat{s}_x = \partial \hat{s} / \partial x$ and $\hat{s}_y = \partial \hat{s} / \partial y$. This (generally overdetermined) system of equations determines A up to a *generalized bas-relief* (GBR) transformation [4], i.e., a depth estimate $\hat{z}(x, y)$ is obtained that is related to the original depth $z(x, y)$ by the following:

$$\hat{z}(x, y) = \alpha x + \beta y + \gamma z(x, y) \quad (15)$$

with arbitrary constants α , β , and γ .

Photometric Stereo with General Lighting

The derivations above assume that each of the input images is produced by illuminating the object by a single directional source. More recently, Basri et al. [5, 6] proposed an approach to extend this and to handle Lambertian objects illuminated by arbitrary combinations of directional and extended light sources. Their algorithm is based on the observation that the light reflected by Lambertian objects, as a function of the surface normal, is a low-pass filtered version of the surrounding ambient light [7–9]. This allows one to describe the images of Lambertian objects, with great accuracy, as linear combinations of a small set (typically four or nine) of basis images, which are determined by the low-order spherical harmonic functions of the surface normal. This linear representation can now be exploited to construct factorization algorithms to photometric stereo under general lighting. The experimental results below show an example of a reconstruction achieved with this approach.

Application

Three-dimensional reconstruction is one of the fundamental tasks of computer vision. Photometric stereo is a reliable method for reconstruction. It is however used mostly in "laboratory conditions" that are partly controlled. This is because

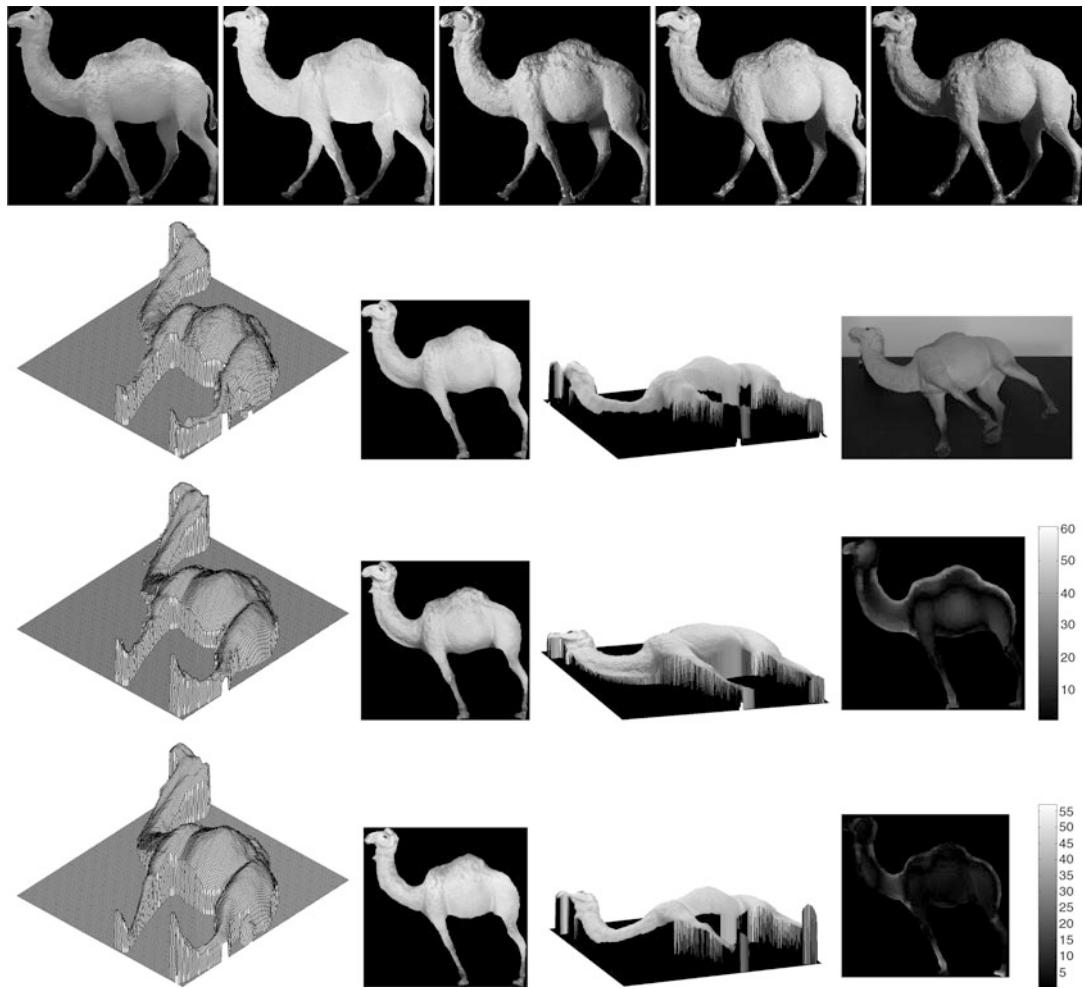

its required input should include a stationary scene under variable lighting conditions.

Open Problems

The majority of existing photometric stereo methods (see review in [10]) are designed to handle Lambertian objects. Initial work has been devoted to handling objects that exhibit specular reflectance, either simply by removing highlighted pixels [11] or by a detailed modeling of reflectance [12, 13]. Another challenge is to model the effects of cast shadows and inter-reflections (see, e.g., [14]). More recent work uses learning-based techniques to approach these problems, most often using deep learning architectures [15–18]. Finally, a challenging problem is to recover the 3D shapes of objects when the objects are moving with respect to a light source. Preliminary work in this subject can be found in [19–23].

Experimental Results

Figure 1 shows a photometric stereo reconstruction obtained with the algorithms proposed in [5, 6] and a comparison to a laser scan of the same object. In this experiment, 13 images of a camel-shaped doll were obtained under varying lighting conditions. The lighting setting was general and involved a number of sources along with reflections from surrounding objects. A factorization method was applied to recover both the lighting and the three-dimensional shape of the doll. Two results are shown. In the first case, reflectance was approximated by a first-order harmonic approximation. This approximation is analogous to assuming that the lighting setting includes a single directional source in addition to a uniform, ambient source. In the second case, reflectance was approximated by the more accurate, second-order harmonic approximation. The figure shows a subset of the input images and the laser-scanned reconstruction along with the shapes and albedos produced by the photometric stereo algorithms. It can be seen that both methods managed to recover the shape of the camel

Photometric Stereo, Fig. 1 Top row: five (of 13) images used for reconstruction. Second row: the shape of the camel obtained with a laser scanner (from left to right: surface, albedo, and albedo-painted surface) and an image taken from roughly the same view (right). Third row:

correctly (the results produced by the second-order method are slightly more accurate), as can be judged by comparing the reconstructions to the shape produced by the laser scanner.

Definition

Photon noise, also known as Poisson noise, is a basic form of uncertainty associated with the measurement of light, inherent to the quantized nature of light and the independence of photon detections. Its expected magnitude is signal dependent and constitutes the dominant source of image noise except in low-light conditions.

Background

Image sensors measure scene irradiance by counting the number of discrete *photons* incident on the sensor over a given time interval. In digital sensors, the photoelectric effect is used to convert photons into electrons, whereas film-based sensors rely on photosensitive chemical reactions. In both cases, the independence of random individual photon arrivals leads to *photon noise*, a signal-dependent form of uncertainty that is a property of the underlying signal itself.

In computer vision, a widespread approximation is to model image noise as signal *independent*, often using a zero-mean additive Gaussian. Though this simple model suffices for some applications, it is physically unrealistic. In real imaging systems, photon noise and other sensor-based sources of noise contribute in varying proportions at different signal levels, leading to noise which is dependent on scene brightness. Under-

standing photon noise and modeling it explicitly is especially important for low-level computer vision tasks treating noisy images [2, 8] and for the analysis of imaging systems that consider different exposure levels [1, 4, 10] or sensor gains [5].

Theory

Individual photon detections can be treated as independent events that follow a random temporal distribution. As a result, photon counting is a classic Poisson process, and the number of photons N measured by a given sensor element over a time interval t is described by the discrete probability distribution

$$\Pr(N = k) = \frac{e^{-\lambda t} (\lambda t)^k}{k!}, \quad (1)$$

where λ is the expected number of photons per unit time interval, which is proportional to the incident scene irradiance. This is a standard Poisson distribution with a rate parameter λt that corresponds to the expected incident photon count. The uncertainty described by this distribution is known as *photon noise*.

Because the incident photon count follows a Poisson distribution, it has the property that its variance is equal to its expectation, $E[N] = \text{Var}[N] = \lambda t$. This shows that photon noise is signal dependent and that its standard deviation grows with the square root of the signal.

In practice, photon noise is often modeled using a Gaussian distribution whose variance depends on the expected photon count [1, 2, 4, 5, 8, 10],

$$N \sim \mathcal{N}(\lambda t, \lambda t). \quad (2)$$

This approximation is typically very accurate. For small photon counts, photon noise is generally dominated by other signal-independent sources of noise, and for larger counts, the central limit theorem ensures that the Poisson distribution approaches a Gaussian.

Since photon noise is derived from the nature of the signal itself, it provides a lower bound on

the uncertainty of measuring light. Even under ideal imaging conditions, free from all other sensor-based sources of noise (e.g., read noise), any measurement would still be subject to photon noise. When photon noise is the only significant source of uncertainty, as commonly occurs in bright photon-rich environments, imaging is said to be *photon limited*.

In general, the only way to reduce the effect of photon noise is to capture more signal. The ratio of signal to photon noise grows with the square root of the number of photons captured, $\sqrt{\lambda t}$. This shows that photon noise, while growing in absolute terms with signal, is relatively weaker at higher signal levels. However, in order to capture more photons, longer exposure times are required, and the number of photons captured in a single shot is limited by the full well capacity of the sensor. Note that while squeezed coherence lasers and other forms of nonclassical light can achieve amplitude noise below the photon noise limit [11], such exotic lighting configurations are typically not relevant for computer vision applications.

In digital sensors, a related source of noise that also follows a Poisson distribution is dark current noise. Dark current refers to “phantom” photon counts due thermal energy causing the sensor to release electrons at random. While photon noise is a property of the signal itself, dark current comes from the embodiment of the sensor and depends on both temperature and exposure time.

P

Application

Photon noise is inherent to the measurement of light, has no parameters to be calibrated, and is independent of other noise sources. As a result, the effect of photon noise on imaging can be characterized using the *radiometric response function* that relates the photon count and the expected pixel intensity [3, 6].

To handle the signal dependence caused by photon noise, a first step is to estimate the noise variance for each pixel. This can be approximated in a straightforward way by inverting the forward model for imaging noise [5, 6, 9]. For increased accuracy, several other factors can be taken into

account as well: the coupling between signal and noise leads to a recursive estimation [3]; pixels near saturation have reduced variance which can lead to bias [2, 8]; and on-camera processing such as demosaicking may introduce spatial correlation [8].

Image processing methods that explicitly incorporate more realistic signal-dependent models of noise, either calibrated [3, 5, 6] or inferred from the image [7, 8], adapt naturally to pixels of different intensities. As a result, for a variety of computer vision tasks such as denoising [3, 8] and edge detection [7], these methods can perform better than those handicapped by the assumption of scene-independent noise.

An alternative approach for handling signal-dependent noise is to transform the image using a *variable-stabilizing transformation* that amounts to applying per pixel nonlinearities that effectively reduce the signal dependence [2, 9]. Because the transformed signal approximates one with signal-independent noise, it may be processed using methods that assume a simpler noise model.

Definition

The pinhole camera model is the basic camera model used in computer vision. Its name originates from the concept of pinhole camera and it models perspective projections.

Background

The pinhole model is the basic camera model used in computer vision. Its name stems from the concept of pinhole camera [1] (also related to the *camera obscura* [2]): usually, a closed box into which a single tiny hole is made with a pin, through which light may enter and hit a photosensitive surface inside the box (cf. Fig. 1). Pinhole cameras allow to take photographs of objects, which usually requires long exposure times due to the small aperture. The principles behind pinhole cameras and the *camera obscura* have been known, at least partially, since the fourth century BC [2].

The pinhole camera model mimics the geometrical projection carried out by a pinhole camera, as follows (see also Fig. 1). The entire optics and aperture of a camera are reduced to a single point – the *optical* or *center of projection*. The photosensitive surface is assumed to be planar and is, geometrically, represented by the so-called

image plane. To determine where a 3D point is depicted in the image, it suffices to construct a straight line from that point and going through the optical center (one may consider this as a light ray). This line's intersection with the image plane gives the desired image point of the 3D point. A key property of this model is that points that are collinear in 3D get imaged to image points that are also collinear.

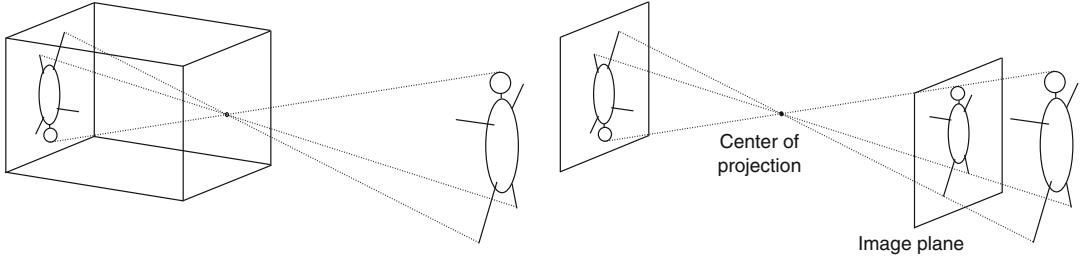

The pinhole model is simple and neglects many aspects of true cameras. For instance, apertures are finite and thus most 3D points are not imaged in a unique image point but within a finite area of the image plane. Likewise, pixels in digital cameras gather incoming light across finite areas. Thus, the pinhole model does not tell anything about blur, point spread functions, quantization, or other effects such as vignetting that occur in true cameras.

Other effects that are not modeled by it are radial or other geometric distortions, which usually occur with small focal lengths and that violate the above property of mapping collinear points in 3D to collinear points in the image. To handle such distortions, the pinhole model may be extended by adding models for radial distortion for instance, or by using different models altogether, such as becomes necessary for fisheye cameras. Despite the above limitations, the pinhole model is already a good approximation for many regular cameras.

P

Theory

Above, the geometrical projection mapping described by the pinhole model is described. Before translating this into an algebraic formulation, a few notations are introduced. The *focal length* f is the distance between the center of projection and the image plane. The line passing through the optical center and that is orthogonal to the image plane is called *optical axis*. The intersection point of the optical axis and the image plane is the *principal point*. These definitions are only based on the optical center and the image plane. When considering digital cameras, one in addition needs to take into

Pinhole Camera Model, Fig. 1 *Left:* sketch of a pinhole camera. *Right:* the two basic constituents of the pinhole camera model are the center of projection and the image plane. The true image plane shows inverse images of objects. To ease drawings, a common convention is to

replace the true image plane by a virtual one between the center of projection and the scene, at the same distance from the center as the original image plane and parallel to it. This image plane produces an identical image, but that is “correctly” oriented

account the layout of pixels in the image plane. The usual layout consists of a regular rectangular grid (although other arrangements, such as log-polar ones, were also experimented with [3, 4]): pixels are arranged into rows and columns. Let k_u and k_v be the column-wise and row-wise density of pixels, respectively (e.g., measured as number of pixels per millimeter). The value of k_u/k_v is also called the *aspect ratio* of a camera. Usually, the two densities are equal to one another, that is, cameras have a unit aspect ratio, but especially with video cameras, this should not be taken for granted.

The following coordinate systems are used to derive algebraic expressions for the pinhole model (Fig. 2). The *camera coordinate system* has its origin in the optical center. A usual convention is to define the Z -axis as being coincident with the camera’s optical axis and the X/Y -axes to be parallel to the columns and rows of pixels in the image plane. The *image coordinate system* has its origin in the principal point. The x -axis and y -axis are parallel to the X -axis and Y -axis, respectively, of the camera coordinate system. Typically, the camera and image coordinate systems use metric units. To represent the final digital image, one defines the *pixel coordinate system*. Its origin usually lies in one of the image area’s corners. Let its coordinates, relative to the image coordinate system, be $(-x_0, -y_0)$. The two axes, u and v , are parallel to x and y , respectively; their unit is (number of) pixels, counted row-wise and column-wise, respectively.

Note that the above choices of coordinate systems are not unique; other choices are possible, for example, for the X and Y axes and the origin of the pixel coordinate system, although care should be taken to use right-handed systems. The following equations will have to be adapted accordingly.

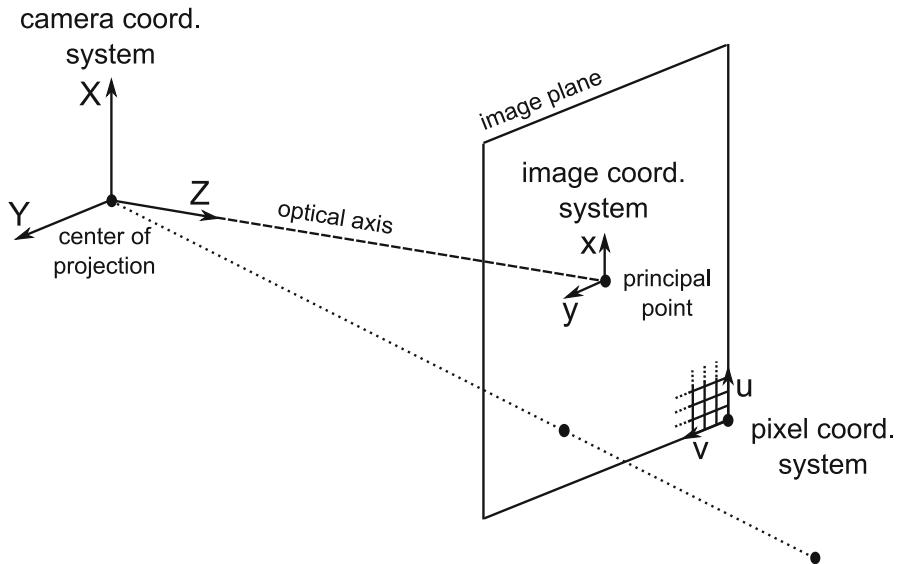

With the above definitions, the projection carried out by the pinhole camera model can be formulated as follows. Let (X, Y, Z) be the coordinates of a 3D point, expressed in the camera coordinate system. From the comparison of similar triangles, one obtains the image point’s coordinates in the image coordinate system as:

$$x = f \frac{X}{Z} \quad y = f \frac{Y}{Z}.$$

The coordinates in the pixel coordinate system are obtained by applying a translation corresponding to the shift of origin and scalings corresponding to the conversion from metric coordinates to pixel ones:

$$\begin{aligned} u &= k_u (x + x_0) = k_u f \frac{X}{Z} + k_u x_0 \\ v &= k_v (y + y_0) = k_v f \frac{Y}{Z} + k_v y_0. \end{aligned}$$

It is often useful to express these projection equations using homogeneous coordinates for the 3D and image points:

Pinhole Camera Model, Fig. 2 The components of the pinhole camera model. The distance between the center of projection and the image plane is the focal length f

$$\begin{pmatrix} x \\ y \\ 1 \end{pmatrix} \sim \begin{pmatrix} k_u f & 0 & k_u x_0 & 0 \\ 0 & k_v f & k_v y_0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix}, \quad (1)$$

where \sim signifies equality up to scale of vectors or matrices.

It is common to replace the above “metric” entities f , k_u , k_v , x_0 , and y_0 by equivalent ones given in pixel units:

$$\alpha_u = k_u f \quad \alpha_v = k_v f \quad u_0 = k_u x_0 \quad v_0 = k_v y_0.$$

Here, α_u and α_v measure the focal length in number of pixels (column-wise and row-wise, respectively) and (u_0, v_0) are the coordinates of the principal point given in the pixel coordinate system. These four entities are also called the *intrinsic parameters* of the pinhole camera model, since they describe what happens “inside” a camera. They are often grouped together in an upper triangular so-called *calibration matrix*:

$$K = \begin{pmatrix} \alpha_u & 0 & u_0 \\ 0 & \alpha_v & v_0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (2)$$

Sometimes, a fifth intrinsic parameter is added to the model – a so-called skew parameter that replaces the zero in the first row of the calibration matrix and which allows to model pixel layouts with skewed axes or cameras with desynchronized pixel readout. With modern digital cameras, these issues can usually be neglected though.

In order to model cameras in motion or multi-camera systems, one needs to describe the position and orientation of a camera. To do so, a final coordinate system, the *world coordinate system*, is considered. This may be attached to a physical object, for instance, an object to be inspected; otherwise, it can be assumed arbitrarily, as long as it remains fixed throughout an application. Let \mathbf{t} be the coordinates of the center of projection in the world coordinate system and let the rotation matrix R represent the camera’s orientation. Then, a 3D point is mapped from the world to the camera coordinate system, as:

$$\begin{pmatrix} X \\ Y \\ Z \\ 1 \end{pmatrix} = \begin{pmatrix} R & -R\mathbf{t} \\ \mathbf{0}^T & 1 \end{pmatrix} \begin{pmatrix} X^w \\ Y^w \\ Z^w \\ 1 \end{pmatrix}, \quad (3)$$

where as above, homogeneous coordinates are used.

Putting together (Eq. 1) and (Eq. 3), we get the complete expression of the pinhole camera model:

$$\begin{pmatrix} x \\ y \\ 1 \end{pmatrix} \sim \begin{pmatrix} k_u f & 0 & k_u x_0 & 0 \\ 0 & k_v f & k_v y_0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} R & -Rt \\ 0^T & 1 \end{pmatrix} \begin{pmatrix} X^w \\ Y^w \\ Z^w \\ 1 \end{pmatrix}.$$

With the above definitions of intrinsic parameters and calibration matrix (Eq. 2), this can be written more compactly as:

$$\begin{pmatrix} x \\ y \\ 1 \end{pmatrix} \sim \underbrace{KR(Id_3 - t)}_P \begin{pmatrix} X^w \\ Y^w \\ Z^w \\ 1 \end{pmatrix},$$

where Id_3 is the 3×3 identity matrix. The 3×4 matrix P is called *projection matrix* or *camera matrix*.

The projection expressed by the pinhole model is a perspective projection. Even simpler camera models exist in the form of orthographic or other affine projections.

Application

The pinhole camera model, like any other camera model [5], can be used to infer geometrical information about an imaged scene, from one or more images. Some of the most common applications are sketched below. It is usually assumed that a camera is calibrated prior to an application, that is, that its intrinsic parameters are known through a *camera calibration* procedure. Most camera calibration procedures utilize a reference object of known shape, a calibration grid. However, there also exist approaches for *self-calibration* (or autocalibration or on-line calibration) that allow to compute the intrinsic parameters directly from images of an unknown scene.

Pose estimation refers to the computation of an object's position and orientation relative to a camera, or vice-versa. Here, it is usually assumed

that the object's shape is known and the camera calibrated. *Motion estimation* is the determination of the camera's motion between two or more acquisitions; this is possible even if the scene is unknown, that is, if it does not contain any reference object of known shape or type. Motion estimation usually requires some amount of image matching, that is, the determination of projections of the same scene feature in different images. *3D modeling* is usually done from two or more images of a rigid scene and also usually requires image matching, although exceptions exist, such as shape-from-shading, photometric stereo, and interactive single-view 3D modeling.

Note that none of these applications is specific to the pinhole model, although the theory underlying them has most extensively been studied for this model, as parts of perspective multi-view geometry [6]. It is also reminded, as said above, that the pinhole model neglects many aspects of image formation and does not model non-perspective image distortions. A camera model, be it the pinhole or another one, should only be used in an application if it is sure that it is appropriate for the camera used.

Planckian Locus

Rajeev Ramanath¹ and Mark S. Drew²

¹San Jose, CA, USA

²School of Computing Science, Simon Fraser University, Vancouver, BC, Canada

Synonyms

Blackbody radiator; Thermal radiator

Definition

The Planckian locus as it relates to color is the locus of points in a color space that would be followed by an incandescent blackbody radiator as its temperature changes. This locus is typically described in the CIE x , y or CIE u' , v' chromaticity spaces.

Background

The CIEXYZ color space is defined by

$$\begin{aligned} X &= k \int_{\lambda} \bar{x}(\lambda) i(\lambda) r(\lambda) d\lambda \\ Y &= k \int_{\lambda} \bar{y}(\lambda) i(\lambda) r(\lambda) d\lambda \\ Z &= k \int_{\lambda} \bar{z}(\lambda) i(\lambda) r(\lambda) d\lambda, \end{aligned} \quad (1)$$

where k denotes a normalization factor that is set to 683 lumens/Watt in the case of absolute colorimetry and to $100 / \int_{\lambda} \bar{y}(\lambda) i(\lambda) d\lambda$ for relative colorimetry and $i(\lambda)$ denotes the spectrum of an illuminant. The functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$ are the CIE color-matching functions.

In the case of relative colorimetry, this means that a value of $Y = 100$ denotes the brightest color – the illuminant reflecting from a perfect reflecting diffuser [1, 3].

Planck's radiation law describes the spectral distribution of radiant excitation M_e as a function of wavelength λ and temperature T and is given

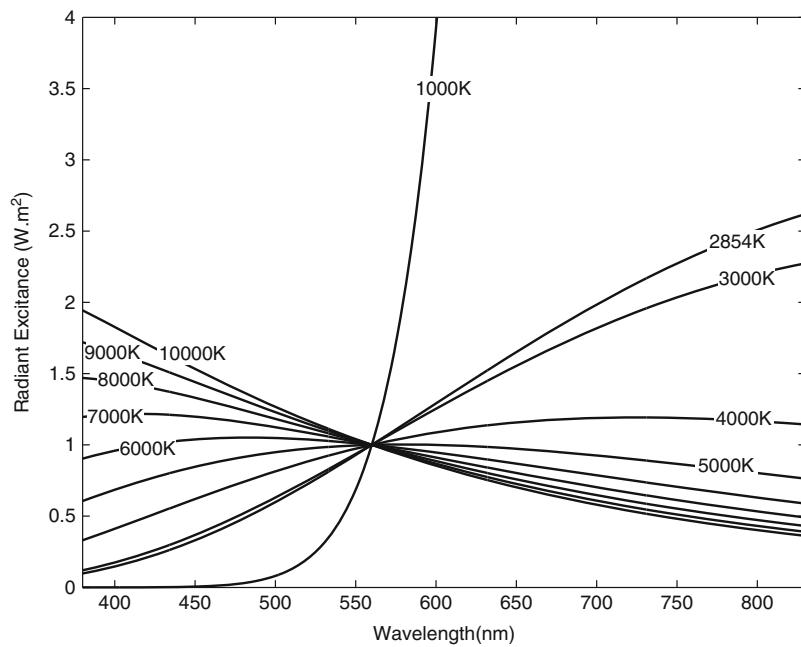

by Planck's Law:

$$M_e(\lambda, T) = \frac{c_1}{\lambda^5 \left[\exp\left(\frac{c_2}{\lambda T}\right) - 1 \right]} \quad (2)$$

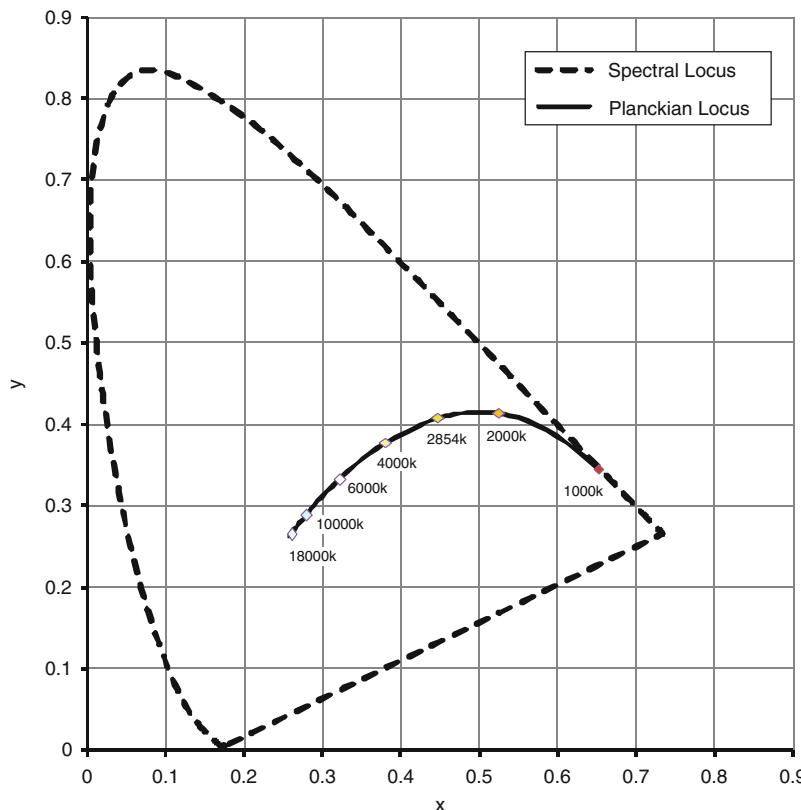

where $c_1 = 2\pi hc^2 = 3.74183 \times 10^{-16} \text{ W.m}^{-2}$, $c_2 = h.c/k = 1.4388 \times 10^{-2} \text{ m.K}$ (c is the speed of light in vacuum, h is Planck's constant, k is Boltzmann's constant), and the excitance is defined in units of W.m^{-3} .

Radiation emitted from blackbody radiators is defined by Planck's Law and is among the few radiations from sources that has its relative spectral power distribution match those of illuminants. In other words, blackbody radiators are the select few sources of illumination that match standard illuminant spectral power distributions – this may be seen as valid in the case of the equivalence of standard illuminant "A" and a blackbody with a temperature 2,856 K. Radiation from these radiators is typically seen as "white" to human observers. This makes it important to plot a locus of these points in a space such as CIEXYZ, or shown in a simpler view such as the two-dimensional space of the CIE x , y chromaticity diagram. The locus of points followed by illuminants defined by Planck's Law is called the Planckian locus. Figure 1 shows the spectral power distribution of various blackbody radiators from 1,000 to 10,000 K, with all spectral power distributions normalized to unity at 560 nm. As the blackbody gets hotter (T increases), one can see that the red content in the spectrum reduces and the blue content increases – an indication of the color as would be seen by the human observer.

The projection of the emission spectra of various blackbody radiators onto the CIEXYZ color space via Eq. (2), and then further projected onto the CIE x , y 2-D chromaticity diagram, is shown in Fig. 2, for the CIE 2-degree observer [1]. One can see that the cooler blackbody radiators (lower T) are more red in their appearance (as given by their location in the chromaticity diagram) and the hotter blackbody radiators (higher T) are more blue in their appearance – the chromaticity

► [Multi-baseline Stereo](#)

Definition

Plane sweeping is a multi-view stereo algorithm notable for its efficiency, especially on modern graphics hardware (GPU).

Background

Plane sweeping addresses the stereo problem, which is to find the surface of a scene, given two or more calibrated views of the scene. Assuming that surfaces are Lambertian and that there are no occlusions, a point on the surface will have the same appearance in all views. Therefore, a conceptual solution to the stereo problem is to find the points that maximize *photoconsistency*.

This can be done by searching along the viewing rays for some image. The distance to the surface along the ray is called *depth*, and the set of all depths is called a depth map. Plane sweeping is a technique for efficiently organizing this search by sweeping a plane through space. Projecting all points on a plane into a perspective camera is simply a homography transformation, which can be executed efficiently on modern graphics hardware (GPU) [8].

Binocular stereo would typically *rectify* a pair of images such that searching along a viewing ray is equivalent to looping over the pixels in a row of the other image [6]. But three or more views, in general, cannot be rectified simultaneously. Plane sweeping avoids this problem by operating in 3D, searching along rays, one plane at a time, instead of searching image pixels. However, the proper sampling of 3D space is an issue. The image signal is sampled in 2D image space, and the sampling of the plane sweep must map to a similar sampling rate in image space. The right sampling is important for both correctness and efficiency.

Theory

The input to the plane sweep algorithm is a set of *views*. Let a view be defined as an image plus camera parameters. For simplicity, choose one view to be a *reference view*. All other images will be compared against the reference image to measure photoconsistency. The output of the algorithm will be a depth map for the reference view. Let the reference camera be identity, that is, its camera matrix is

$$\mathbf{P}_{\text{ref}} = \mathbf{K}_{\text{ref}} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}. \quad (1)$$

Let $\mathcal{I} = \{I_1, I_2, \dots, I_N\}$ be a set of matching views whose cameras are $\mathcal{P} = \{\mathbf{P}_1, \mathbf{P}_2, \dots, \mathbf{P}_N\}$, where

$$\mathbf{P}_i = \mathbf{K}_i [\mathbf{R}_i \ \mathbf{t}_i]. \quad (2)$$

Let a plane π be defined as

$$\pi = [\mathbf{n}_x \mathbf{n}_y \mathbf{n}_z d]^\top. \quad (3)$$

The plane can be swept through space in direction \mathbf{n} by varying d . For a given plane, photoconsistency will be evaluated on the plane at each point. This can be accomplished by projecting all images onto the plane and comparing the image values. Ultimately, it is desired to compute photoconsistency in the image to be reconstructed, and so, each image will be projected onto the plane and then into reference image. This transformation is known as a plane homography. The equation for the plane homography from I_{ref} to I_i via the plane π is

$$\mathbf{H}_i^\pi = \mathbf{K}_i \left(\mathbf{R}_i - \frac{\mathbf{t}_i \mathbf{n}^\top}{d} \right) \mathbf{K}_{\text{ref}}^{-1}. \quad (4)$$

The homography \mathbf{H}_i^π maps from the reference image to the image i so that pixel (x, y) in the warped image can be computed as

$$\begin{aligned} \tilde{I}_i(x, y) &= I \left(\frac{\tilde{x}}{\tilde{w}}, \frac{\tilde{y}}{\tilde{w}} \right) \text{ where } [\tilde{x} \ \tilde{y} \ \tilde{w}]^\top \\ &= \mathbf{H}_i^\pi [x \ y \ w]^\top. \end{aligned} \quad (5)$$

The photoconsistency at any point in the reference view can be computed using any number of matching scores. Common choices include the sum of squared differences (SSD), sum of absolute differences (SAD), and normalized cross correlation (NCC). These scores are window-based because they operate over a neighborhood or correlation window. This produces a more robust matching score at the expense of some overextension artifacts [3]. As an example, the SSD can be computed as follows:

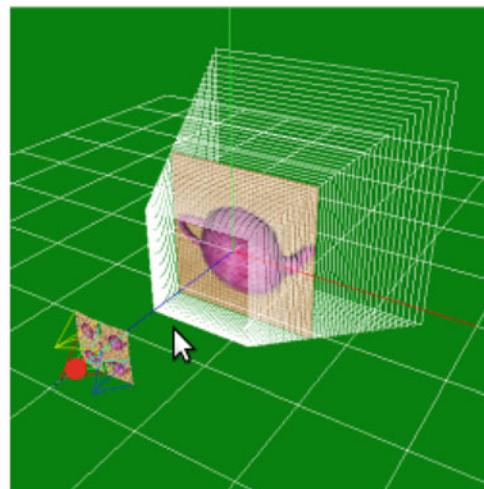

$$\begin{aligned} SSD(x, y) &= \sum_{i=1}^N \sum_{(i,j) \in \mathcal{N}} (I_{\text{ref}}(x+i, y+j) \\ &\quad - \tilde{I}_i(x+i, y+j))^2. \end{aligned} \quad (6)$$

The SSD is actually a photoconsistency *cost*, and it will be *minimized* by points near the surface. Defining the neighborhood \mathcal{N} in the space of the reference image assumes that points in the neighborhood are on the plane π . For scenes with highly slanted surfaces, better results can be achieved by sweeping the plane through space in different directions (different \mathbf{n}). Searching all directions is slow, but in some cases, like man-made scenes, a few dominant directions are sufficient [1].

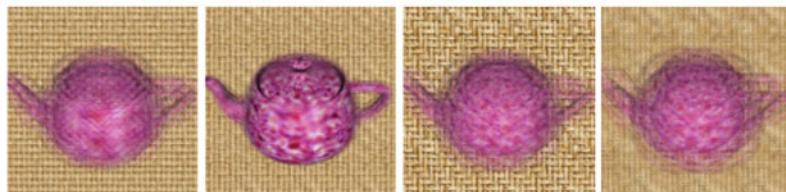

Equation 5 assumes that all matching views are unoccluded, but this is often not the case, and an occluded view can produce an arbitrarily high matching cost. Because plane sweeping can use many views, occlusion handling amounts to summing over some subset of views likely to be unoccluded. In the case where the camera path is close to linear, the subset can be either the previous or the subsequent half-set of matching views. A more general solution is to assume the best 50% of scores are unoccluded [4].

While sweeping the plane through space, the plane with the best photoconsistency score is recorded per pixel. The depth for each pixel can be computed by intersecting the viewing ray with the recorded best plane. The warped images at various positions in the plane sweep are shown in Fig. 1.

Proper sampling of the 3D space during the plane sweep is important for both correctness and efficiency. Sampling too sparsely could miss the photoconsistency optimum, and sampling too densely is inefficient. During the plane sweep, the plane should move so that the motion of the warped images is no more than 1 pixel (or the desired image sampling rate). Not all pixels move at the same rate, but measuring the corner pixels of the reference image is sufficient. Since the planar warps are linear, the interior points are linear combinations of corners and are therefore bounded. Sampling can be sped up by using downsampled images, effectively making pixels larger. Varying the resolution as well as varying the set of matching images (to control the baseline) can be used to control the sampling rate

Four views of a synthetic scene.

The warped images blended together at different stages of the plane sweep.

Plane Sweeping, Fig. 1 Plane sweep of a synthetic scene. As the plane sweeps from front to back, you can see the alignment of the teapot followed by the mat behind it

to achieve an optimal balance between efficiency and precision [2].

Application

The plane sweep algorithm has been popular for several real-time and large-scale systems, where efficiency is a key concern. The Urbanscape system is able to process VGA resolution video at over 30 frames per second, allowing it to reconstruct entire cities from street-level video in a matter of hours [1, 5].

A plane sweep approach was used in [7] for real-time view synthesis which allowed virtual views of the scene to be rendered from camera positions that were not physically captured. This algorithm differs slightly from plane sweep stereo in that the most consistent color, rather than the depth, is returned.

Definition

The plenoptic function describes the intensity of each light ray in the world as a function of visual angle, wavelength, time, and viewing position.

Background

The term plenoptic was derived from the word roots plen- (plenus) and opti- (optos), which means full/complete and eye/view, respectively. The plenoptic function was coined by Bergen and Anderson [1] to describe the intensity of each light ray in the world as a function of visual angle, wavelength, time, and viewing position. It captures everything that can potentially be seen

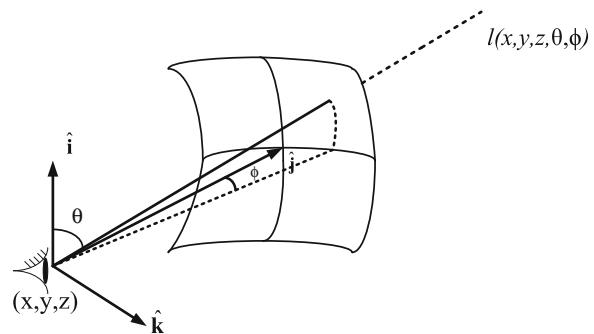

by an optical device and is related to previous concept of J. J. Gibson's "the structure of ambient light" and Leonardo da Vinci's "visual pyramid."

A light ray in the space can be parameterized by a position with three dimensions and a direction or visual angle in two dimensions (Fig. 1). Therefore, together with the wavelength and time dimensions, the plenoptic function is a seven dimensional (7D) function. The study of early vision is thus closely related to the sampling and processing of the plenoptic function. For instance, the derivatives of the plenoptic function with the position and time give usual information regarding the motion of objects, etc. In computer vision and video processing, the wavelength domain is simplified by sampling in the (*R*, *G*, *B*) color system. Consequently, images and videos are just two-dimensional (2D) and three-dimensional (3D) special cases or samples of the 7D plenoptic function. Based on this function, theoretically, novel views at different positions and time can be reconstructed from its samples, provided that the sample rate is sufficiently high. Because of the multidimensional nature of the plenoptic function, various such simplifications called image-based representations have been proposed to render new views from the representations with different complexity/functionalities trade-offs. This is the foundation of image-based rendering (IBR) without using geometry, and it usually requires large amount of samples.

As the plenoptic function observed is a consequence of the interaction of the light sources with objects in the scene, which further involve their geometries and surface properties, there is considerable redundancy in the plenoptic function, which can be further exploited by estimating or measuring the geometry, lightings, and surface properties of the scene to different extent. Image-based representations employing such modeling approach and auxiliary information, called image-based modeling, generally will provide improved user interaction and require fewer samples for rendering. The capturing, sampling, rendering, and processing of the plenoptic function are important areas of research in IBR and related applications such

Plenoptic Function,

Fig. 1 Plenoptic function
as a light energy received

as computational photography, 3D/multiview videos and displays, etc.

Theory

The amount or intensity of light along a ray is measured in radiance which is the power transmitted per unit area perpendicular to the direction of travel, per unit solid angle. Therefore, the plenoptic function that describes the radiance along light rays traveling in every direction through every point, denoted by l , is in watts (W) per meter squared (m^2) per steradian (sr) ($\text{W}/(\text{m}^2\text{sr})$).

The 7D plenoptic function can be parameterized using different coordinate systems, such as the familiar Cartesian, spherical, or cylindrical coordinates system. For instance, if the position V is parameterized by the Cartesian coordinates (x, y, z) while the direction is parameterized by the spherical coordinate (θ, ϕ) where θ and ϕ are the elevation and azimuth angles, respectively, as shown in (Fig. 1), the plenoptic function can be written as $l(x, y, z, \theta, \phi, \lambda, \tau)$ where λ and τ denote respectively the wavelength and time. By employing different parameterization and simplification, different image-based representations can be derived from the plenoptic function.

Representation

The conventional camera employs a lens to compress the light rays passing through an opening called the aperture and obtain a 2D image by placing an array of imaging sensors at the focal plane of the lens. For static scene, one can rotate

the camera along the camera center and capture the rays at a given position V with different elevation and azimuth angles. The plenoptic function is then reduced to a panorama $l_V(\theta, \phi)$ with two dimensions. Since the sensor array is usually rectangular in shape, some rebinning or stitching of the images is necessary [5, 19]. Moreover, due to the finite field of view of cameras, the samples may be incomplete near the two poles of the sphere. This spherical set of rays can also be projected on a cube or a cylinder, which provides other convenient representation of panoramas. A panoramic video can be obtained by employing multiple closely spaced video cameras, instead of rotating a single camera, to obtain a 3D plenoptic function $l_V(\theta, \phi, \tau)$ for dynamic scenes. The close relationship between plenoptic function and image-based rendering was due to McMillan and Bishop [14] who proposed plenoptic modeling using the 5D complete plenoptic function for static scene $l(x, y, z, \theta, \phi)$.

In the free space, the radiance along rays remains constant. This one-dimensional redundancy in the plenoptic function allows us to reduce it to a 4D function for static scene, which is called the light field [11] and lumigraph [8] in computer graphics. A similar concept in video communications is called the ray space [7]. The collection of light rays in a 4D static light field can be parameterized in a number of ways. A commonly used parameterization is the two-plane parameterization, where a light ray in the light field is parameterized as its intersections or coordinates with two parallel planes. These rays can be captured by taking a series of pictures on a 2D rectangular plane, which results in an array of images. Lumigraph differs from light

| Dimension | Year | View space | Name |

Plenoptic Function, Fig. 2 A taxonomy of plenoptic functions

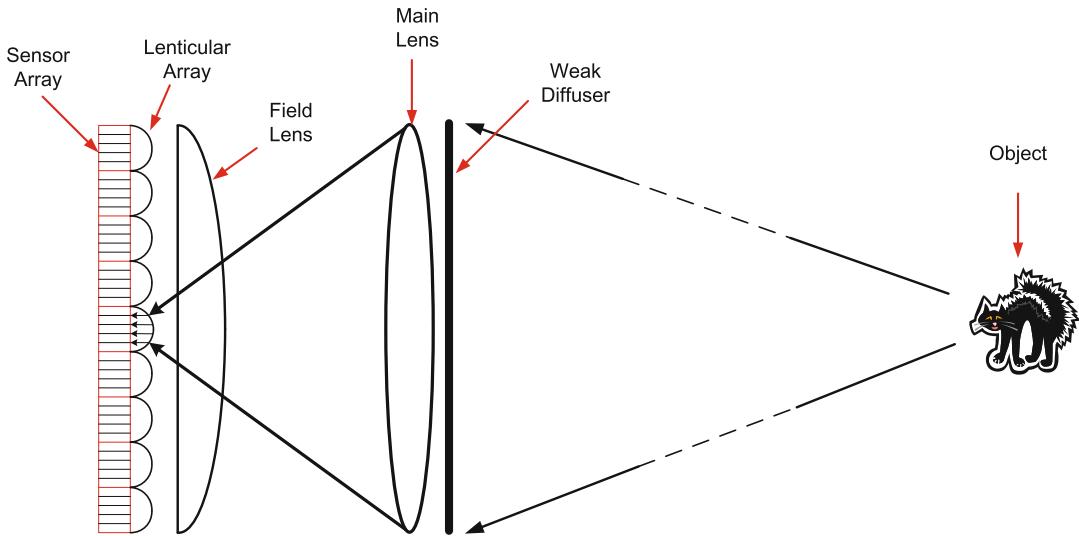

field in that geometry in form of depth map is utilized to improve the rendering quality, which paves the way to more sophisticated representations in image-based modeling. For more information, see the section on light field and lumigraph. In [17], an outward facing camera moving on a circle was used to capture a series of densely sampled images, called concentric mosaic, of a static scene. This gives rise to a 3D representation, which can be used to render views inside the circle. A brief summary of these classical representations is given in Fig. 2. See the section on IBR for more illustration. These parameterizations can be further simplified by restricting the camera locations to line, line segments [4, 23], circle, circular arc, etc. to reduce hardware complexity of the capturing system. This gives rise to a wide range of image-based representations specified by different camera geometry [18]. For time-varying or dynamic scenes, similar parameterization can be employed. However, light rays at the viewing locations have to be captured continuously. This can be done by an array of video cameras or specially design capturing devices.

The plenoptic function of static scene has also been extended to include the change of illumination direction as in the plenoptic illumination

function [21] at the expenses of increased data samples to be recorded at different lighting directions. Since the effect of multiple light sources is additive, one can relight a panorama or light field with arbitrary lightings using such representations.

Plenoptic Cameras

The term plenoptic camera was coined by Anderson and Wang [2]. It is a camera that captures a chunk of the optical structure of the light impinging on the lens. Basically, it records information about how the world appears from all possible viewpoints within the lens aperture. The plenoptic camera in [2] collects light with a single lens, but it uses a microlens or lenticular array at the image plane to redirect lights at certain directions at this location as collected from the lens aperture onto the sensor array (Fig. 3). Effectively, the plenoptic camera captures the cylindrical or spherical light fields over the lens aperture as macropixels onto a sensor array, depending respectively on whether a cylindrical or spherical lenticular array is used. The same principle has been used to produce autostereoscopic/multiview 3D display [10]. As a ray has to be mapped to an imaging pixel and there may be several directions to be recorded in a macropixel, the effective

Plenoptic Function, Fig. 3 Plenoptic camera employing lenticular lens [2]

resolution of sensor array will be reduced. In [2], a (5×5) macropixel is employed. One can therefore expect such resolution reduction will be more severe for spherical than cylindrical lenticules.

Using the rays or light field recorded by the plenoptic camera, one can render novel views by arranging the light rays captured as in light field rendering. The images captured by a cylindrical lenticules is a 3D light field which support viewpoint changes along a horizontal line, whereas a spherical lenticules is able to capture a 4D light field as demonstrated and refined later by Ng et al. [16]. Moreover, as mentioned in [2], one can measure the parallax corresponding to these virtual displacements and derive depth estimates for objects in the scene. Since the virtual displacement, and hence the potential resolution of depth, is somewhat limited by the size of the lens aperture, it tends to be lower than using stereo cameras.

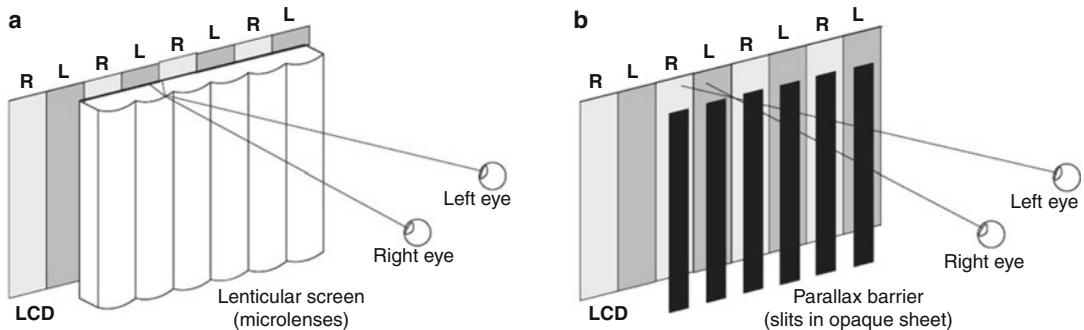

The concept of inserting optical elements or masks in the camera for 3D imaging dates back nearly a century ago, called integral photography or parallax panoramagrams and realized using a fly-eye lens array or a slit plate [9, 13]. Basically, these manipulate the 4D light field spectrum by modulation or reparameterization to make it fit

into a 2D sensor array [2]. Another technique is to make use of coded aperture or shutter as an optical modulator to capture stereoscopic images [6] and more recently to preserve the high-frequency components of motion-blurred images and to provide high-dynamicrange. Another recent technique is to employ multiple capturing of the scene sequentially by using beam splitters and camera arrays where at each exposure, the image parameters such as lighting, exposure time, focus, viewpoints, or spectral sensitivity are made different. After processing, a quality image or additional information is obtained. In [12], a coded aperture implemented using a programmable liquid crystal array, and multiple exposure was employed to capture light field using a single camera and derive the corresponding depth information.

Early systems for capturing light fields or plenoptic function for large environmental model usually involves camera arrays [4, 15, 20, 22, 23]. They are more expensive and difficult to build, as compared with a single plenoptic camera. On the other hand, due to their large baseline, it can also support a larger range of possible view points.

Sampling and Compression

During the capturing and display of plenoptic function, it is important to determine the

Plenoptic Function, Fig. 4 Multiview display employing (a) lenticular array and (b) parallax barrier

number of samples required and how to obtain a satisfactory rendering quality. This problem was first studied for the light fields in [3] using the concept of Fourier transform. For Lambertian surfaces and rectangular sampling (see the section on light field for a more detailed treatment), it was found that the maximum camera spacing in the v plane is $\Delta t_{\max} = 1 / \left(2\pi K_{\Omega_v} f \left(\frac{1}{z_{\min}} - \frac{1}{z_{\max}} \right) \right)$ (assuming the notation of the lumigraph), where z_{\min} and z_{\max} denote respectively the minimum and maximum depth values of the scene and K_{Ω_v} is the maximum frequency of the light field in the v plane, which depends on the maximum frequency of texture variations B_v , the resolutions of the sampling camera $1/\Delta v$, and the rendering camera $1/\delta v$ as $K_{\Omega_v} = \min(B_v, 1/(2\Delta v), 1/(2\delta v))$. Similar results hold for the s plane. To reduce the sampling rate and avoid dense sampling, the value of K_{Ω_v} can be decreased by reducing B_v and $1/(2\Delta v)$, through prefiltering the light field images, to the desired rendering resolution. A more thorough discussion on the effect of geometry on this minimum sampling density or rate can be found in [18, 22]. It was found that the sampling rate can be reduced by decomposing the light fields into depth layers. Therefore, recent research has focused on the estimation of geometry of objects using stereo or multiview vision techniques, special depth sensing devices, and lighting techniques as in photometric stereo.

Since the plenoptic function is a high-dimensional and highly correlated signal, they need to be compressed for efficient storage

and transmission. Comprehensive reviews of the subjects are available at [18]. See also the sections on image-based rendering and light field.

Multiview Displays

Multiview three-dimensional displays consist of view-dependent pixels that reveal a different color according to the viewing angle and offer viewing of simple plenoptic function such as light fields with limited number of views without glasses. A view-dependent pixel can be implemented by multiplexing the image pixels of different views and rely on a lenticule arranged in an array or slits arranged in parallel (parallax barriers) to angularly separate (filter) them to create the given color at the desired viewing direction. This is illustrated in Fig. 4 for a display using the lenticular array and parallax barriers, respectively. To suppress the artifacts due to the periodic lenticules and slits in automultiscopic displays, they are slightly slanted so that pixels of a given view are made nonuniform rather than widely separated as periodic vertical lines. Prefiltering has to be applied to generate the nonuniform samples so as to avoid aliasing due to down-sampling since all the pixels from all views have to be multiplexed on the same display [10].

The bandwidth of such displays is also limited because an object with increasing depth becomes smaller, and smaller and hence it will eventually reach the minimum sampling interval and aliasing will occur. To display a light field on such multiview displays, one may also need to bandlimit the plenoptic function [24] as studied in plenoptic sampling [3].

Application

The plenoptic function serves an important concept for describing visual information in our world. Its sampling analysis also serves as a basic for designing plenoptic cameras and automultiscopic displays for capturing and displaying such high-dimensional function, respectively.

Open Problems

The efficient capturing and processing of plenoptic function has always been a problem in visual computing and vision research. Due to the multi-dimensional nature of the plenoptic function and its dependence on the scene geometry, the analysis is very difficult because the function itself may not even be bandlimited. Appropriate optical elements have to be used to reduce the aliasing due to sampling. This makes a general analysis very difficult, though some simple cases such as Lambertian surface, occlusion, and lighting on light field spectrum have been analyzed and found to be useful in practice. Recent advances in computational photography, microelectronics, and processing algorithms have accelerated the development of more sophisticated capturing devices and techniques to improve the rendering quality and reducing the hardware complexity. However, how to achieve high-quality renderings supporting a wide range of view points in large scale environmental modeling remains open.

Definition

Polarization refers to the orientation distribution of the electromagnetic waves that constitute light rays. Light can assume a range of polarization states including unpolarized (uniformly mixed orientations), linearly polarized (fixed orientations), and circularly polarized (rotating field about the line of sight).

Background

The polarization of light is a property that relates to the directionality of the constituent electric and magnetic fields. In free space, light consists

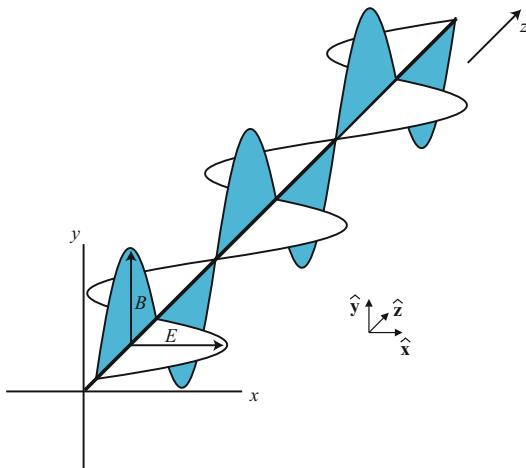

of sinusoidally oscillating electric and magnetic fields that are orthogonal to each other and to the direction of propagation. In the case of *perfectly linearly polarized light*, as shown in Fig. 1, the two types of field remain in a fixed plane through space. For *unpolarized light*, the orientations of these planes are randomized through temporal and spatial location. *Circular and elliptical polarizations* are also possible, whereby in a plane normal to the ray, the field is radial at each point with an orientation following a circular or elliptical temporal pattern. Finally, it is possible to have light consisting of combinations of polarization types. For example, *partially linearly polarized light* involves fields oscillating in all directions but with one particular preferred direction. Polarization can be caused by a range of phenomena such as scattering, reflection, and transmission through media interfaces. In most computer vision and industrial applications, polarized light is generated and measured using polarizing filters.

Theory

Plane Wave Versus Photon Representation

Most texts on polarization regard light as an electromagnetic wave and explain the various phenomena via interactions of the constituent electric and magnetic fields with matter or other waves. However, in the realm of quantum optics, light consists of streams of particles known as photons. The details of this [1] are beyond the scope of this entry, although it is worthwhile noting a few basic points:

- Each photon has an associated energy that is proportional to its frequency.
- The angular momentum of each individual photon is quantized and can only take values of $-h/2\pi$ or $+h/2\pi$, where h is the *Planck constant* [2].
- Circular polarization consists of identical photons (for monochromatic light) all with angular momentum vectors oriented either parallel to the direction of propagation (left-

Polarization, Fig. 1 A linearly polarized wave consisting of vertical magnetic fields (B) and horizontal electric fields (E)

or \mathcal{L} -state) or antiparallel to the direction of propagation (right- or \mathcal{R} -state).

- Linear polarization (\mathcal{P} -state) can be described by a linear combination of \mathcal{L} - and \mathcal{R} -states.

For the remainder of this entry, the electromagnetic wave description of light will be employed.

Linear Polarization

In linearly polarized light, the electric and magnetic fields assume a fixed orientation through space, as shown in Fig. 1. For the remainder of this entry, the focus will be on the electric field (similar arguments to those below can be applied to the magnetic component – see [3] for a thorough description). In the simplest case, the electric wave of linearly polarized light can be described using a standard equation of a plane wave:

$$\mathbf{E}(z, t) = \hat{\mathbf{x}}E_0 \cos(kz - \omega t) \quad (1)$$

where the coordinate axes (x, y, z) and unit vectors $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, and $\hat{\mathbf{z}}$ are defined in Fig. 1, E_0 is the amplitude of the wave, k is the wave number, ω is the angular frequency, and t is time. A detailed overview of the construction of the plane wave equation and its manipulation can be found in [4].

The wave described by (1) is horizontally oriented. Of course, it is possible to replace the $\hat{\mathbf{x}}$ in (1) with $\hat{\mathbf{y}}$, in which case, a vertical plane polarized wave will be represented. In general, an arbitrary case can be represented as a sum of orthogonal components:

$$\mathbf{E}(z, t) = \mathbf{E}_x(z, t) + \mathbf{E}_y(z, t) \quad (2)$$

where

$$\mathbf{E}_x(z, t) = \hat{\mathbf{x}}E_{0x} \cos(kz - \omega t) \quad (3)$$

$$\mathbf{E}_y(z, t) = \hat{\mathbf{y}}E_{0y} \cos(kz - \omega t + \phi) \quad (4)$$

Here, E_{0x} and E_{0y} refer to the amplitude components in the x and y directions, respectively, and ϕ is the *phase difference* between the components (the absolute phases are irrelevant).

A wave is linearly polarized wherever $\phi = m\pi$, where m is an integer:

$$\begin{aligned} \mathbf{E}(z, t) &= (\hat{\mathbf{x}}E_{0x} + \hat{\mathbf{y}}E_{0y}) \cos(kz - \omega t) && \text{even } m \\ \mathbf{E}(z, t) &= (\hat{\mathbf{x}}E_{0x} - \hat{\mathbf{y}}E_{0y}) \cos(kz - \omega t) && \text{odd } m \end{aligned} \quad (5)$$

where $(\hat{\mathbf{x}}E_{0x} + \hat{\mathbf{y}}E_{0y})$ and $(\hat{\mathbf{x}}E_{0x} - \hat{\mathbf{y}}E_{0y})$ define both the amplitude and direction of the electric field (or *plane of polarization*) for each case.

P

Circular and Elliptical Polarization

The linear polarization case of (5) is essentially a special case of the general electric field equation (2). A second special case is where $\phi = \pi(m - 1/2)$, where m is, again, an integer. For the case where $E_{0x} = E_{0y} = E_0$, (4) can be substituted into (2), to generate the following wave:

$$\begin{aligned} \mathbf{E}(z, t) &= E_0(\hat{\mathbf{x}} \cos(kz - \omega t) + \hat{\mathbf{y}} \sin(kz - \omega t)) \\ &\quad \text{even } m \\ \mathbf{E}(z, t) &= E_0(\hat{\mathbf{x}} \cos(kz - \omega t) - \hat{\mathbf{y}} \sin(kz - \omega t)) \\ &\quad \text{odd } m \end{aligned} \quad (6)$$

This case has two interesting properties. Firstly, in contrast to the linearly polarized case (5), the scalar amplitude is fixed at E_0 . Secondly, the direction of the electric field is rotating at a fixed angular velocity in a clockwise (for even m) or anticlockwise (for odd m) direction relative to the direction of propagation. An alternative way to envisage this is that for a given point along the line of propagation of the wave, the tip of the electric field vector follows a circular motion about that point. The clockwise case is referred to in the optics literature as *right circularly polarized* light, while the anticlockwise case is called *left circularly polarized*. Note that a superposition of right and left circularly polarized light gives rise to a linearly polarized wave of amplitude $2E_0$. This is conducive to the photon angular momentum arguments discussed earlier.

For the general case, where $E_{0x} \neq E_{0y}$, and for nonintegral values of m , the tip of the electric field vector follows an elliptical path. This can be found by seeking a time- and position-independent solution to (2) and (4). The result [1] is that

$$\left(\frac{E_x}{E_{0x}}\right)^2 + \left(\frac{E_y}{E_{0y}}\right)^2 - 2\left(\frac{E_x}{E_{0x}}\right)\left(\frac{E_y}{E_{0y}}\right)\cos\phi = \sin^2\phi \quad (7)$$

This is the equation of an ellipse oriented at an angle, γ , given by

$$\tan 2\gamma = \frac{2E_{0x}E_{0y}\cos\phi}{E_{0x}^2 - E_{0y}^2} \quad (8)$$

For the simplest case, where $\gamma = 0$ the relationship reduces to

$$\frac{E_x^2}{E_{0x}^2} + \frac{E_y^2}{E_{0y}^2} = 1 \quad (9)$$

Elliptically polarized light is often referred to as the \mathcal{E} -state.

Partial Linear Polarization

Often in nature and technology, light assumes a partially polarized form. The most common of these is partially linearly polarized light. This consists of a superposition of linearly polarized light and unpolarized light. It is often desirable to define a quantity known as the *degree of polarization*, ρ , that relates the intensity (or flux density) of the polarized component, I_p , to that of the unpolarized component, I_u :

$$\rho = \frac{I_p}{I_p + I_u} \quad (10)$$

This is often expressed as a percentage, such that light of equal components is 50% polarized. The degree of polarization can be analyzed using a polarizing filter (often referred to as an “analyzer” in optics texts). If the maximum and minimum transmitted light intensities as the polarizer is rotated are I_{\max} and I_{\min} , then $I_{\min} = I_u/2$ and $I_{\max} = I_u/2 + I_p$ so that

$$\rho = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \quad (11)$$

Alternative Representation

Stokes Vectors

In many practical applications of polarized light, the physical wave description above is of little use due to the minuscule quantities involved. The Stokes vectors aim to represent the polarization state of light in a compact form that most detectors can measure (see [5] for derivations and further details).

The general Stokes vector is defined by

$$S = [S_0, S_1, S_2, S_3]^T \quad (12)$$

The first of the parameters of the Stokes vector, S_0 , is simply the intensity of the light. The second parameter, S_1 , quantifies the tendency for vertical or horizontal polarization and is related to the difference in the corresponding vertical and horizontal components of the wave’s electric field. Where $S_1 > 0$, the light resembles a horizontal \mathcal{P} -state, while $S_1 < 0$ relates to vertical \mathcal{P} -

states. For the case where $S_1 = 0$, there is no tendency either way as in circular polarized light, elliptical light at 45° , and unpolarized light. S_2 is interpreted in a similar fashion but relates to angles of 45° and -45° . Finally, S_3 relates to the handedness of the polarization ($S_3 > 0$ is right-handed, $S_3 < 0$ is left-handed, and $S_3 = 0$ is neither).

Often, the Stokes vectors are normalized by S_0 so that, for example, unpolarized light has $S = [1, 0, 0, 0]^T$; vertically linearly polarized light has $S = [1, -1, 0, 0]^T$; linearly polarized light at 45° has $S = [1, 0, 1, 0]^T$; and right circularly polarized light has $S = [1, 0, 0, 1]^T$. Furthermore, light may consist of superpositions of different states, in which case the individual vectors are simply added together.

The Stokes vectors provide useful representations of polarization for *incoherent light*, which is abundant in nature. Computer vision and other fields may utilize the Stokes representation of the degree of polarization. In the case of partially linearly polarized light, for example, the degree of polarization is

$$\rho = \frac{\sqrt{S_1^2 + S_2^2}}{S_0} \quad (13)$$

Jones Vectors

For *coherent light*, typically from lasers, an alternate representation is also possible. The Jones vector of a polarized light wave is simply given by

$$\mathbf{E} = \begin{bmatrix} E_x(t) \\ E_y(t) \end{bmatrix} \quad (14)$$

The electric fields in the Jones vectors are generally represented as a wave via the imaginary number approach [4] ($E = E_0 e^{i(kz - \omega t + \phi)}$). They are then normalized by the intensity in a similar fashion to the Stokes vectors. The results [1] are that horizontal and vertical \mathcal{P} -states are given by $[1, 0]^T$ and $[0, 1]^T$, respectively; \mathcal{P} -states at 45° are given by $(1/\sqrt{2})[1, 1]^T$ and $(1/\sqrt{2})[1, -1]^T$; and \mathcal{R} - and \mathcal{L} -states are given by $(1/\sqrt{2})[1, -i]^T$ and $(1/\sqrt{2})[1, i]^T$.

The advantage of the Jones representation (aside from its compactness) is that certain optical operations can be described sequentially in terms of matrix operations. For example, light passing through a linear vertical polarizer has its Jones vector modified by the a *Jones matrix* of $\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$. A related set of matrices for operating on Stokes vectors has also been derived. These are called *Mueller matrices* and have dimensions of 4×4 . Further details of Jones and Mueller matrices can be found in [1] and references therein.

Polarized Light in Nature

Sunlight, which constitutes the overwhelming majority of natural light on Earth, is unpolarized. Despite this, linearly polarized light is abundant in nature as a result of various phenomena that convert unpolarized light to polarized light. Circularly polarized light by contrast is rare in nature and only occurs under certain ideal conditions. The two most common causes of polarization are reflection from surfaces and light scattering in the atmosphere, and these are discussed below. Other causes [6] include internal reflection, rainbows, clouds, and birefringence (in materials where optical properties are anisotropic).

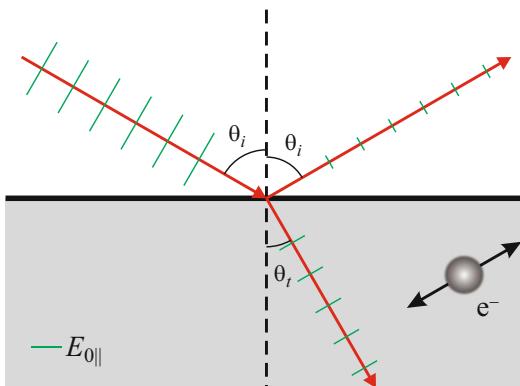

P

Reflection

Consider a light wave impinging upon a smooth dielectric surface, as shown in Fig. 2. A fraction of the light penetrates the surface and the remainder is reflected. In real surfaces, the penetrated light undergoes a series of complicated scattering interactions according to the radiative transfer equation [7]. However, the problem can be simplified by assuming that no scattering occurs apart from at the interface. In this case, the transmitted wave is refracted according to the well-known Snell's law [1]:

$$n_i \sin \theta_i = n_t \sin \theta_t \quad (15)$$

where n_i and n_t refer to the refractive indices of air (≈ 1) and the reflecting material and θ_i and

Polarization, Fig. 2 Polarization from specular reflection

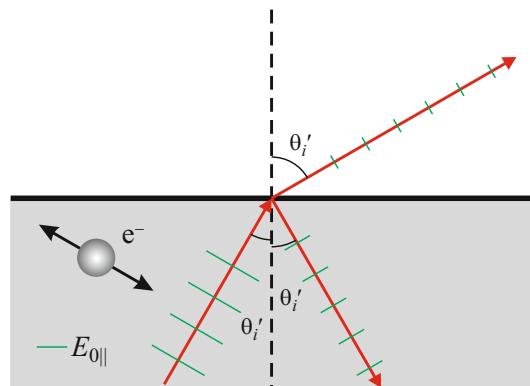

θ_t refer to the incident and transmitted angles, respectively.

Consider the component of the electric field of the wave that is parallel to the plane of incidence. This component results in electron dipole oscillations in the medium at angle θ_t (see Fig. 2). These dipoles close to the interface emit the reflected wave. However, this reflected wave is at a different angle to θ_t meaning that the parallel component of the reflected wave is attenuated due to foreshortening. For the component of the electric field that is perpendicular to the plane of incidence, the foreshortening effect is not present. This difference in wave attenuation caused by foreshortening gives rise to a partially linearly polarized reflection.

Note that, for the case where $\theta_i + \theta_r = 90^\circ$, foreshortening eliminates the parallel component of the reflection entirely. The angle at which this occurs is known as the *Brewster angle*, θ_B , and it follows from (15) that, for the case where $n_i = 1$,

$$\theta_B = \arctan n_t \quad (16)$$

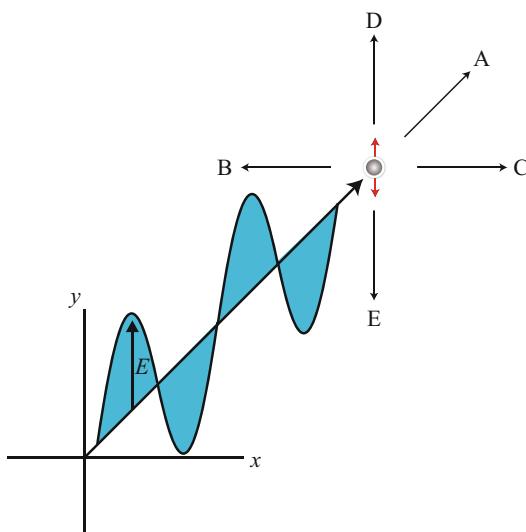

Much of the light present in everyday life is not specularly reflected from surfaces, as discussed above, but diffusely reflected. That is, the light is scattered either at the surface or below the surface, and both of these phenomena affect the polarization state of the reflected light. For the latter case, several efforts have been made to model the precise means by which

Polarization, Fig. 3 Polarization from diffuse reflection (refraction)

light is scattered to form a reflection [8]. The important point, so far as polarization is concerned, is that after undergoing internal scattering, the light impinges upon the air-medium interface from within, as shown in Fig. 3. This light then undergoes a refraction as it passes the interface. A similar argument to that above for specular reflection can then be applied to establish that a foreshortening effect polarizes the diffusely reflected light also. Note however, that as the incident wave can never be perpendicular to the reflected wave, there is no angle by which the diffusely reflected light becomes completely polarized. The degree and angles of polarization can be determined from the Fresnel equations and are discussed in detail in the entry “► [Polarized Light in Computer Vision](#).” Note also that polarization by refraction occurs as light from the Sun enters water, causing light near the surface of lakes, seas, and oceans to be partially polarized.

For the case of surface scattering, several attempts to model the microscopic roughness patterns have been made, such as [9, 10]. For both specular and diffuse reflection, the random nature of microscopic surface corrugations has the effect of mixing the orientations of reflected light fields. One of the effects of this is to depolarize the reflection. As predicted by the *Umov effect* [11], rough surfaces with lower albedo retain higher degrees of polarization than light surfaces. This is due to the fact that fewer inter-reflections take

Polarization, Fig. 4 Polarization from scattering

place on dark surfaces before the light waves are completely absorbed by the medium. This effect was first noted in astronomy, where the degree of polarization of an astronomical body is inversely proportional to its albedo.

Scattering

As unpolarized light is scattered by small particles (e.g., a molecule in the atmosphere or a dust particle), it becomes partially linearly polarized. The effect can be explained in a similar fashion to that with surface reflection. Consider a light wave impinging on a particle. The particle will scatter the light in a range of directions. It turns out that, when viewed at an angle of 90° to the direction of the light wave, the scattered light is completely polarized, while the waves that are scattered close to the direction of propagation or scattered by $\approx 180^\circ$ are only slightly polarized. This phenomenon is observed on a grand scale in the Earth's atmosphere. When a clear sky is viewed at an angle of 90° from the Sun, it can be observed to be $\approx 75\%$ polarized, compared to almost no polarization at $\approx 0^\circ$ and approaching 180° . In practice, light scattered at 90° is not completely polarized due to a range of factors such as molecular anisotropies and multiple-scattering depolarization.

The phenomenon of polarization by scattering can be explained as follows. The wave shown in Fig. 4 induces an oscillating dipole in the scattering particle as a result of the redistribution of the electron cloud and nucleus location caused by the electric field. The dipole, in turn, generates the scattered wave. Assume that the impinging wave is linearly vertically polarized, as in Fig. 4. The new wave has maximum amplitude at an angle perpendicular to the dipole orientation and zero amplitude when parallel to the dipole due to foreshortening. In relation to Fig. 4, amplitude maxima would be found in directions *A*, *B*, and *C* (in addition to backscatter), while no scattering occurs in directions *D* or *E*. Next consider an impinging wave that is polarized horizontally. In this case, directions *A*, *D*, and *E* are the maxima, while directions *B* and *C* have no scattering. Finally, by representing an unpolarized incident wave as a linear combination of randomized linearly polarized states, it can be seen that direction *A* and backscatter remain unpolarized, directions *B* and *C* retain only the vertical polarization, and directions *D* and *E* retain only the horizontal polarization. Directions intermediate between those discussed will, of course, become partially linearly polarized. For such angles with the common case of scattering by atmospheric dust or smoke, the degree of polarization is given by [3]

$$\rho = \frac{\sin^2 \beta}{1 + \cos^2 \beta} \quad (17)$$

where β is the scattering angle. This is known as Rayleigh scattering. However, complete polarization is not typically observed due to the reasons mentioned above.

P

Application

Many creatures, including some insects and marine animals, have eyes that are sensitive to the polarization state of light [12]. Bees and ants, for example, use the polarization pattern in the sky or water to aid navigation [6]. Several marine creatures use similar patterns found underwater for the same purpose [13]. There is evidence [14]

that certain aquatic creatures use polarization to isolate objects of interest within their field of view. It is also believed that some species communicate by reflecting light only of a certain polarization angle.

In everyday life, a common application of polarization is in sunglasses and camera filters. A pair of polarizing sunglasses with vertical transmission axis blocks out large amounts of specular glare from surfaces as Fig. 2 suggests. A correctly oriented camera lens filter can also be used to diminish glare. In addition, such a filter can increase contrast between clouds and the sky by cutting out the polarized component of sky and having less impact on light from clouds.

Liquid crystal displays (LCDs) are based on crystals placed between crossed polarizers. Light is transmitted or absorbed in different segments, depending on which areas is subjected to a voltage. Where the voltage is applied, the crystals rotate the angle of polarization by 90°. Stress patterns of many materials can be analyzed by placing samples between crossed polarizers and measuring the transmitted intensity patterns. This is possible due to the changing birefringence properties of materials under strain. In entertainment, 3D images can be generated by time-multiplexing different polarization states onto a screen, with each state representing a different viewpoint of the object being displayed. The viewers wear polarizing spectacles that transmit each state to separate eyes. Finally, polarization is prevalent in astronomy. For example, transmission and absorption effects in strongly magnetic regions of the Sun's surface cause circular polarization, while interstellar dust is responsible for polarization by scattering over long distances.

Within the field of computer vision, polarization has been used for a range of tasks, including the following (further details and references can be found in the separate entry on “► [Polarized Light in Computer Vision](#)”):

- Specularity reduction
- Shape recovery
- Reflectance analysis
- Image enhancement

- Reduction of inter-reflections
- Separation of reflectance components
- Image segmentation

Definition

Polarization refers to the orientation distribution of the electromagnetic waves that constitute light rays. The phenomenon of light polarization has been exploited in computer vision for a range of applications including surface reconstruction, specular/diffuse separation, and image enhancement.

Background

Light consists of orthogonal electric and magnetic fields. Most natural light is unpolarized and so consists of randomly fluctuating field directions. However, a range of natural phenomena (e.g., scattering and reflection) and human inventions (e.g., polarizing filters and liquid crystal displays) cause the light to become polarized. That is, the electric and magnetic fields become confined to specific planes or get constrained in other ways. In the field of computer vision, both natural and artificially generated polarized light has been utilized for a range of applications including specularity reduction, shape recovery, reflectance analysis, image enhancement, automated inspection, segmentation, and separation of reflectance components.

Theory

The majority of research into polarization methods for computer vision rely on passively analyzing the polarization state of incoming light using either uncontrolled, or at least unpolarized, illumination. However, one of the most common uses of polarization in computer vision is to remove specularities from images using a more active approach. This entry first describes this method and is followed by descriptions of techniques for polarization measurement. It then covers the relevant theory of the two most common natural causes of polarization (reflection and scattering) and their exploitation in computer vision.

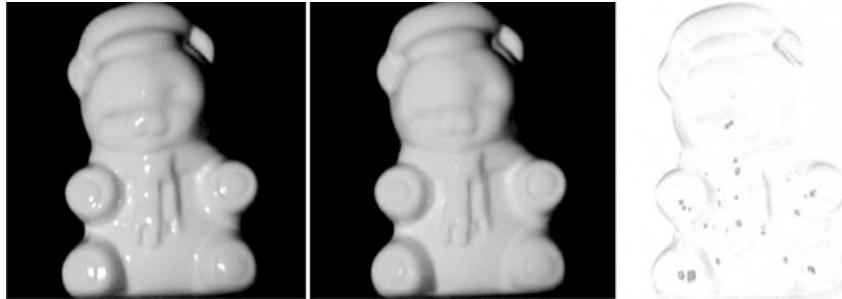

Polarization and Specularities

The images of the porcelain bear model in Fig. 1 were obtained using a camera with one linear polarizer (often referred to as an “analyzer” in optics texts) mounted on the lens and another in front of the only light source. For the first image, the two polarizers were oriented parallel to each other, while for the second image they were at 90°. The second image clearly shows a minimization of specularity. This is of great benefit to a range of computer vision methods that assume specularities are absent from images such as shape-from-shading [1] and photometric stereo [2].

The theory behind the specularity reduction is that the polarized incoming light induces electron oscillations in the reflecting medium in only one direction (see the entry on ▶ “[Polarization](#)”). This means that the *specularly* reflected light, which is generated by these oscillations, has an electric field that is constrained to a single plane also. If the lens polarizer is oriented at right angles to this plane, then all of this light is blocked from the camera. On the other hand, the *diffusely* reflected light is depolarized by subsurface scattering and surface roughness. This means that much of the diffusely reflected light is transmitted through the lens polarizer.

Polarization Imaging

For the cases where the incident light is unpolarized, the simplest and most common method of

Polarized Light in Computer Vision, Fig. 1 *Left:* Uncrossed polarizers, *center*, crossed polarizers; *right*, difference image [3]. N.B. The difference image has been inverted and undergone nonlinear intensity scaling to aid clarity

measuring polarization is to take a sequence of images with a rotating linear polarizer. Consider a camera's field of view where the incoming light is partially linearly polarized with varying degrees between 0% and 100% (see the entry on ▶ “[Polarization](#)” for the definition of the degree of polarization). The aim is to acquire a *polarization image*: a three-channel image where each pixel has components corresponding to (1) the grayscale intensity, (2) the degree of polarization, and (3) the phase angle (not to be confused with the phase of the electric and magnetic fields of the wave that constitute the light ray) of the linearly polarized component of the incoming light.

As the polarizer on the lens rotates, the transmitted intensity at each point is given by the *transmitted radiance sinusoid*:

$$I(\theta_{\text{pol}}, \varphi) = \frac{I_{\max} + I_{\min}}{2} + \frac{I_{\max} - I_{\min}}{2} \cos(2\theta_{\text{pol}} - 2\varphi) \quad (1)$$

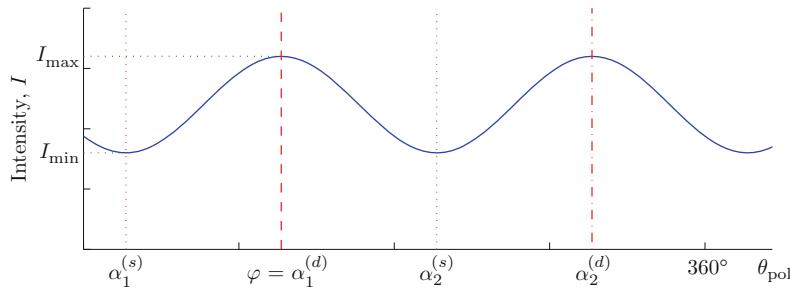

where θ_{pol} is the polarizer orientation, I_{\min} and I_{\max} are the minimum and maximum observed pixel brightness, and φ is the phase angle. The transmitted radiance sinusoid is shown graphically in Fig. 2.

The complete polarization image is then constructed by fitting the transmitted radiance sinusoid to three or more different intensity images for different polarizer angles. This assumes that the pixel brightness is proportional to the light impinging on the sensor – i.e., the camera response function is linear. For

typical 8-bit imaging equipment, the intensity component is in the range [0, 255], the degree of polarization is always in the range [0, 1], and the phase is always in the range [0, 180°]. Figure 3 shows a synthetic example of the three components of a polarization image.

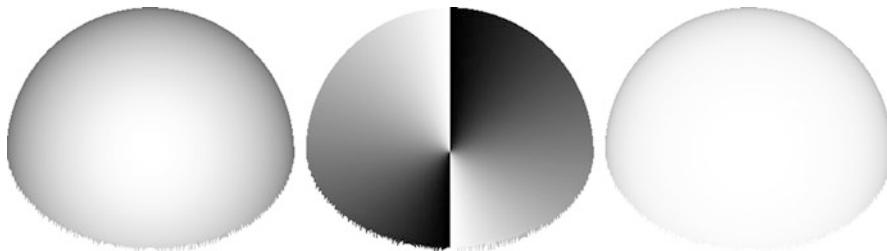

A major weakness of many polarization methods until recently is the amount of time needed to acquire the data (the actual processing of the data is often highly efficient). For the rotating polarizer method described above, three or more images are required with the polarizer at different orientations. If exactly three or four polarizer angles are used, then sinusoid fitting can be done using a closed-form solution [4]. Otherwise a least-squares fit is needed. Either way, the need for multiple sequential images limits applications to static scenes. Matters were improved after the development of *polarization cameras* [5] that used liquid crystals to rapidly switch the axis of the polarizing filter. Subsequently, PLZT (polarized lead zirconium titanate) cameras [6] were designed with the aim of recovering all four components of the Stokes vectors (defined in the entry on ▶ “[Polarization](#)”)[7]. The Stokes vectors, in turn, yield the phase and degree of polarization from a single image [4].

More recently, specialist cameras have been commercialized that embed micro-filter arrays directly onto the sensor elements [8]. These generally involve precise placement of a pattern of polarizing filters onto each sensor pixel and are oriented at angles of 0°, 45°, 90°, and 135° relative to the image. A simple algorithm is then applied to deduce the Stokes Vectors [4]. There

**Polarized Light in Computer Vision, Fig. 2**

Transmitted radiance sinusoid. $\alpha_1^{(s)}$ and $\alpha_2^{(s)}$ are the two possible surface azimuth angles for a given phase angle

φ , assuming that the reflection is specular. For diffuse reflection, the possible azimuth angles are $\alpha_1^{(d)}$ and $\alpha_2^{(d)}$

**Polarized Light in Computer Vision, Fig. 3** Synthetic rendering of a polarization image of a hemisphere. *Left*, intensity; *center*, phase angle; *right*, degree of polarization

are, of course, variations in terms of how the filters are applied to the sensor [9, 10], but all have the advantage of capturing all required data in a single exposure.

Other methods of rapid polarization image capture include placing multiple cameras with different polarizers but near-parallel optical axes [11]; using a detector array-like Bayer pattern to capture the polarization field on chip [9]; using a lightfield camera, where the aperture is divided into segments, some of which contain polarizers [12]; and employing multiple CCDs to capture all the polarization components using beam splitters [13]. The interested reader is also referred to [4, 14] for a detailed survey.

a specular reflection being viewed through a rotating polarizer. Because the electric field of the reflected wave is most attenuated in the plane of reflection, the greatest transmission through the polarizer occurs when it is oriented at right angles to the plane. Minimum transmission occurs when the polarizer is parallel to the plane. Note however, that the polarizer is unable to distinguish two planes of reflection oriented 180° apart. If α is the azimuth angle of the surface (the angle of the projection of the surface normal onto the image plane), then there are two possible values for a given measurement of φ :

$$\alpha_1^{(s)} = \varphi - 90^\circ \quad \alpha_2^{(s)} = \varphi + 90^\circ \quad (2)$$

Polarization and Reflection in Images

Perhaps the most common exploitation of polarization in computer vision is to measure the polarization state of light reflected from dielectric surfaces [15]. As described in the entry on ► “Polarization”, natural light undergoes partial polarization when it is reflected from surfaces. Consider

where the superscript s indicates that the reflection is specular.

As explained in [15], the Fresnel equations can be used to represent the maximum and minimum intensities passing through a rotating polarizer as

$$I_{\min} = \frac{R_{\parallel}(n, \theta)}{R_{\perp}(n, \theta) + R_{\parallel}(n, \theta)} I_r \quad (3)$$

$$I_{\max} = \frac{R_{\perp}(n, \theta)}{R_{\perp}(n, \theta) + R_{\parallel}(n, \theta)} I_r$$

Here R_{\parallel} and R_{\perp} are the parallel and perpendicular Fresnel intensity reflectivity components, respectively (see the entry on ► “[Fresnel Equations](#)”), n is the refractive index, θ is the angle of incidence, and I_r is the magnitude of the specularity. In an imaging situation, θ is equivalent to the zenith angle of the surface (the angle between the surface normal and the line of sight of the camera). Rewriting in terms of the degree of polarization and rearranging gives [15]

$$\rho_s(n, \theta) = \frac{2 \sin^2 \theta \cos \theta \sqrt{n^2 - \sin^2 \theta}}{n^2 - \sin^2 \theta - n^2 \sin^2 \theta + 2 \sin^4 \theta} \quad (4)$$

where the suffix s is appended to the degree of polarization as this assumes a purely specular reflection.

Equations 2 and 4 allow one to impose constraints on the angle of a reflecting surface for shape recovery applications using measurements taken of φ and ρ . The azimuth angle of the surface has two possibilities as shown by (2) and Fig. 2. Apart from at the Brewster angle, where $\rho = 1$, there are also two solutions to (4), meaning two zenith angles are also possible.

Combining the above theory with the subsurface scattering model of reflection [15, 16], the following relations for *diffuse* reflection can be derived:

$$\alpha_1^{(d)} = \varphi \quad \alpha_2^{(d)} = \varphi + 180^\circ \quad (5)$$

$$\rho_d = \frac{(n - 1/n)^2 \sin^2 \theta}{2 + 2n^2 - (n + 1/n)^2 \sin^2 \theta + 4 \cos \theta \sqrt{n^2 - \sin^2 \theta}} \quad (6)$$

On this occasion, there is only one solution for the zenith angle, but the degree of polarization is lower and therefore more difficult to measure. Indeed, the information contained in this degree of polarization is only useful for large zenith angles [17].

Outdoor Polarization Imaging

One of the most common causes of polarization in nature is atmospheric scattering [18]. Consider the imaging process of a distant outdoor object or scene. Light that arrives at a detector consists of a component transmitted from the object itself, D , and a component of “airlight,” A . The former of these is typically reflected sunlight, while the latter is light scattered from the atmosphere, as shown in Fig. 4. The total intensity at the camera can be represented by

$$I_{\text{tot}} = A + D \quad (7)$$

It can be shown [19] that

$$A = A_{\infty} (1 - t(z)) \quad (8)$$

$$D = L_{\text{obj}} t(z) \quad (9)$$

where A_{∞} is the airlight radiance for an object at infinity, L_{obj} is the object radiance, z is the distance to the object, and $t(z)$ is given by

$$t(z) = \exp \left(- \int_0^z \beta(z') dz' \right) \quad (10)$$

where β is called the *coefficient of extinction*.

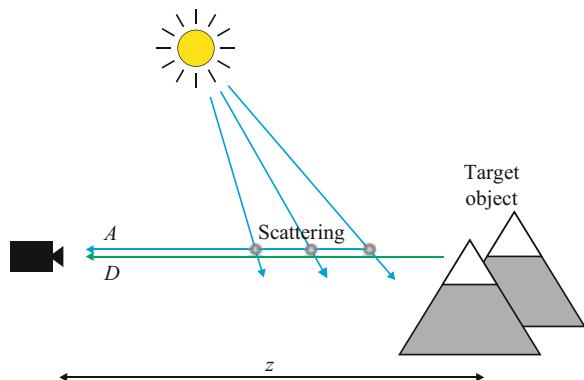

As explained in the ► “[Polarization](#)” entry, atmospheric scattering causes polarization. The degree of polarization for the airlight component is be given by

$$\rho = \frac{A_{\perp} - A_{\parallel}}{A_{\perp} + A_{\parallel}} \quad (11)$$

where A_{\perp} and A_{\parallel} are the scattered components parallel to and perpendicular to the plane of scattering, respectively. If it is assumed that the target object is emitting/reflecting unpolarized light, then the light measured through a linear polarizer is a transmitted radiance sinusoid, as in Fig. 2, but with an intensity offset equal to the light directly transmitted from the target object. Clearly, the simple task of rotating a lens-mounted polarizer to the angle that allows minimum transmission removes some of the airlight and so enhances the image of the target object. Taking images at more than one polarizer orientation allows to solve for the unknowns in

Polarized Light in Computer Vision, Fig. 4

Haze in an image due to atmospheric scattering

(7)–(11) and dehaze an image more effectively [19]. A related polarization analysis can also be used for images taken in murky water [20].

other applications including reflectance analysis [26] and cosmetics [27] and inspection [28].

Application

The above theory, and extensions thereof, has been used in a range of areas within computer vision. Perhaps the most studied is in shape recovery. This is due to the ease by which strong constraints can be placed on the surface normals from single viewpoints. Polarization therefore offers huge benefits to shape-from-shading and related methods. As explained above, the normals are not fully constrained using these techniques, so additional methods are required to complete the reconstruction [17, 21]. It is also possible to model surfaces that are usually inaccessible to computer vision such as transparent surfaces [21]. As already mentioned, polarization from the atmosphere has been applied to image enhancement outdoors [19] and underwater [20].

The difference in polarizing properties between metallic and dielectric reflection [18] has been used for segmentation [15], while the difference between specular and diffuse properties has allowed the two reflection components to be separated [22]. Related work has allowed improved laser-based range finding, by minimizing the effects of inter-reflections [23]. Other work has exploited polarization by specular reflection for separating transmitted scenes from reflected scenes in a glass window [24, 25]. Polarization has also found a range of

Definition

The device which polarizes the light when the light goes through it.

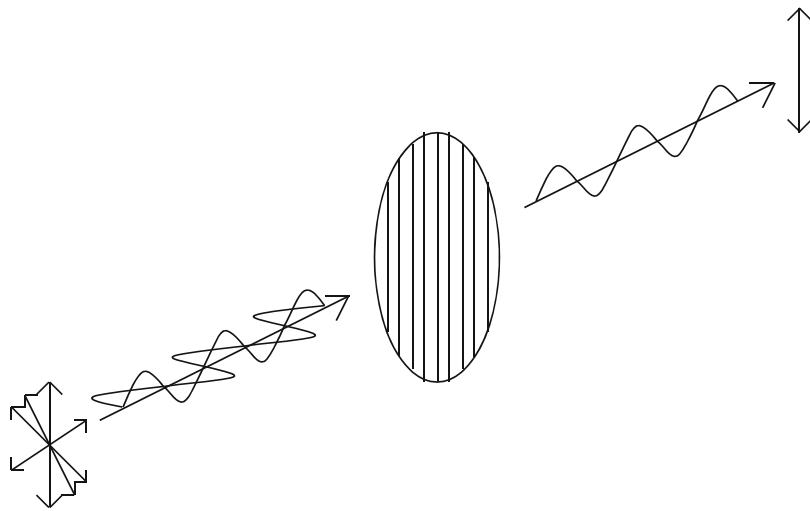

Background

Polarizers makes the light oscillate in one direction. The polarization state of light changes if it hits any materials, and polarization of the light is useful in many application fields. Polarizers are made artificially since natural objects usually do not change the light to be always perfectly polarized.

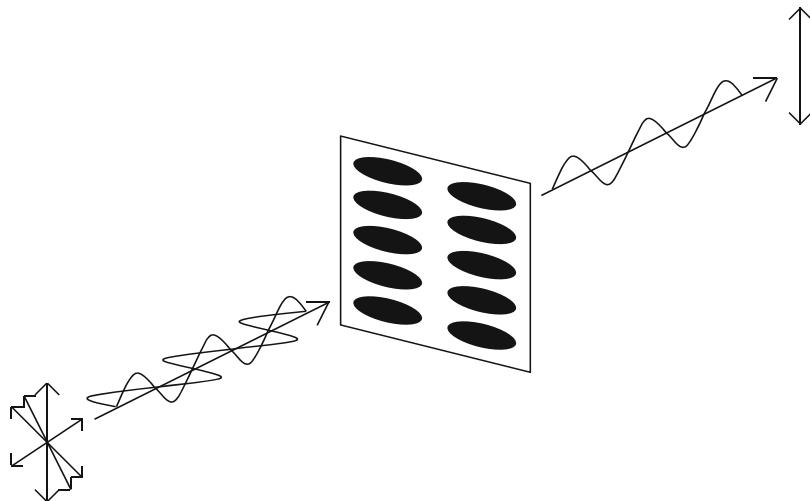

Theory

There are two kinds of perfectly polarized light: linearly polarized light and circularly polarized light. This entry first explains linear polarizers, and then explains circular polarizers.

Figure 1 is the typical illustration of linear polarizer. Linear polarizer is often expressed as a circle with some straight lines inside. The orientation of the lines expresses the orientation of oscillation of the light transmitted through the polarizer. Figure 1 represents the case when the

Polarizer, Fig. 1 Illustration of linear polarizer

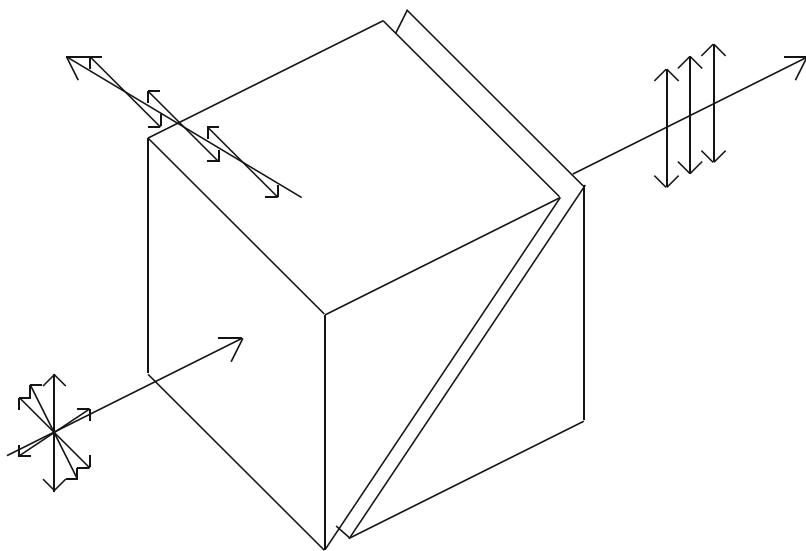

Polarizer, Fig. 2 Dichroic polarizer

unpolarized light goes through the polarizer, and then, the electric vector field of the transmitted light oscillates only in vertical direction.

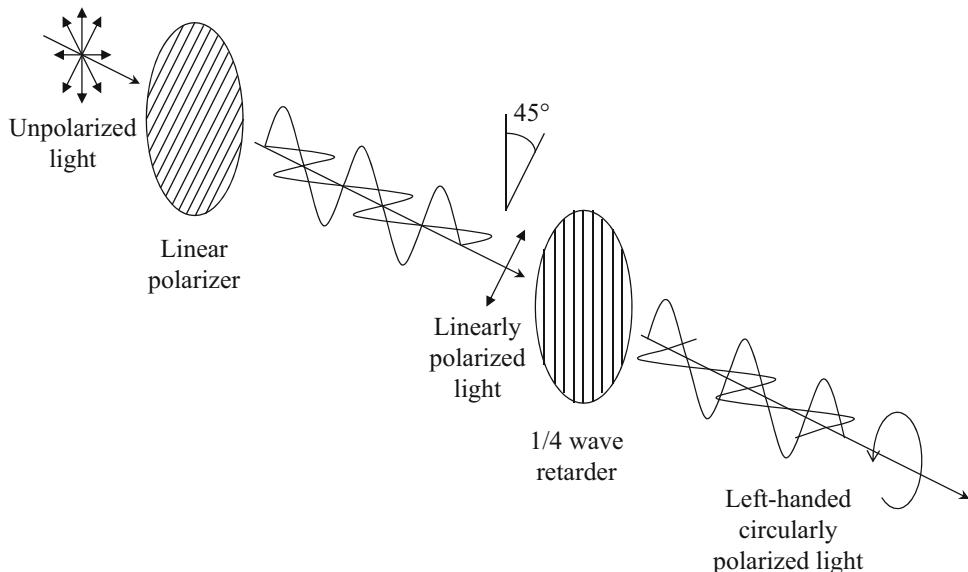

Typical polarizers are dichroic polarizers and wire-grid polarizers. The typical material used in dichroic polarizer is iodine. As is shown in Fig. 2, if the long axis of iodine molecule is lining up horizontally, the light transmitted through the polarizer will be vertically polarized. In this case, the horizontal component of the light is absorbed by the iodine molecule. The same applies to the wire-grid polarizers: If the wire-grid is aligned

horizontally, the transmitted light becomes vertically polarized.

Polarizers composed of prisms are also widely used. The typical material used in these polarizers is calcite. There are many types of prism polarizers such as Glan Taylor Polarizer, Glan Thompson Polarizer, Wollaston Polarizer, Rochon Polarizer, Nicol Polarizer, etc. Figure 3 is an illustration of Glan Taylor Polarizer. Two calcite prisms are separated by thin layer of the air. Calcite is a birefringent material, and the extraordinary ray is only transmitted through this polarizer.

Polarizer, Fig. 3 Polarization prism which is called Glan Taylor Polarizer

Polarizer, Fig. 4 Circular polarizer

Circularly polarized light is generated by circular polarizer. The circular polarizer is consisted of linear polarizer and 1/4 wave retarder as is shown in Fig. 4. The angle between the transmission axis of linear polarizer and the fast axis of 1/4 wave retarder is set to be 45°.

Application

Liquid crystal display and liquid crystal projector use two linear polarizers in order to change the brightness of the light. In order to produce a three-dimensional view using projectors, polar-

ized 3D glasses are often used. The viewer wears the polarized 3D glasses, and watch the screen. Two images are superimposed into the screen; however, each eye perceives different image. This structure makes the viewer to recognize the 3D effect.

Definition

Principal component analysis (PCA) is a standard tool in modern data analysis and is used by almost all scientific disciplines. The goal of PCA is to identify the most meaningful basis to reexpress a given data set. It is expected that this new basis will reveal hidden structure in the data set and filter out the noise. There are so many applications such as dimensionality reduction, data compression, feature extraction, and data visualization.

Background

Describe the background of the entry. The modern form of PCA was formalized by [1] who also introduced the term *principal component*. It is also known as the Karhunen–Loëve transform.

Observations are often described by several dependent variables which are, in general, intercorrelated and include noise. PCA is used to extract the important information from such observations and to reduce the noise. To achieve this goal, PCA computes a set of new orthogonal variables called *principal components* which are obtained as linear combinations of the original variables. The values of these new variables for the observations are called *factor scores*. They can be interpreted as the projections of the observations onto the principal components. PCA can be also formulated as the linear projection that minimizes the average projection cost defined as the mean squared distance between the data points and their projections [2].

Several reformulations or extensions of PCA have been proposed. PCA can be expressed as the maximum likelihood solution of a probabilistic latent variable model [3]. This reformulation is known as *probabilistic PCA*. A nonlinear generalization of PCA, which is known as *kernel PCA*, is also proposed by using the approach of kernel learning [4]. Sparse principal component analysis finds sparse coefficients by introducing a constraint on the norm of the coefficients [5]. This sparseness makes the interpretation of the results of PCA easier.

Theory

Let $X = [\mathbf{x}_1, \dots, \mathbf{x}_N]$ be the data set to be analyzed by PCA, where each column is a single observation described by M variables. Then the sample mean vector $\bar{\mathbf{x}}$ and the sample covariance matrix Σ can be represented by

$$\bar{\mathbf{x}} = \frac{1}{N} \sum_{i=1}^N \mathbf{x}_i \quad (1)$$

$$\Sigma = \frac{1}{N} \sum_{i=1}^N (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})^T = \frac{1}{N} \tilde{X} \tilde{X}^T \quad (2)$$

where the matrix \tilde{X} is defined as $\tilde{X} = [\mathbf{x}_1 - \bar{\mathbf{x}}, \dots, \mathbf{x}_N - \bar{\mathbf{x}}]$.

To extract the important information from the observations, PCA computes factor scores as linear combinations of the original variables

$$y_{1i} = \mathbf{a}_1^T (\mathbf{x}_i - \bar{\mathbf{x}}), \quad (i = 1, \dots, N) \quad (3)$$

where $\mathbf{a}_1 = (a_{11}, \dots, a_{M1})^T$ is a set of weights of the linear combinations. The optimum weight vector \mathbf{a}_1 is obtained so that the sample variance of the new variable is maximized under the normalization constraint $\mathbf{a}_1^T \mathbf{a}_1 = 1$. Since the sample variance is represented by

$$V(y_{11}, \dots, y_{1N}) = \mathbf{a}_1^T \Sigma \mathbf{a}_1, \quad (4)$$

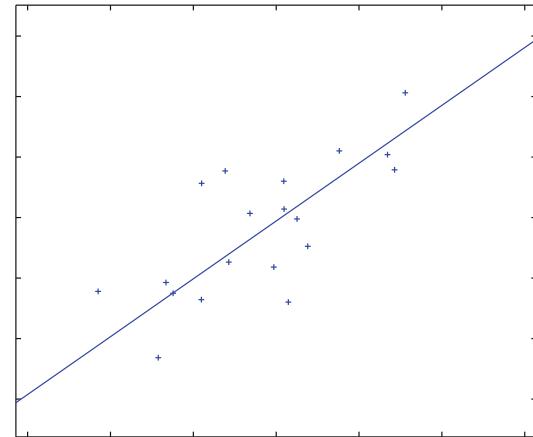

the optimization problem can be defined by using Lagrange multiplier λ_1 as the maximization of the Lagrange function

$$L(\mathbf{a}_1, \lambda_1) = \mathbf{a}_1^T \Sigma \mathbf{a}_1 - \lambda_1 (\mathbf{a}_1^T \mathbf{a}_1 - 1). \quad (5)$$

By setting the derivative of the Lagrange function with respect to the weight vector \mathbf{a}_1 equal to zero, the solution of this problem can be obtained as a unit eigenvector of the covariance matrix Σ corresponding to the largest eigenvalue λ_1 as

$$\Sigma \mathbf{a}_1 = \lambda_1 \mathbf{a}_1. \quad (6)$$

If the vector \mathbf{a}_1 is multiplied from the left, the maximum variance is given by

Principal Component Analysis (PCA), Fig. 1 An example of principal axis for two-dimensional samples

$$V(y_{11}, \dots, y_{1N}) = \mathbf{a}_1^T \Sigma \mathbf{a}_1 = \lambda_1. \quad (7)$$

Figure 1 shows an example of the first principal axis for the two-dimensional samples.

The second principal components

$$y_{2i} = \mathbf{a}_2^T (\mathbf{x}_i - \bar{\mathbf{x}}), \quad (i = 1, \dots, N) \quad (8)$$

can be defined as a new variable which maximizes the projected variance among all possible directions orthogonal to the first principal axis under the constraint on the normalization. The optimum coefficient vector \mathbf{a}_2 is also obtained as a unit eigenvector of the covariance matrix Σ corresponding to the second largest eigenvalue λ_2 . Similarly, additional principal components can be defined in an incremental fashion. For the general case of L -dimensional projection, the optimal linear projection of PCA

$$Y = A^T \tilde{X} \quad (9)$$

can be obtained by taking the L eigenvectors $A = [\mathbf{a}_1, \dots, \mathbf{a}_L]$ of the covariance matrix Σ corresponding to the L largest eigenvalues $\lambda_1, \dots, \lambda_L$. Then the eigenvector equation is given by

$$\Sigma A = A \Lambda, \quad (10)$$

where $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_L)$.

PCA is closely related with the singular value decomposition (SVD) of the data matrix. The data matrix \tilde{X} can be decomposed by SVD as

$$\tilde{X} = S\Delta V^T, \quad (11)$$

where S is the matrix of left singular vectors, V is the matrix of right singular vectors, and Δ is the diagonal matrix of singular values. By using this relation, the covariance matrix can be rewritten as

$$\Sigma = \frac{1}{N} \tilde{X} \tilde{X}^T = \frac{1}{N} S \Delta V^T V \Delta S^T = \frac{1}{N} S \Delta^2 S^T. \quad (12)$$

By multiplying S from the right, the eigenvector equation is obtained as

$$\Sigma S = S \frac{1}{N} \Delta^2. \quad (13)$$

This shows that the weight vectors A are equal to S and the diagonal matrix of the eigenvalues Λ is equal to $\frac{1}{N} \Delta^2$ if the number of principal components L is equal to the rank of the data matrix \tilde{X} . From these relations, the matrix of factor scores Y can be represented as

$$Y = A^T \tilde{X} = S^T S \Delta V^T = \Delta V^T. \quad (14)$$

This shows that the principal components are also obtained from the SVD of the data matrix \tilde{X} . By using this relation, the data matrix \tilde{X} can be represented as the product of the score matrix by the weight vectors A :

$$\tilde{X} = S \Delta V^T = A Y = A A^T \tilde{X}. \quad (15)$$

This means that the original data matrix \tilde{X} can be reconstructed from the factor scores.

If the number of principal components L is less than the rank of \tilde{X} , this reconstruction gives

an approximation of the original data matrix. The mean squared errors between the original observations and the approximations are then given by

$$\begin{aligned} \varepsilon^2(L) &= \frac{1}{N} \sum_{i=1}^N \|(\mathbf{x}_i - \bar{\mathbf{x}}) - A A^T (\mathbf{x}_i - \bar{\mathbf{x}})\|^2 \\ &= \sum_{i=1}^{\text{rank}(\tilde{X})} \lambda_i - \sum_{i=1}^L \lambda_i \end{aligned} \quad (16)$$

which is simply the sum of the $\text{rank}(\tilde{X}) - L$ smallest eigenvalues. This means that PCA is minimizing this approximation errors by selecting the principal subspace spanned by the eigenvectors corresponding to the L largest eigenvalues.

Application

There are many applications of PCA in pattern recognition or computer vision. One of the famous applications of PCA is for face recognition [6]. Face images are decomposed into a set of characteristic feature images called “eigenfaces,” which are the eigenvectors computed by PCA to the training set of face images. Recognition is performed by projecting a new face image into the subspace spanned by the eigenfaces and then classifying the face by comparing the distances of factor scores. Figure 2 shows examples of the eigenfaces computed from 200 face images.

PCA is also used to construct 3-D object models from their appearances [7]. To obtain a low-dimensional subspace of object appearance parameterized by pose and illumination, PCA is applied to a large set of images obtained by varying pose and illumination. Then a new image is projected to the constructed subspace, and the

Principal Component Analysis (PCA), Fig. 2 Examples of eigenfaces computed from 200 face images

recognition is performed on the subspace. The object's pose in the image is also determined from the position of the projection on the subspace.

Definition

Projection transformation describes the transformation from a 3D scene to a 2D image.

Background

The actual projection transformation depends on the camera's projection model and is determined by the relationship between the center of projection (optical center) and the projection plane (image plane). If the center of projection is at a finite distance from the projection plane, it is a perspective transformation. If the center of projection is at infinity, the projection is parallel, known as an orthographic projection. There are several possible transformations between the two extremes, and the reader is referred to entry “[Affine Camera](#)” for more information.

In computer graphics a projection transformation transforms three-dimensional eye coordinates into points in three-dimensional *clip coordinates*. Besides various types of projection as mentioned above, it defines the *viewing volume*, which determines which objects or parts of objects are projected onto the screen. The viewing volume, also known as *viewing frustum*, is an six-sided enclosure defined by clipping planes: Primitives outside the viewing volume are not displayed.

Definition

From several images of a scene and the coordinates of corresponding points identified in the different images, it is possible to construct a three-dimensional point-cloud model of the scene and compute the camera locations. From uncalibrated images the model can be reconstructed up to an unknown projective transformation, which can be upgraded to a Euclidean model by adding or computing calibration information.

P

Background

Projective reconstruction refers to the computation of the structure of a scene from images taken with uncalibrated cameras, resulting in a scene structure, and camera motion that may differ from the true geometry by an unknown 3D projective transformation.

Suppose that a set of interest points are identified and matched (or tracked) in several images. The configuration of the corresponding 3D points and the locations of the cameras that took these images are supposed unknown. The task of reconstruction is to determine the values of these unknown quantities.

Formally, assume that a set of image points $\{\mathbf{x}_{ij}\}$ are known, where \mathbf{x}_{ij} represents the image coordinates of the j -th point seen in the i -th image. It is generally not required that every point's location be known in every image, so only a subset of all possible \mathbf{x}_{ij} are given. The structure-from-motion (SfM) problem is to determine the camera projection matrices \mathbf{P}_i and the 3D point locations \mathbf{X}_j such that the projection of the j -th point in the i th image is the measured \mathbf{x}_{ij} . Assuming a pinhole (projective) camera model, this relationship is expressed as a linear relationship:

$$\mathbf{x}_{ij} = \mathbf{P}_i \mathbf{X}_j, \quad (1)$$

where \mathbf{P}_i is a 3×4 matrix of rank 3, \mathbf{X}_j and \mathbf{x}_{ij} are expressed in homogeneous coordinates, and the equality is intended to hold only up to an unknown scale factor λ_{ij} . More precisely, therefore, the projection equation is

$$\lambda_{ij} \mathbf{x}_{ij} = \mathbf{P}_i \mathbf{X}_j. \quad (2)$$

In the SfM problem, cameras \mathbf{P}_i and points \mathbf{X}_j are to be determined, given only the point correspondences.

Homogeneous Coordinates

Both 2D (image) points and 3D (world) points are most conveniently expressed in *homogeneous coordinates*. Thus, an image point \mathbf{x} is represented by a 3-vector $\mathbf{x} = (u, v, w)^\top$, known as its homogeneous representation. The relationship to the standard Euclidean (nonhomogeneous) coordinates (x, y) of the point is given by $x = u/w$ and $y = v/w$. This process of division by the final coordinate of the homogeneous vector is known as *dehomogenization*. Note that two vectors $\mathbf{x} = (u, v, w)^\top$ and $\mathbf{x}' = (u', v', w')^\top$ represent the same point in Euclidean coordinates if and only if $\mathbf{x} = k\mathbf{x}'$ for some nonzero constant k . Thus, a given point may be expressed in infinitely many different ways in homogeneous coordinates. This is analogous with the way a given rational number has many different representations, such as $1/2 = 2/4 = 3/6 = k/2k$ for any k . One particularly convenient homogeneous representation of

a point is the 3-vector with unit final coordinate: $(x, y, 1)^\top$.

Homogeneous coordinates (3-vectors) with final coefficient zero do not coincide to any real point in nonhomogeneous coordinates, since the process of dehomogenization involves division by zero. Such points are commonly known as points at infinity. The vector $(0, 0, 0)^\top$ is not considered to be a valid set of homogeneous coordinates.

In a similar way, 3D points are represented by homogeneous 4-vectors $\mathbf{X} = (x, y, z, t)^\top$. The main advantage of using homogeneous coordinates to represent world and image points is that Eq. (1) has a particularly simple form as a linear relationship between the homogeneous coordinates of the points.

Two homogeneous vectors differing by a constant multiplicative factor are considered to be *equivalent* representations of the same point. The set of all equivalence classes of (nonzero) homogeneous $(n+1)$ -vectors form the *projective n-space*, \mathcal{P}^n . In studying projective reconstruction, it is conventional to consider image points to lie in projective 2-space \mathcal{P}^2 , whereas 3D points lie in projective 3-space \mathcal{P}^3 . This identifies the projective space \mathcal{P}^2 consisting of the (image) plane, augmented with points at infinity. Similarly, \mathcal{P}^3 consists of \mathbb{R}^3 along with a plane of points at infinity.

Ambiguity

Expressed in full generality, the solution to the reconstruction problem may only be determined up to an unknown projective transformation, applied both to points and cameras.

A projective transformation of \mathcal{P}^3 , the model for 3-space containing world points, is a mapping:

$$\mathbf{X} \mapsto \mathbf{H}\mathbf{X}$$

where \mathbf{H} is a non-singular 4×4 matrix representing a mapping between homogeneous coordinates. Using this relationship, it is easily seen that the determination of camera matrices \mathbf{P}_i and points \mathbf{X}_j cannot be unique, given only corresponding image coordinates \mathbf{x}_{ij} . Consider

$$\begin{aligned}\mathbf{x}_{ij} &= \mathbf{P}_i \mathbf{X}_j \\ &= (\mathbf{P}_i \mathbf{H}^{-1})(\mathbf{H} \mathbf{X}_j) \\ &= \mathbf{P}'_i \mathbf{X}'_j.\end{aligned}\quad (3)$$

In this relationship, new points $\mathbf{X}'_j = \mathbf{H} \mathbf{X}_j$ are defined in terms of points \mathbf{X}_j and similarly new camera matrices $\mathbf{P}'_i = \mathbf{P}_i \mathbf{H}^{-1}$ in terms of the camera matrices \mathbf{P}_i . Since both $(\{\mathbf{P}_i\}, \{\mathbf{X}_j\})$ and $(\{\mathbf{P}'_i\}, \{\mathbf{X}'_j\})$ give rise to the same projected image coordinates \mathbf{x}_{ij} , there is no way to choose between these two solutions to the reconstruction problem. In fact, there exists a complete family of solutions to the problem, corresponding to all possible choices of the matrix \mathbf{H} . All such solutions are related to each other by the application of a projective transformation and are hence called *projectively equivalent*. A particular solution, consisting of camera matrices \mathbf{P}_i and points \mathbf{X}_j satisfying Eq. (1) is known as a *projective reconstruction* of the scene, computed from the given corresponding image points.

The effect of projective ambiguity is given shown in Fig. 1.

The Projective Reconstruction Theorem

The above analysis does not rule out the possibility that other solutions to this reconstruction problem exist, not related to a particular obtained solution by any projective transformation.

However, this possibility is excluded by the projective reconstruction theorem, which essentially says that if the set of corresponding points \mathbf{x}_{ij} are sufficiently numerous (at least 8 in number), and do not lie in some degenerate configuration, then the solution to the reconstruction problem is unique up to a projective transformation.

The exact statement of the theorem requires the definition of the *fundamental matrix* which will be considered next.

Theory and Applications

Two View Reconstruction

Consider the reconstruction problem for only two images. Rather than using a subscript, entities

belonging to the second camera are distinguished by a prime. Thus, the given input to this problem consists of corresponding points $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i; i = 1, \dots, n$, where the points \mathbf{x}_i come from one image and the \mathbf{x}'_i are the corresponding points in the other.

Let the camera matrices (unknown) be \mathbf{P} and \mathbf{P}' , and let \mathbf{X}_i be the 3D point corresponding to the image points $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i$. The projection equations are

$$\begin{aligned}\lambda_i \mathbf{x}_i &= \mathbf{P} \mathbf{X}_i \\ \lambda'_i \mathbf{x}'_i &= \mathbf{P}' \mathbf{X}_i,\end{aligned}$$

where the scale factors λ_i and λ'_i are explicitly written (but are unknown). These equations may be written in a single system

$$\begin{bmatrix} \mathbf{P} & \mathbf{x}_i \\ \mathbf{P}' & \mathbf{x}'_i \end{bmatrix} \begin{pmatrix} \mathbf{X}_i \\ -\lambda_i \\ -\lambda'_i \end{pmatrix} = \mathbf{0}. \quad (4)$$

Since this equation must have a nonzero solution $(\mathbf{X}_i, -\lambda_i, -\lambda'_i)^\top$, the determinant of the matrix on the left (which shall be denoted as \mathbf{A}) must be zero. Since the point coordinates \mathbf{x}_i and \mathbf{x}'_i each appear in a single column, it follows that the determinant is a bilinear expression in $(\mathbf{x}_i, \mathbf{x}'_i)$, and hence, the equation $\det(\mathbf{A}) = 0$ can be written in the form

$$\mathbf{x}'^\top \mathbf{F} \mathbf{x}_i = 0, \quad (5)$$

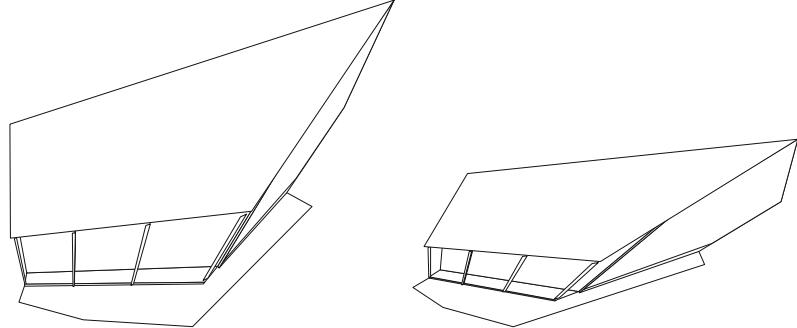

where \mathbf{F} is a 3×3 matrix depending only on the two camera matrices \mathbf{P} and \mathbf{P}' . Consequently, this equation will hold for any pair of corresponding points $(\mathbf{x}_i, \mathbf{x}'_i)$. The matrix \mathbf{F} is called the *fundamental matrix* corresponding to the camera pair $(\mathbf{P}, \mathbf{P}')$.

Closer examination of the matrix \mathbf{A} appearing in (4) reveals the exact form of the matrix \mathbf{F} . Expanding $\det(\mathbf{A})$ by cofactors down the last two columns yields the following formula:

$$F_{jk} = (-1)^{j+k} \det \begin{bmatrix} \mathbf{P}^{(\sim j)} \\ \mathbf{P}'^{(\sim k)} \end{bmatrix}, \quad (6)$$

 correct model. (Figures
 derived from [15])

where $\mathbb{P}^{(\sim j)}$ is the 2×4 matrix obtained by omitting the j th row of \mathbb{P} and $\mathbb{P}'^{(\sim k)}$ is similarly defined.

Another way of writing the Eq. (5) is

$$(\mathbf{x}_i \otimes \mathbf{x}'_i)^\top \mathbf{f} = 0, \quad (7)$$

where $(\mathbf{x}_i \otimes \mathbf{x}'_i)^\top$ is the vector

$$(u'_i \ u_i, u'_i \ v_i, u'_i \ w_i, v'_i \ u_i, v'_i \ v_i, \\ v'_i \ w_i, w'_i \ u_i, w'_i \ v_i, w'_i \ w_i) \quad (8)$$

expressed in terms of coordinates $\mathbf{x}_i = (u_i, v_i, w_i)^\top$ and $\mathbf{x}'_i = (u'_i, v'_i, w'_i)^\top$. Further, \mathbf{f} is the vector $(F_{11}, F_{12}, \dots, F_{33})^\top$ made up of the entries of the fundamental matrix F .

Computing the Fundamental Matrix

Note that the Eq. (7) is a linear equation with unknowns equal to the entries of the fundamental matrix. The explicit form of the equation is given by (8). Given $n \geq 8$ point correspondences, one has a set of linear equations

$$\mathbf{A}\mathbf{f} = \mathbf{0},$$

where \mathbf{A} is an $n \times 9$ matrix, with entries determined by the coordinates of the matched image points. This set of equations is solved to find \mathbf{f} .

Since this is a set of homogeneous equations, there is a solution $\mathbf{f} = \mathbf{0}$, which is not interesting; a nonzero solution is required. With exactly 8-point correspondences, there is an exact solution to this problem. With more points, a least-squares solution is computed. This is most conveniently done by solving the problem

$$\begin{aligned} &\text{Minimize } \|\mathbf{A}\mathbf{f}\| \\ &\text{subject to } \|\mathbf{f}\| = 1, \end{aligned}$$

where the condition $\|\mathbf{f}\| = 1$ is imposed in order to obtain a unique solution (apart from sign). The solution is the eigenvector of $\mathbf{A}^\top \mathbf{A}$ corresponding to the smallest eigenvalue. Alternatively, if \mathbf{A} has singular value decomposition

$$\mathbf{A} = \mathbf{U}\mathbf{D}\mathbf{V}^\top,$$

then the required \mathbf{f} is the last column of \mathbf{V} (assuming that the singular values of \mathbf{D} are in descending order). Once the solution \mathbf{f} is found, the fundamental matrix F is reconstituted from the entries of \mathbf{f} .

The algorithm just described is the so-called 8-point algorithm for computing the fundamental matrix [20]. In order to get good results, it is necessary to preprocess the input image coordinates, using the so-called *normalized 8-point* algorithm, which will be described later.

Projective Reconstruction Theorem

This discussion leads to the basic theorem of projective reconstruction, which states that under appropriate conditions, the reconstruction of a scene from sufficiently many point correspondences in two views is unique up to projective transformation.

Theorem 1 Let $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i; i = 1, \dots, n$ be point correspondences in two views and let $(\mathbf{P}, \mathbf{P}', \{\mathbf{X}_i\})$ be a pair of camera matrices, and some 3D points forming a 3D reconstruction specifically stated

$$\begin{aligned} \lambda_i \mathbf{x}_i &= \mathbf{P} \mathbf{X}_i \\ \lambda'_i \mathbf{x}'_i &= \mathbf{P}' \mathbf{X}'_i \end{aligned} \quad (9)$$

for some unknown $\lambda_i, \lambda'_i \neq 0$. Let \mathbf{H} be an invertible 4×4 matrix \mathbf{H} , and define

$$\begin{aligned} \tilde{\mathbf{P}} &= \mathbf{P} \mathbf{H}^{-1} \\ \tilde{\mathbf{P}}' &= \mathbf{P}' \mathbf{H}^{-1} \\ \tilde{\mathbf{X}}_i &= \mathbf{H} \mathbf{X}_i. \end{aligned} \quad (10)$$

Then the triple $(\tilde{\mathbf{P}}, \tilde{\mathbf{P}}', \{\tilde{\mathbf{X}}_i\})$ is also a reconstruction satisfying the Eq. (9).

Furthermore, if the set of vectors $(\mathbf{x}_i \otimes \mathbf{x}'_i)$ has rank 8 (spans a linear subspace of dimension 8 in \mathbb{R}^9), then any reconstruction $(\tilde{\mathbf{P}}, \tilde{\mathbf{P}}', \{\tilde{\mathbf{X}}_i\})$ satisfying (9) is related to the original reconstruction $(\mathbf{P}, \mathbf{P}', \{\mathbf{X}_i\})$ by (10) for some non-invertible matrix \mathbf{H} .

This theorem was proved in [17, 16].

Note the condition that the set of vectors $(\mathbf{x}_i \otimes \mathbf{x}'_i)$ has rank 8 is exactly the condition that the set of equations of the form (7) has a unique solution. If the rank of the vectors $(\mathbf{x}_i \otimes \mathbf{x}'_i)$ is equal to 9, then there is no solution to the Eq. (7) and the point correspondences $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i$ cannot be

a valid set of points corresponding to projections of a set of 3D points in two images.

If the vectors $(\mathbf{x}_i \otimes \mathbf{x}'_i)$ span a space of dimension less than 8 (for instance, if there are fewer than 8-point correspondences), then there is not a unique matrix \mathbf{F} satisfying the condition (5), and the reconstruction may not be unique up to projectivity.

Extraction of Camera Matrices

Once the fundamental matrix has been computed, it is possible to extract a pair of camera matrices directly from \mathbf{F} . The decomposition is not unique, since according to Theorem 1, there are many pairs of camera matrices $(\mathbf{P}, \mathbf{P}')$ that correspond to the same fundamental matrix \mathbf{F} . It is always possible to assume that one of the camera matrices is of the form $\mathbf{P} = [\mathbf{I}|\mathbf{0}]$, so the problem is simply to compute the other camera matrix \mathbf{P}' .

An algorithm to do this is as follows:

1. Compute the singular value decomposition

$$\mathbf{F} = \mathbf{U} \mathbf{D} \mathbf{V}^\top,$$

where $\mathbf{D} \approx \text{diag}(p, q, 0)$. Note that since \mathbf{F} should have rank 2, the last singular value should be zero, but with noise this will not exactly hold.

2. Define matrices

$$\mathbf{W} = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}; \mathbf{Z} = \begin{bmatrix} 0 & -1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

Define $\hat{\mathbf{D}} = \text{diag}(p, q, r)$ for some value of r , and observe that

$$\mathbf{F} = \mathbf{U} \mathbf{D} \mathbf{V}^\top = (\mathbf{U} \mathbf{Z} \mathbf{U}^\top) (\mathbf{W} \mathbf{D} \mathbf{V}^\top) = \mathbf{S} \mathbf{M}, \quad (11)$$

where \mathbf{S} is a skew-symmetric matrix and \mathbf{M} is defined by this equation. The value of r may be arbitrarily chosen.

3. A pair of camera matrices corresponding to the fundamental matrix F is now

$$P = [I|\mathbf{0}]; P' = [M|\mathbf{u}_3] \quad (12)$$

where \mathbf{u}_3 is the third column of U .

Notes

1. The vector \mathbf{u}^3 satisfies $\mathbf{u}_3^\top F = \mathbf{u}_3^\top S = \mathbf{0}$; it is the generator of the left null-space of F .
2. The value of r , the last diagonal entry of \hat{D} , may be chosen arbitrarily, but a good choice is to set $r = (p + q)/2$ so that M is far from singular.
3. If $r = 0$, the matrix M is singular, but has a particularly simple form, namely, $M = SF$. The corresponding camera $P' = SF|\mathbf{u}_3]$ is sometimes used, but it has the property that the right-hand 3×3 block is singular, so the camera center lies at a nonfinite point.

Complete Projective Reconstruction

Algorithm

It is now possible to state a complete algorithm for projective reconstruction of a scene from two images. Suppose a set of image correspondences $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i; i = 1, \dots, n$ are given.

1. From the image correspondences, compute the fundamental matrix F linearly from Eq. (7), as described in section 3.1.
2. From F find the two camera projection matrices $P = [I|\mathbf{0}]$ and $P' = [M|\mathbf{t}]$, as in section 3.2.
3. The corresponding 3D points \mathbf{X}_i may be computed linearly as the least-squares solution to Eq. (4). This process is called *triangulation*.

The linear triangulation method via Eq. (4) does not give optimal results. A method optimal in the presence of noise is given in [13, 14].

The Normalized Eight-Point Algorithm

It was pointed out in [11] that the simple version of the 8-point algorithm given above can lead to very poor results in some circumstances, but this problem is largely alleviated by simple normalization of the image coordinates.

The issue with the 8-point algorithm for computing F is that the vector (Eq. 8) expressed in terms of image-point coordinates can contain entries of widely different magnitude. This leads to poor conditioning of the linear equations used to solve for F . In addition, the results are dependent on the particular coordinate system (origin and scale) used to express image points.

Given corresponding image points $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i$, one may define normalized coordinates $\hat{\mathbf{x}}_i$ and $\hat{\mathbf{x}}'_i$ obtained from the original coordinates by the following operations:

1. Each \mathbf{x}_i is replaced by $\mathbf{x}_i - \bar{\mathbf{x}}$, where $\bar{\mathbf{x}}$ is the mean (barycenter) of all the coordinates \mathbf{x}_i . This corresponds to a shift of the coordinate origin so that the mean of the \mathbf{x}_i is at the origin.
2. The points are scaled so that their average (alternatively, their root-mean-squared) Euclidean distance from the origin is equal to $\sqrt{2}$. This is done by applying a common scaling to all the points $\mathbf{x}_i - \bar{\mathbf{x}}$. The resulting point is $\hat{\mathbf{x}}_i$.

The reason for choosing an average distance of $\sqrt{2}$ is so that the *average* point has homogeneous coordinates $(1, 1, 1)^\top$.

One applies these operations to the points \mathbf{x}_i and \mathbf{x}'_i independently. Note that both normalization steps are simple affine transformations of the points. These transformations may be written as

$$\hat{\mathbf{x}}_i = T\mathbf{x}_i : \hat{\mathbf{x}}'_i = T'\mathbf{x}'_i \quad (13)$$

where T and T' are 3×3 matrices acting on the homogeneous representations of the points.

Once this normalization has taken place, the computation of the fundamental matrix and the complete projective reconstruction may be carried out using the normalized coordinates. The result is a fundamental matrix \hat{F} satisfying the condition

$$\mathbf{x}_i'^\top \hat{F} \hat{\mathbf{x}}_i = 0 \quad (14)$$

from which by substitution using (13), one has

$$(\mathbf{x}_i'^\top T'^\top) \hat{F} (T\mathbf{x}_i) = 0 = \mathbf{x}_i'^\top F \mathbf{x}_i.$$

From this it follows that $\mathbf{F} = \mathbf{T}'^\top \hat{\mathbf{F}} \mathbf{T}$ is the fundamental matrix corresponding to the original points.

Similarly, if $\hat{\mathbf{P}}$ and $\hat{\mathbf{P}}'$ are camera matrices belonging to a reconstruction from the normalized image coordinates, then

$$\hat{\mathbf{x}}_i = \hat{\mathbf{P}} \hat{\mathbf{X}}_i; \hat{\mathbf{x}}'_i = \hat{\mathbf{P}}' \hat{\mathbf{X}}_i.$$

Once more, substituting for $\hat{\mathbf{x}}_i$ and $\hat{\mathbf{x}}'_i$, it follows that

$$\mathbf{x}_i = \mathbf{T}^{-1} \hat{\mathbf{P}} \hat{\mathbf{X}}_i; \mathbf{x}'_i = \mathbf{T}'^{-1} \hat{\mathbf{P}}' \hat{\mathbf{X}}_i$$

which implies that the reconstruction $(\mathbf{P}, \mathbf{P}', \{\mathbf{X}_i\})$ for the original points $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i$ is given by

$$\mathbf{P} = \mathbf{T}^{-1} \hat{\mathbf{P}}; \mathbf{P}' = \mathbf{T}'^{-1} \hat{\mathbf{P}}'; \mathbf{X}_i = \hat{\mathbf{X}}_i.$$

This normalized 8-point algorithm gives markedly superior results to the unnormalized algorithm, which should never be used directly. For more details and analysis, see [11].

Three View Reconstruction

The 8-point algorithm and other methods involving the fundamental matrix are useful for reconstruction from two views.

If three images of a scene are available and point correspondences are known across all three views, then such linear methods can be extended to three-image reconstruction, using the *trifocal tensor*. This is an extension of the fundamental matrix to three views.

In this analysis of three-view reconstruction, it is convenient from a notational point of view to denote the three camera matrices as \mathbf{A} , \mathbf{B} , and \mathbf{C} , instead of \mathbf{P}_1 , \mathbf{P}_2 , and \mathbf{P}_3 .

Given a three-way image-point correspondence $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i \leftrightarrow \mathbf{x}''_i$, the goal is to find camera matrices \mathbf{A} , \mathbf{B} , and \mathbf{C} and points \mathbf{X}_i such that

$$\mathbf{x}_i = \mathbf{A} \mathbf{X}_i; \mathbf{x}'_i = \mathbf{B} \mathbf{X}_i; \mathbf{x}''_i = \mathbf{C} \mathbf{X}_i. \quad (15)$$

This may be written in a form similar to (4), as follows:

$$\begin{bmatrix} \mathbf{A} & \mathbf{x}_i \\ \mathbf{B} & \mathbf{x}'_i \\ \mathbf{C} & \mathbf{x}''_i \end{bmatrix} \begin{pmatrix} \mathbf{X}_i \\ -\lambda_i \\ -\lambda'_i \\ -\lambda''_i \end{pmatrix} = \mathbf{0}. \quad (16)$$

In this case, the 9×7 matrix on the left is not square. Nevertheless, since there is a solution $(\mathbf{X}_i, -\lambda_i, -\lambda'_i - \lambda''_i)^\top$, the matrix must be rank-deficient. Consequently, any 7×7 submatrix must have vanishing determinant. Each such determinant implies a trilinear relationship between the coefficients of the matching points $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i \leftrightarrow \mathbf{x}''_i$.

It is not necessary to consider all possible 7×7 submatrices to obtain useful relationships. Given three camera matrices \mathbf{A} , \mathbf{B} , and \mathbf{C} , one can define a triply indexed entity \mathcal{T}_i^{qr} :

$$\mathcal{T}_i^{qr} = (-1)^{i+1} \det \begin{bmatrix} \mathbf{A}^{(\sim i)} \\ \mathbf{B}^{(q)} \\ \mathbf{C}^{(r)} \end{bmatrix}. \quad (17)$$

Here, all indices range from 1 to 3. Further, $\mathbf{B}^{(q)}$ and $\mathbf{C}^{(r)}$ represent rows q and r of the matrices \mathbf{A} and \mathbf{B} , whereas $\mathbf{A}^{(\sim i)}$ means the matrix \mathbf{A} with row i omitted. This results in a 4×4 matrix, whose determinant with the indicated sign is the chosen value \mathcal{T}_i^{qr} . This triply indexed set of 27 values is known as the *trifocal tensor* corresponding to the three cameras. Note that this tensor depends only on the camera matrices and not any image points.

Now, it may be shown [12, 15] that the coordinates of any matching triple $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i \leftrightarrow \mathbf{x}''_i$ satisfy trilinear relations:

$$\sum_{i,j,k,q,r=1}^3 x^i x'^j x''^k \epsilon_{jqu} \epsilon_{krv} \mathcal{T}_i^{qr} = 0_{uv}. \quad (18)$$

This relation is to be interpreted as follows:

1. The indices on the point coordinates, such as x^i , denote the i th coordinate of the homoge-

- neous vector representing the point $\mathbf{x} = (x^1, x^2, x_3)^\top$.
2. The symbol ϵ_{jqu} (and similarly ϵ_{krv}) has value 0 unless j, q , and u are all distinct; otherwise, it is +1 if jqu is an even permutation of the three indices 1, 2, and 3 and -1 if it is an odd permutation.
 3. The indices u and v are free indices, and each choice of u and v leads to a different trilinear relation, for a total of 9 distinct relations. However, only 4 of these relations are linearly independent.

In the case where the first camera matrix \mathbf{A} has the canonical form $[\mathbf{I}|\mathbf{0}]$, the expression (Eq. 17) for the trifocal tensor may be written simply as

$$\mathcal{T}_i^{qr} = b_i^q c_4^r - b_4^q c_i^r, \quad (19)$$

where b_i^q is the element in row q and column i of \mathbf{B} and c_i^r is defined analogously.

A complete three-view reconstruction algorithm can then be outlined as follows:

1. From point correspondences $\mathbf{x}_i \leftrightarrow \mathbf{x}'_i \leftrightarrow \mathbf{x}''_i$ for $i = 1, \dots, n$, each relation of the form (18) gives 4 linearly independent linear constraints on the entries of the trifocal tensor. From 7-point correspondences there are sufficiently many equations to compute \mathcal{T}_i^{qr} linearly.
2. As with two-view reconstruction, it is possible to determine the form of the two other camera matrix \mathbf{B} and \mathbf{C} from the entries of the trifocal tensor using the formula (19).
3. Finally, by triangulation from three views based on the Eq. (16), one can find the image points \mathbf{X}_i , completing the reconstruction from three views.

A few more comments.

1. In the definition (18), the first camera matrix \mathbf{A} is treated differently from the two others (in that two rows of \mathbf{A} appear in the determinant, but only one from \mathbf{B} and \mathbf{C}). There are two other similarly defined trifocal tensors in

which matrices \mathbf{B} or \mathbf{C} are distinguished in this way.

2. Unlike with the fundamental matrix, there are relations similar to (18) that hold for line correspondences or mixed line and point correspondences. Thus, computation of the trifocal tensor and hence projective reconstruction is possible not only from point correspondences but from mixed correspondences of this type.

Minimal Configurations

The reconstruction algorithms from two or three views described in Sections “Two View Reconstruction” and “Three View Reconstruction” require 8 or 7 points, respectively. However, it is possible to carry out reconstruction using only 7 points from 2 views, or as few as 6 points from 3 views.

From two views, the algorithm is easily explained. Given only 7-point correspondences, the set of equations $\mathbf{x}_i'^\top \mathbf{F} \mathbf{x}_i = 0$ represents a set of 7 homogeneous equations in the 9 entries of \mathbf{F} . The solution to this equation set is a two-parameter family $\mathbf{F} = \lambda \mathbf{F}_1 + \mu \mathbf{F}_2$ where \mathbf{F}_1 and \mathbf{F}_2 are determined by solving this system.

The condition that the fundamental matrix \mathbf{F} must be a singular matrix gives a further equation $\det \mathbf{F} = 0$. Since \mathbf{F} is a 3×3 matrix, this leads to a cubic homogeneous equation in λ and μ . Solving this cubic equation gives either one or three real solutions for the ratio $\lambda : \mu$ and hence one or three solutions (determined as ever up to scale) for the fundamental matrix \mathbf{F} . In short, from 7-point correspondences one or three possible fundamental matrices may be computed. From these possible values of \mathbf{F} , the rest of the method described previously will lead to a projective reconstruction, in fact either a unique or three possible reconstructions.

A method for computing the projective reconstruction from three views of 6 points is described in [27].

Factorization Algorithms

The algorithms described previously for projective reconstruction work on two or three images.

In many cases, one has many more images of a scene to use for reconstruction. To handle this situation, a variant of the Tomasi-Kanade factorization algorithm [30] may be used to do reconstruction from many views at once. This is the algorithm of Sturm and Triggs [29] for projective reconstruction.

As input, consider a set of image points \mathbf{x}_{ij} for $i = 1, \dots, m$ and $j = 1, \dots, n$, where \mathbf{x}_{ij} represents the image of the j th point in the i th image. It is assumed (and required) that every point should be visible in every image, so \mathbf{x}_{ij} is defined for all (i, j) .

The projection equations are of the form

$$\lambda_{ij} \mathbf{x}_{ij} = \mathbf{P}_i \mathbf{X}_j, \quad (20)$$

where the constants λ_{ij} are required scale factors, the so-called *projective depths* of the points. This set of equations may be put together in one matrix equation as follows:

$$\begin{bmatrix} \lambda_{11} \mathbf{x}_{11} & \lambda_{12} \mathbf{x}_{12} & \cdots & \lambda_{1n} \mathbf{x}_{1n} \\ \lambda_{21} \mathbf{x}_{21} & \lambda_{22} \mathbf{x}_{22} & \cdots & \lambda_{2n} \mathbf{x}_{2n} \\ \vdots & \ddots & & \vdots \\ \lambda_{m1} \mathbf{x}_{m1} & \lambda_{m2} \mathbf{x}_{m2} & \cdots & \lambda_{mn} \mathbf{x}_{mn} \end{bmatrix} = \begin{bmatrix} \mathbf{P}_1 \\ \mathbf{P}_2 \\ \vdots \\ \mathbf{P}_m \end{bmatrix} [\mathbf{X}_1 \ \mathbf{X}_2 \ \dots \ \mathbf{X}_n]. \quad (21)$$

In this equation the matrix on the left has dimension $3m \times n$, since each $\lambda_{ij} \mathbf{x}_{ij}$ is a 3-vector.

This set of equations has the form

$$\Lambda \odot \mathbf{W} = \mathbf{P} \mathbf{X} \quad (22)$$

where

$$\Lambda = \begin{bmatrix} \lambda_{11} & \dots & \lambda_{1n} \\ \vdots & \ddots & \vdots \\ \lambda_{m1} & \dots & \lambda_{mn} \end{bmatrix}; \mathbf{W} = \begin{bmatrix} \mathbf{x}_{11} & \dots & \mathbf{x}_{1n} \\ \vdots & \ddots & \vdots \\ \mathbf{x}_{m1} & \dots & \mathbf{x}_{mn} \end{bmatrix} \quad (23)$$

and \odot is to be interpreted as an elementwise product, so that $\Lambda \odot \mathbf{W}$ is the matrix on the left of (21).

From the form of (21), it is evident that the matrix on the right has rank 4, since it is the product $\mathbf{P} \mathbf{X}$ of matrices of dimension $3m \times 4$ and $4 \times n$. This is a low-rank constraint on the matrix $\Lambda \odot \mathbf{W}$ of depth-weighted image coordinates.

Unfortunately, although the matrix \mathbf{W} of image coordinates is known, the matrix Λ of projective depths is not known. With an incorrect set of projective depths, the matrix $\Lambda \odot \mathbf{W}$ will not have the expected rank 4. This suggests an algorithm in which the factorization and the projective depths are estimated alternately as follows:

1. Form the matrix \mathbf{W} of homogeneous image coordinates as given in (Eq. 23), and define Λ^0 in which all $\lambda_{ij}^0 = 1$. Then carry out the following steps iteratively for $k = 0, \dots, N$:
 - (a) Find the closest rank-4 matrix \mathcal{W}^k to $\Lambda^k \odot \mathbf{W}$.
 - (b) Define Λ^{k+1} to be the matrix of weights λ_{ij}^{k+1} so that $\Lambda^{k+1} \odot \mathbf{W}$ is as close as possible to \mathcal{W}^k under Frobenius norm.
2. Compute a final factorization $\mathcal{W}^N = \mathbf{P} \mathbf{X}$, to obtain \mathbf{P} and \mathbf{X} providing the camera matrices and point locations, respectively.

In step 1(a), the low-rank factorization is carried out by singular value decomposition. Suppose $\Lambda^k \odot \mathbf{W} = \mathbf{U} \mathbf{D} \mathbf{V}^\top$. Let $\hat{\mathbf{D}}$ be the matrix obtained by setting all but the four first (largest) diagonal entries of \mathbf{D} to zero. Then set $\mathcal{W}^k = \mathbf{U} \hat{\mathbf{D}} \mathbf{V}^\top$. The number of iterations N is vaguely defined in this algorithm. The intention is to continue until “convergence,” but as will be remarked below, continuing to convergence is problematic.

P

Variants of the Method

It has been observed [24] that the bare projective algorithm as given above will converge to a trivial limit in which all the values of λ_{ij} will be zero, except for those values in 4 columns of

Λ . This solution is spurious, since zero values of the projective depths are not possible for a geometrically valid reconstruction. In addition, convergence is very slow. Therefore, different variants on the algorithm have been proposed, as follows:

1. In the original paper of Sturm and Triggs [29], an initialization of the projective depths is proposed, in which projective depths are derived from two-view reconstructions.
2. A viable strategy is to carry out only a fixed small number of alternation steps, since this significantly improves the solution without encountering a trivial solution.
3. A further step of normalization of the projective depths λ_{ij} may be used [15]. Observe that if $\lambda_{ij}\mathbf{x}_{ij} = \mathbf{P}_i\mathbf{X}_j$, for all (i, j) , then for any constants c_i and d_j ,

$$c_i d_j \lambda_{ik} \mathbf{x}_{ij} = (c_i \mathbf{P}_i) (d_j \mathbf{X}_j). \quad (24)$$

Thus, each λ_{ij} may be replaced by $c_i d_j \lambda_{ij}$ without materially changing the factorization. Thus, one may at will multiply each i th row of Λ by c_i and the j th column by a constant d_j . In [15] it is suggested that constants c_i and d_j may be chosen so that first the rows and then the columns of Λ sum to unity. However, no analysis of this normalization procedure is given there.

4. More complex schemes for normalization schemes are given in [24] and [21, 22], for which convergence to a meaningful (local) minimum of some cost function is demonstrated.
5. Methods to accommodate missing data or outliers in projective factorization algorithms have been proposed. Though many algorithms have addressed missing data in matrix factorization (for instance, [2–4, 18, 28]), a notable paper addressing projective factorization specifically is [5].
6. L_1 -factorization has been recognized as more robust alternative to matrix factorization; an effective method is given in [6].

Bundle Adjustment

Given measured image points \mathbf{x}_{ij} in several images, the projection equations $\lambda_{ij}\mathbf{x}_{ij} = \mathbf{P}_i\mathbf{X}_j$ cannot be satisfied exactly if there is any inaccuracy, or noise, in the measurements. Therefore, in finding the projection matrices \mathbf{P}_i and 3D points \mathbf{X}_j to satisfy these equations, it is appropriate to find an approximate solution. Typically, this solution will be one that minimizes some appropriate cost function representing a residual error in the solution.

Since errors arise in the measurement of the coordinates of image points, it is appropriate to seek a solution that minimizes the error with respect to the measured image coordinates. This corresponds to choosing a cost function of the form

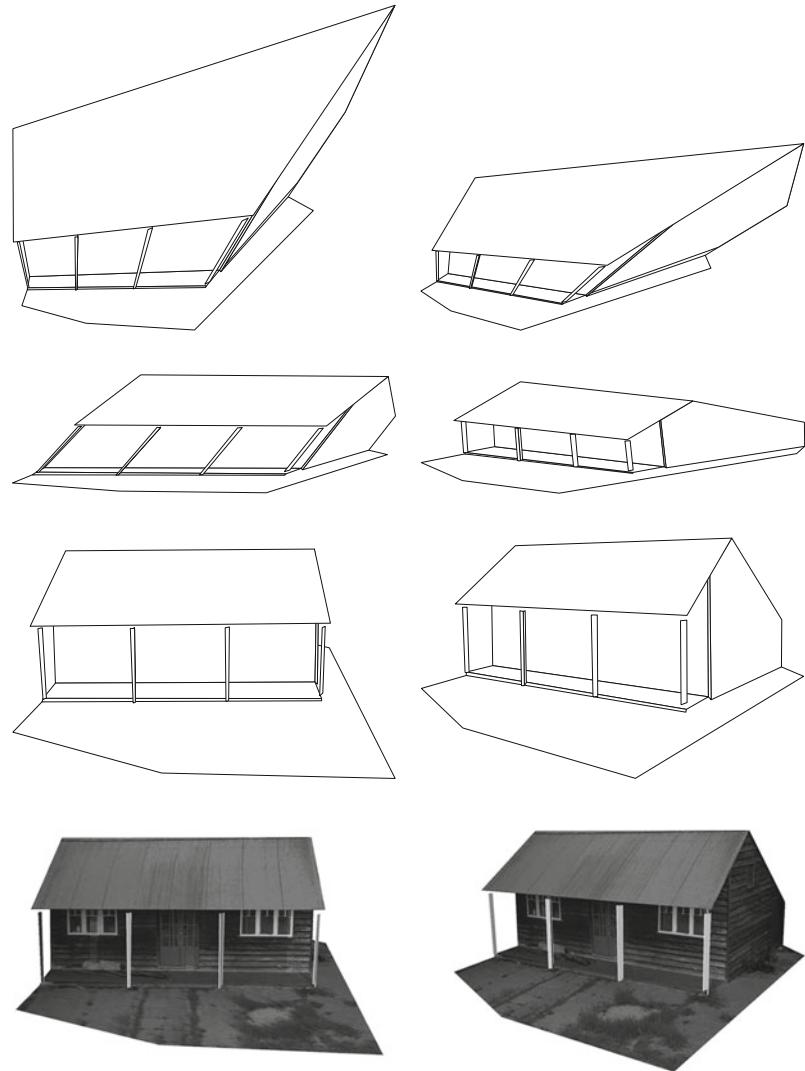

$$C(\{\mathbf{X}_j\}, \{\mathbf{P}_i\}) = \sum_{i,j \in \mathcal{N}} d(\mathbf{x}_{ij}, \mathbf{P}_i\mathbf{X}_j)^2, \quad (25)$$

where \mathcal{N} is a set of pairs (i, j) for which \mathbf{x}_{ij} is measured. Further, $d(\mathbf{x}_{ij}, \mathbf{P}_i\mathbf{X}_j)$ represents the Euclidean distance in the two-dimensional image plane between the measured point \mathbf{x}_{ij} and the projected point $\mathbf{P}_i\mathbf{X}_j$. This is commonly referred to as the *reprojection error*. The cost is to be minimized over all choices of \mathbf{P}_i and \mathbf{X}_j . This is a nonlinear function. The choice of the squared distance means that a nonlinear least-squares cost function is to be minimized. The motivation for this choice is the observation that the solution to this least-squares problem represents the maximum likelihood (ML) solution, under the assumption that each image measurement error conforms to an isotropic Gaussian distribution, each point measurement being independent of the others.

Minimizing the cost function (25) over all choices of the variables \mathbf{P}_i and \mathbf{X}_j is known as *bundle adjustment*. Since this is a nonlinear optimization problem, an iterative algorithm is required. The most common algorithm used to minimize this cost function is the Levenberg–Marquardt algorithm [15, 19, 23, 31]. In order to converge to the globally optimal solution, a good initial solution is necessary. Such an initial solu-

Projective Reconstruction, Fig. 2

Stratification. The projective reconstruction (top row) obtained by uncalibrated reconstruction techniques is first upgraded to an affine reconstruction (second row). In the affine reconstruction, parallel lines in the image are parallel in the reconstruction, but geometric structures are still skewed. In the final stage of the reconstruction, the true Euclidean model (third row) is computed, in which angles and dimensions are correct up to an indeterminate scale. The fourth row shows two views of the texture-mapped model. (Figures derived from [15])

tion is found by applying any of the algorithms previously described in this chapter.

Robust Cost Functions

The cost function (25) is suitable and represents the ML solution if the measured point coordinates conform to a Gaussian distribution, and may be used if there are no gross errors (outliers) among the measured points. In most cases, this is unlikely, and a more robust cost function is to be preferred. In this case, the squared Euclidean distance function $d(\cdot, \cdot)^2$ is replaced by some other function $f(\cdot, \cdot)$ that is more tolerant of outliers, meaning that $f(\mathbf{x}, \mathbf{y})$ grows less rapidly

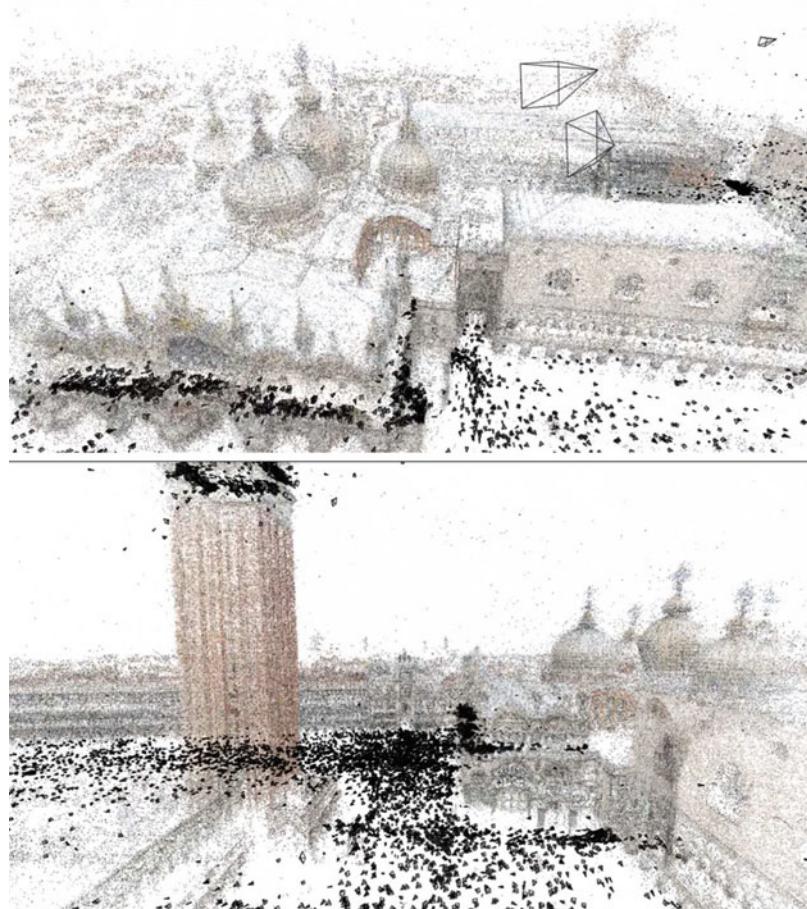

than $d(\mathbf{x}, \mathbf{y})^2$ as the distance between the two arguments \mathbf{x} and \mathbf{y} increases. A good choice of robust cost function is the Huber cost function [15, 17]:

$$C(\{\mathbf{X}_j\}, \{\mathbf{p}_i\}) = \sum_{i,j \in \mathcal{N}} H(d(\mathbf{x}_{ij}, \mathbf{p}_i \mathbf{X}_j))^2, \quad (26)$$

where $H(x)^2$ is quadratic for $|x| < \delta$ and linear for $|x| \geq \delta$, and δ is some threshold approximately equal to the standard deviation of the measurements.

Projective Reconstruction, Fig. 3

Below is shown the campanile at *left* and the palace on the *right*. Black pyramids show the position and orientation of the cameras. (Figures are reproduced with thanks to Noah Snavely)

Sparse Methods

A reasonable sized reconstruction problem may involve 1,000 camera matrices P_i and 100,000 points X_j . Consequently, the cost function (25) depends on a large number of variables (311,000 parameters if the cameras are parametrized by 11 parameters). Since the central step in the Levenberg-Marquardt optimization process involves the solution of equations to compute the update of the parameters, this would involve solving a very large set of equations in all the variables. For a dense set of equations in 300,000 parameters, this would be almost impossible.

Fortunately, the set of equations involved in this update process is quite sparse, so the problem is tractable. To see this, note that if a single point X_j is moved, then only the image points x_{ij} involving this point are affected.

Similarly, if some camera matrix P_i is altered, then only image points x_{ij} are changed. This means that each image measurement depends only on the parameters of one 3D point and one camera. This sparse dependence structure for the cost function results in a special sort of sparse structure for the Jacobian matrix. Sparse solution methods may then be used to accelerate the update step and allow it to be run in reasonable time. Methods that are used for this numerical problem include the Schur complement method [15], in which the sparseness of the Jacobian is used to allow the camera updates to be computed first, followed by the point updates. The exact form of the equations is given in [15]. Alternatively, conjugate gradient methods [1] may be used; in such methods the sparseness of the equation set lends itself naturally to sparse methods.

Euclidean Update

A projective reconstruction may be used as an initial step towards a geometrically correct (Euclidean) reconstruction. There are various ways in which this can be done:

1. By determining or knowing the calibration of the cameras. The camera calibration may be known *a priori*, or determined through the process of auto-calibration [9]. Constraints on the camera parameters, such as known focal length, or an assumption that some cameras have the same shared internal parameters, may be enforced easily during bundle adjustment. Automatic methods for auto-calibration often compute an affine reconstruction first, followed by an update to a Euclidean reconstruction and full determination of the camera calibration parameters [8, 10, 25]. This process is known as stratification.
2. By the knowledge of the 3D Euclidean coordinates of some number of *ground-control points*, at least five such points are required [16].
3. If partial camera calibration is known, the full calibration and Euclidean reconstruction may be computed more simply than if no calibration information is given. A notable paper demonstrating this is [26] and more details on self-calibration given different types of partial camera calibration are given in [15].

Figure 2 illustrates the steps from projective to Euclidean reconstruction via stratification.

A large-scale reconstruction, computed from thousands of images, is shown in Fig. 3.

Definition

Human movement modeling is a static and dynamic human appearance representation with feature descriptors. Typical feature descriptors include local and holistic descriptors. Local descriptors mean sparse features extracted locally, i.e., local features [1] or local space-time features [2]; holistic descriptors means dense features extracted inside a human bounding region, i.e., shape/appearance descriptors [3], and motion descriptors [4, 5].

Prototype-based methods [6–9] are a category of approaches representing original feature descriptors with a finite set of indices through feature quantization. Given a large number of descriptors extracted from training images or videos, a vector quantization (or data clustering) algorithm is used to divide the feature space into nonoverlapping cells where each cell is uniquely represented with an integer index. Given the quantization, each test feature can be mapped to an integer index (corresponding to the center of a quantization cell or cluster center) based on exact (or approximate) nearest neighbor search, and finally, recognition can be performed through simple index matching. This scheme is significantly more efficient than the direct descriptor matching schemes due to the

speedup in calculating Euclidean distances in high-dimensional feature spaces.

Background

There are two categories of methods to model human appearances and movements. The first category is local feature-based approaches. In this category, usually a set of local features are extracted across all image regions or video frames, and recognition is based on matching of those features either via histogram comparisons or class voting. For example, a bag-of-features representation is computed and used as the descriptors [10, 11], or a Hough voting-based approaches [12] are used to simultaneously locate humans and recognize their movements.

The second category is holistic feature-based approaches. These approaches typically extract a single high-dimensional feature descriptor from a hypothesized bounding region and classifies it with pre-trained classifier. Typically, a sliding window approach is used over all possible sub-rectangles across images [3] or across all space-time volumes [9, 10], and for every hypothetical bounding region, a holistic descriptor (consisting of appearance descriptor [3] and/or motion descriptor [4]) is extracted and classified into human/nonhuman (for human detection) or action IDs (for action recognition) based on a discriminative classifier trained off-line. The descriptors extracted from hypothetical human bounding region are invariant to human translation and scale variations and typically contain more information due to dense extraction; consequently, those features are much more reliable for recognition. In case of human movement understanding or activity recognition, typically, a generic human detector [3] is used to locate most probable human bounding boxes, and holistic descriptors extracted from all the frames are used for recognition.

Once feature descriptors are extracted from human images or videos, they will be fed into a classifier for recognition and categorization purposes. The classification modules are mostly based on machine learning or pattern recognition

techniques as in the object recognition literature. Classifiers commonly used include NN/ k -NN classifiers [6, 7], Support Vector Machine (SVM) classifiers [2], boosting-based classifiers [5, 13], dynamic time warping [8] for sequence alignment and matching, etc.

Direct descriptor matching and classification-based schemes have been common for human movement recognition. However, for large-scale action recognition problems, such a matching scheme may require tremendous amount of time for computing similarities between descriptor sequences and learning discriminative classifiers. Also, sequence matching (action recognition) involves frame alignment issues. In this regard, an efficient and effective descriptor matching scheme is needed to handle both scalability to the number of training classes and training examples and ability to handle sequence alignment.

Theory

Prototype-based approaches have been very effective in handling scalability to large training data. These approaches typically represent a human action as a sequence of basic action units [6–9]. Each action frame or frame segment (multiple consecutive frames) is represented as one of the holistic action units trained off-line or histogram of local action units (similar to bag of visual words). The action units are usually obtained by feature quantization such as k -means clustering in the feature space. The centers of quantization cells are defined as action units, and all test descriptors belong to a cell are assigned the same index (i.e., the index of the cell).

In [6], an action is represented as a set of pose primitives and n -Gram models are used for action matching. Weinland and Boyer [7] models an action as a set of minimum distances from exemplars to action frames in an exemplar-based embedding space. These action representation methods are compact and efficient but might be limited in capturing global temporal consistency between actions because they either use low-

order statistics such as histograms and n -Grams or use a minimum-distance-based representation which does not enforce temporal ordering.

Relaxing temporal constraints [6] makes action representation more invariant to intra-class variation and, consequently, might be effective in recognizing small numbers of actions, but when the number of action classes is large, global temporal consistency is very important for action recognition due to small inter-class variability (i.e., increased ambiguity between actions). In fact, there have been approaches modeling the global temporal consistency.

Prototype Tree-Based Method

Recently, tree-based methods have been popular for human detection and activity recognition problems. Mikolajczyk and Uemura [14] proposes a random forest method on large number local features for action recognition. Although this method is efficient due to fast nearest neighbor search and can handle action detection problems in difficult cases, action frame time alignment issue is not explicitly addressed. Lin et al. [8] learns an action prototype tree based on hierarchical k-means clustering [15] and aligns action sequences with a fast dynamic time warping algorithm in order to compute accurate similarities between action sequences. More specifically, the cluster centers of leaf nodes (of the tree) are defined as the set of action prototypes. Distances between action prototypes are precomputed and stored in a lookup table, so the sequence alignment and matching stage is very efficient. The action prototype tree-based method learns action prototypes in joint shape and motion space so that human movements can be described more accurately and compactly. This prototype tree model is also applied to sliding window-based framework for simultaneous action detection and recognition in [9]. The prototype tree-based motion modeling methods can also be combined with a Markov model to incorporate prototype transition priors between frames.

Application

Appearance prototype-based methods generally can be applied to all the human-related recognition problems in computer vision including appearance-based human identification, human detection, and human action detection and recognition. More broadly, they can be applied to video surveillance, human-computer interaction, virtual reality, and multimedia understanding.

Open Problems

Human movement modeling still remains challenging due to articulated nature of human bodies and varying camera viewpoints. Although there has been a significant progress on view-dependent appearance and movement modeling, view-invariant human movement modeling is still an open research topic. There has been several efforts to introduce view-invariant descriptors for human movements, but still more research is to be done to be practical in real applications.

► Irradiance

Definition

Radiance L is defined as the power received or emitted per unit solid angle $d\omega$ and per unit projected area $dA \cos \theta$ at a point x in direction (θ, ϕ) :

$$L(x, \theta, \phi) = \frac{d^2\Phi}{d\omega dA \cos \theta}.$$

Φ is the radiant power, which describes the total amount of energy that flows through a surface per time interval [1]. θ is the angle between the surface normal of the differential area dA and the direction under consideration (see Fig. 1). The unit of radiance is watt per steradian per square meter ($\text{W} \cdot \text{sr}^{-1} \cdot \text{m}^{-2}$).

Background

Radiance is a concept from radiometry, the science of measuring radiant energy transfer. It is an essential concept for global illumination algorithms [1]. In computer vision, it is mostly used in the context of light transport in scenes [2]. The equivalent concept in photometry is luminance, with the key difference being that luminance is adjusted to account for the varying sensitivity of the human eye to different wavelengths of light.

Theory

An important aspect of radiance is that it is constant along a line of sight in an empty medium. This follows from the conservation of energy in a small bundle of light rays between two differential surface patches. More formally, given two points x and y at distance $r = |x - y|$ and two small areas dx and dy located at x and y ,

respectively, the radiance leaving dx towards dy is written as

$$L(\mathbf{x} \rightarrow \mathbf{y}) = \frac{d^2\Phi}{d\omega_{x \leftarrow dy} \cos \theta_x dx}. \quad (1)$$

$d\omega_{x \leftarrow dy}$ denotes the solid angle covered by dy as seen from \mathbf{x} . Similarly the radiance arriving at dy from dx is written as

$$L(\mathbf{y} \leftarrow \mathbf{x}) = \frac{d^2\Phi}{d\omega_{y \leftarrow dx} \cos \theta_y dy}. \quad (2)$$

Considering a total vacuum and no additional source of power, all energy in the system must be conserved. This means that all energy leaving from dx towards dy must arrive at dy . Therefore $d^2\Phi$ is equal in both equations, and we can derive

$$L(\mathbf{x} \rightarrow \mathbf{y}) = \frac{d^2\Phi}{d\omega_{x \leftarrow dy} \cos \theta_x dx} \quad (3)$$

$$\begin{aligned} &= \frac{d^2\Phi}{\frac{\cos \theta_y dy}{r^2} \cos \theta_x dx} \\ &= \frac{d^2\Phi}{\frac{\cos \theta_x dx}{r^2} \cos \theta_y dy} \end{aligned} \quad (4)$$

$$= \frac{d^2\Phi}{d\omega_{y \leftarrow dx} \cos \theta_y dy} = L(\mathbf{y} \leftarrow \mathbf{x}). \quad (5)$$

Application

An application of the fact that radiance is constant along a ray can be seen in photography. The correct exposure is hereby determined by measuring the radiance (or more precisely the luminance) of a scene or part of a scene that should be correctly exposed. Once exposure is determined, the scene can be photographed from an arbitrary distance without changing the exposure settings of the camera.

Definition

Radiometric calibration is a process of determining radiometric response functions, which relate sensor irradiance with measured intensity values.

Background

Many computer vision algorithms rely on the assumption that image intensities are linearly related to the image irradiance recorded at the camera sensor. Since most cameras non-linearly alter irradiance values for purposes such as dynamic range compression, this assumption generally does not hold. It is, therefore, important to calibrate the response function of a camera, so that the non-linear mapping can be inverted and subsequent algorithms can assume linearity of intensity observations.

Radiometric calibration aims to estimate the response function f of a camera. The radiometric response function f maps the irradiance I that is captured at the sensor to the image intensity M in the image:

$$M = f(I). \quad (1)$$

For vision algorithms that require irradiance values I rather than measured intensity M as input, the inverse response function $g = f^{-1}$ needs to be determined so that measured intensities can be made linear with respect to irradiances. Since response functions f are monotonic and continuous, they are invertible to determine inverse response functions g uniquely.

Theory

Radiometric calibration methods require means to collect samples of the radiometric response function with some known relationship. One traditional approach is to use a special target, such as a Macbeth color chart [1], which has color patches with known reflectances. By uniformly illuminating the target, known radiances from the color patches are recorded. The radiometric response function is then obtained by relating the sensor irradiance I with the recorded intensity values M . Nayar and Mitsunaga [2] use an optical filter with spatially varying transmittance; the variation corresponds to the radiance ratio.

To avoid using such special equipment, some methods use a set of images of a static scene from a fixed viewpoint, taken with different exposure times, so the radiance ratio is known. Known exposure times provide information about sensor irradiance ratios, which are the ratios of exposure times. In a similar manner with the approach of using a special target, by relating the sensor irradiance I with the measured intensities M , a radiometric response function is estimated. The early work of Mann and Picard [3] uses a gamma correcting function to represent response functions. With known exposure ratios, their method can successfully recover the inverse response function in the parametric form. With only approximate knowledge of relative exposure levels, Mitsunaga and Nayar [4] iteratively solve for a response function based on the assumption that it has a polynomial form. Other iterative estimation methods include that of Tsin et al. [5], which estimates non-parametric responses

using a statistical model of the CCD imaging process, and of Pal et al. [6], which utilizes probabilistic imaging models and prior models of response functions to compute response functions that can differ from image to image. Debevec and Malik [7] assumed a smoothness property of the response functions and estimated them in a non-parametric manner. As pointed out in [8–10], without the knowledge of exposure ratios, the estimate still has an *exponential ambiguity*. While not unique, such an estimate is still useful for many applications, such as radiometric alignment, high-dynamic range image production, and image stitching.

Several methods have been developed that use multiple exposures, but do not require precise registration. Grossberg and Nayar [8] use the relationship between the intensity histograms of two scenes imaged with different exposures because intensity histograms are relatively unaffected by small changes in the scene. Kim and Pollefeys [9] compute point correspondences between images. Mann [11] estimates response functions from a rotating and zooming camera.

Instead of using varying exposure times, some approaches use statistical or physical properties embedded in images to achieve radiometric calibration. Tsin et al.'s method [5] estimates non-parametric response functions using a statistical model of the CCD imaging process. Pal et al. [6] used probabilistic imaging models and weak prior models for deriving response functions to produce high-quality high-dynamic range images. Matsushita and Lin [12] proposed to use the symmetric property of image noise by observing noise distributions contained in images. Takamatsu et al. [13, 14] improved the noise-based method with a probabilistic intensity similarity measure, which requires a fewer number of images. Lin et al. [15] and Lin and Zhang [16] proposed a method that takes only a single image as input. Their method uses edges for obtaining color or grayscale histogram distributions, and the optimal inverse response function is determined by transforming linear distributions. Their method uses a database of response functions (DoRF) compiled by Grossberg and Nayar [17]. In a similar manner,

Wilburn et al. [18] use temporal color mixtures to directly sample the response function by observing motion blur in an image. More recently, Shi et al. [19] show a calibration method from images taken under varying lighting conditions. In their approach, an inverse response function is determined by linearizing color profiles that are defined as a set of measured RGB values at a pixel across images.

Open Problem

In many practical situations, the input dataset is naturally restricted by the camera's capability or application scenarios. For example, it is difficult to obtain multiple images at different exposures with ordinary web cameras. A more general and robust approach for radiometric calibration is still to be investigated.

Definition

Radiometric response function is a function that transforms sensor irradiance into measured intensities that are the output from the camera.

Background

In most cameras, there exists a radiometric response function that relates sensor irradiance to measured intensity values. The radiometric response functions are typically nonlinear. This nonlinearity is intentionally designed by camera manufacturers for purposes, such as compressing the dynamic range of scene brightness or taking into account the nonlinear mapping of display systems.

While many computer vision algorithms assume a linear (or affine) relationship between the sensor irradiance and the measured image intensity, the radiometric response functions are typically unknown, and these vary with camera parameter settings. Therefore, it is important to estimate the response function to linearize the measured image intensity values for vision algorithms to work. The process of determining radiometric response functions is called *radiometric calibration*. Once the radiometric response function is determined, the measured intensity can be linearized and transformed into sensor irradiance with a scaling ambiguity.

Theory

The radiometric response function f maps irradiance I that is captured at the sensor to the image intensity M by

$$M = f(I). \quad (1)$$

For computer vision algorithms that require irradiance values I rather than measured intensity M as input, the inverse response function $g = f^{-1}$ needs to be determined so that measured intensities can be made linear with respect to irradiances. Since response functions f are continuous and monotonic, they are invertible to determine inverse response functions (Fig. 1).

Representation Many parametrization methods have been used to represent radiometric response functions f . To deal with the scale difference between irradiance I and measured intensity M , both are normalized in the range of $[0, 1]$ so that $f(0) = 0$ and $f(1) = 1$.

When representing a radiometric response function in a certain form, there is a trade-off between complexity and flexibility. A simpler representation makes the estimation problem more tractable at the cost of approximation accuracy. On the other hand, a more flexible representation requires an uneasy solution method. Here we review major representations of radiometric response functions.

Mann and Picard [1] represent the response functions in the form of a gamma correction function as

$$M = f(I) = \alpha + \beta I^\gamma, \quad (2)$$

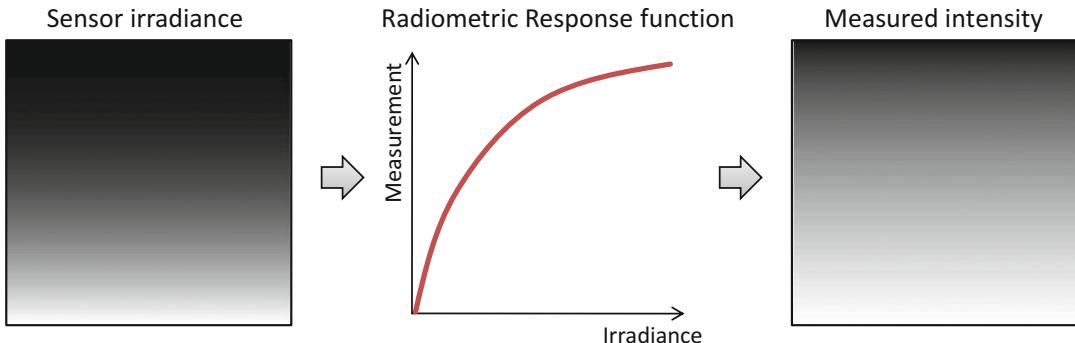

where α and β are offset and scale factors and γ is the power-law parameter.

Mitsunaga and Nayar use a high-order (order of N) polynomial function as the model of inverse response functions g as

$$I = g(M) = \sum_{n=0}^N c_n M^n, \quad (3)$$

where c_n are the coefficients of the polynomial function.

Grossberg and Nayar apply principal component analysis (PCA) to a database of real-world response functions (DoRF) and show that the space of response functions can be represented by

Radiometric Response Function, Fig. 1 A radiometric response function relates the incoming sensor irradiance to measured intensity values

a small number of basis functions [2].

$$g = \bar{g} + \sum_{n=1}^N c_n g_n. \quad (4)$$

In the above equation, \bar{g} is the mean inverse response, and g_i is the i -th principal component of the inverse response functions.

Debevec and Malik [3] use a non-parametric form of the radiometric response functions. The non-parametric representation has great descriptive power, but it is necessary to estimate $f(I)$ (or $g(M)$) for each intensity level (e.g., 256 for 8-bit images). Therefore, the solution methods tend to become more complex. The same representation is also used by Tsin et al. [4].

Existing methods can estimate radiometric response functions from a set of images taken with different known exposure times from a fixed view point [5–7]. More recent methods use different cues to achieve the estimation in more general settings. These include methods using single-image edges [8, 9], image noise observations [10–12], and motion blur [13]. These estimation methods are detailed in the entry “radiometric calibration”.

Application

Estimation of radiometric response functions constitutes an extensively researched area due to its fundamental importance for many computer

vision algorithms, such as shape-from-shading, photometric stereo, high-dynamic range imaging, and photo stitching. Estimated radiometric response functions are used to linearize the measured intensity values as pre-processing for these computer vision algorithms that require a linear (or affine) relationship with the irradiance.

Computer vision

Definition

Vision is a scientific field that investigates biological systems and machines how to use light to gain information about their environments. It covers several subfields such as optics, perception, psychophysics, neurophysiology, information science, signal processing, cognitive science, and related subjects.

Background

Background section will not be a review of all the contributions to the field of vision from all the subfields mentioned above. Rather it shall concentrate on how different subfields try to solve the problem vision and how this field has evolved over time due to better understanding of the problems but also due to more powerful technological tools.

Fundamentally vision utilizes the spatial and temporal information (structure) that stems from the reflection of light from the environment. The focus will be on the computational aspects of processing of this visual information, asking how visual information is represented for recognition, mobility, and manipulation, hence computational vision.

Much of the machine vision has been motivated by various applications: military medical, industrial, cultural, and commercial. The application-driven solution can be a separate article by itself. In this article the emphasis will be more on the scientific rational for computational vision than all the other reasons.

Motivation for this scientific endeavor comes from two very different sources:

1. How to model (mathematically and/or algorithmically) the biological process of vision. Can one design vision-based processes that explain visual perceptual phenomena?
2. How to design machines that will produce the desired outcome (recognition or navigation of a robot) from visual data.

The goals and the evaluation of success of these two approaches are very different.

Computational models of biological systems and machine vision is a very broad subject because it entails mammals as well as humans. It also encompasses fields such as computational neuroscience, through psychophysics up to computational cognitive modeling. In this article only some representative works will be mentioned which in no way does justice to this field. It covers modeling at different scale from neurons with prominent work of Hodgkin–Huxley model

[1] and Hubel and Wiesel [2], through sensory processing and communication of Barlow [3]. Psychologists have seriously considered computational models, especially how to explain visual illusions (exemplars are Gregory [4] and Frisby [5]), mechanisms of binocular vision (see Julesz [6]), and theory of color vision in retinex theory (by Land [7]).

Coincidentally, the engineering community also was heavily engaged in developing computational models for processing data coming from cameras. The limitations of poor resolution of cameras (64 by 64 pixels), limited memory, and compute power limited the applications of this era. Hence the topics were primarily two-dimensional picture recognition, such as digit recognition, finger print recognition, and in medical domain chromosome recognition. The methodologies used were statistical pattern recognition represented by Duda and Hart [8], signal-image processing by Rosenfeld and Kak [9], syntactic pattern recognition by K.S. Fu [10], and many others.

In early 1970s another trend emerged from the newly established Artificial Intelligence Laboratories at MIT and Stanford Universities. This trend emphasized the need for recognizing three-dimensional (3D) objects and scenes, arguing that today beings live in the 3D world; therefore the visual objects need to be represented as such. Guzman [11] was the first one who dealt with this problem using principles of projective geometry. Binford and Agin [12] and his students proposed a generalized cylindrical model (skeleton and corresponding cross-sections) as a generic model of 3D objects. It was argued that the model can represent parts and in turn the part-whole relationships can be represented as graphs.

This was more or less object-centered representation as oppose to the viewer-centered representation, proposed by Koenderink and van Doorn [13] as aspect graphs. This debate object-centered representation vs. viewer-centered representation is still ongoing!

In meantime David Marr [14] in late 1970s and early 1980s questioned the scientific approach of engineering community as ad hoc and not anchored in scientific theory. He

argued that the validation of the engineering approaches must be guided by what is known from neuroscience and psychophysics about human visual processing (this at present is the best model).

He outlined three levels of analysis:

1. The computational theory, specifying the goals of the computation
2. Representation and algorithm, giving a representation of the input and output which transforms one into the other
3. The hardware implementation, how algorithm and representation may be physically realized

Concurrently with Marr's effort in the UK, Christopher Longuet-Higgins [15] introduced cognitive science as the interdisciplinary study of how information is represented and transformed in the brain. It spans many levels of analysis, from low-level learning and decision mechanisms to high-level logic and planning. This field has blossomed with many works of modeling of perceptual and cognitive processes (see Newell and Simon [16], Hinton [17], and many others).

The 1980s benefitted from rapid advancements in hardware both in better cameras and computing power. This development enabled to perform some real-time computation and connect signal processing and perception with action. Motivated by Gibson [18] and Bajcsy [19] proposed a new research paradigm, called Active Perception. In this new framework, it has been shown that there is benefit in controlling the data acquisition and serves as way of modeling focus of attention.

Simultaneously progress has been made in various basic algorithms such as stereo reconstruction, motion detection and interpretation, multiple view reconstruction, shape from shading and photometric stereo, and shape–object–scene representation. Several textbooks cover these advancements, just to cite a few: Faugeras [20], Forsyth and Ponce [21], and Ma et al. [22]:

- Another challenge for machine perception comes from Gestalt psychology founded by

Max Wertheimer [23], in the beginning of the twentieth century. The word Gestalt means a unified or meaningful whole. The laws of Gestalt theory of perceptual organization are as follows:

- The Law of Similarity
- The Law of Prägnanz
- The Law of Proximity
- The Law of Continuity
- The Law of Closure

Computationally however, they are hard to define and map into an algorithm since they deal with rather vague concepts such as proximity and similarity. From the beginning of computational vision, this problem has attracted attention, first just building some distance function (Zobrist and Thompson [24]) later looking at these laws as a guide to perceptual organization (Low [25]) and more recently as “image segmentation,” the partitioning of an image (or video streams) into sets of pixels that correspond to “objects” or parts of objects. This process is based on bottom-up cues such as similarity of pixel brightness, color, texture, and motion as well as top-down input derived from familiar object categories such as faces. Malik and his coworkers [26] aimed at developing a scientific understanding of grouping, both in the context of human perception and for computer vision, and have shown progress in this area but also its limitations.

At the onset of the twenty-first century, the abundance of images on Internet has spurred an interest in Machine Learning Technologies (MLT) as they apply to object recognition and classification. The latest premier vision conferences ICCV and ECCV have been representative examples of this research. The theoretical development related to this effort is compressed sensing; see Emmanuel Candès and Terence Tao [27]. They discovered important results on the minimum number of data needed to reconstruct an image even though the number data would be deemed insufficient by the Nyquist–Shannon criterion. Further effort in combining the compressed sensing with principal component pursuit is in [28].

In conclusion, the scientific community has seen serious progress in computational vision afforded by technological advances (cameras, computing power) but also by the community mastering much more sophisticated mathematical and computational tools than ever before. The emphasis on robustness, sharing code, and creating standard data bases where different approaches can be tested is very good.

Open Problems

The basic representations of visual objects and their dynamics are still open problems. Further, the adaptive nature and flexibility of biological vision is still a dream to be accomplished by the computational vision community

Recovery of Reflectance Properties

Jason Lawrence

Department of Computer Science, School of Engineering and Applied Science, University of Virginia, Charlottesville, VA, USA

Synonyms

Appearance scanning; BRDF measurement; Reflectometry

Definition

Recovering reflectance properties refers to the process of measuring and modeling the manner in which a material scatters incident light. This often involves estimating the parameters of a light scattering function based on measurements of a physical sample.

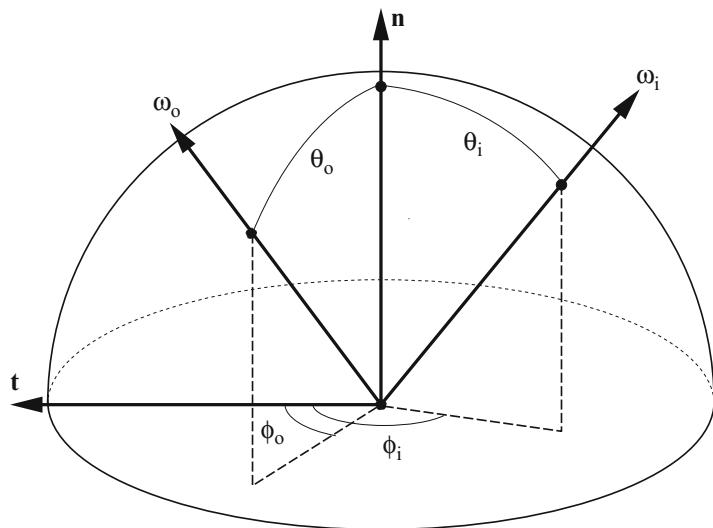

Background

Along with its 3D shape, another crucial aspect of an object's appearance is the manner in which it scatters incident light, often referred to generally as its *reflectance*. In the case of opaque objects, it may be assumed that any light which strikes the surface is either reflected back into the environment at that same incident location, possibly in different amounts along different directions, or absorbed by the material. Translucent objects require consideration of the way light scatters internally within the medium. Only metallic surfaces are technically opaque, although dielectrics may be treated as opaque at an appropriate measurement scale. Further, the reflectance of many objects varies spatially over their surface. This entry focuses on techniques for measuring and representing the optical properties of opaque surfaces.

Recovery of Reflectance Properties, Fig. 1

Geometry of the BRDF.

The incident direction ω_i and exitant direction ω_o are defined with respect to the local surface frame defined by the surface normal \mathbf{n} and tangent \mathbf{t} . These directions are often written in terms of their respective elevation and azimuthal angles θ and ϕ

Theory

The appearance of a homogeneous opaque surface is completely characterized by the Bidirectional Reflectance Distribution Function (BRDF) [1]. This is a scalar-valued function of the ratio of the differential radiance dI leaving the surface along direction ω_o with respect to the differential surface irradiance dE from light arriving along direction ω_i with wavelength λ

$$f_r(\omega_i, \omega_o, \lambda) = \frac{dI(\omega_o, \lambda)}{dE(\omega_i, \lambda)} \left[\text{sr}^{-1} \right]. \quad (1)$$

This is a function of five variables (note that the directions are unit length and thus occupy a 2D domain) defined with respect to the local tangent frame attached to a location on a 2-manifold surface (Fig. 1). A very nice overview of the radiometry underlying the BRDF is available in a chapter written by Pat Hanrahan entitled “Rendering Concepts” in the textbook by Cohen and Wallace [2].

Note that Eq. (1) does not differentiate between the wavelength of the incident and exitant light and thus it cannot capture photoluminescence effects such as phosphorescence or fluorescence. Furthermore, the full dependence on wavelength is often ignored (as will be the case in this entry), in which case λ in Eq. (1)

is omitted and the BRDF is a function of four variables defined within a trichromatic color space such as RGB. The dimensionality of the BRDF can be further reduced to three if the material’s reflectance is *isotropic*, meaning it is unaffected if the incident and exitant directions are rotated together around the surface normal. This is in contrast to *anisotropic* materials which exhibit a visible *surface grain* that causes the reflectance to depend on this azimuthal component such as brushed metal, satin, silk, and velvet.

In many cases, the surface BRDF will vary from one surface location to the next (e.g., a wooden object with visible spatially varying grain densities). The spatially varying BRDF (svBRDF) is used to characterize the reflectance of these inhomogeneous surfaces, and it simply adds surface position \mathbf{x} to the angular variables in the BRDF: $S(\mathbf{x}, \omega_i, \omega_o)$. The svBRDF is thus a function of six variables since two numbers are required to specify a surface location.

R

Representations

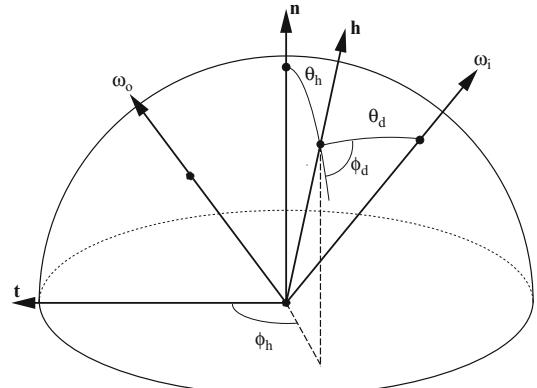

A considerable amount of research has focused on developing efficient BRDF representations that apply to a wide range of materials. This includes a number of early and still

widely popular phenomenological models such as the Phong [3] and related Blinn-Phong models [4], which offer reasonable approximations for plastics and smooth painted surfaces.

An alternative approach is to derive the BRDF from the laws of physics based on a hypothesized physical model of a material's surface. These physically based models include the seminal Torrance-Sparrow [5] and Cook-Torrance models [6], both of which assume that the surface is composed of randomly oriented microscopic mirrors, or *microfacets*. These models capture important effects predicted by Fresnel equations including color shifts near highlights and an overall increased specular response near *grazing angles* (i.e., as ω_o and ω_i approach the horizon in opposite directions). The He-Torrance-Sillion-Greenberg (HTSG) model [7] was derived using a similar methodology, but considers wave-related effects such as diffraction and interference. The Oren-Nayar model [8] is also based on a microfacet theory, but one in which the individual microfacets are perfect Lambertian reflectors and are meant to reproduce the reflectance of matte materials such as dust or chalk. The Kajiya-Kay model [9] considers the way light is reflected from small fibers modeled as cylinders and is intended to model the appearance of hair and fur. In all of these cases, the resulting BRDF is an analytic expression with a handful of parameters that control the magnitude, color, and shape of dominant lobes in the BRDF that are commonly either diffuse (largely nondirectional), specular (forward scattering), or retroreflective (backward scattering).

Another family of BRDFs was derived to fit empirical data. This includes the Lafourture [10] and Ward [11] models. These are both analytic models with parameters similar to those described above. The Lafourture model is defined as the sum of an arbitrary number of cosine lobes and can express a wide range of phenomena. The Ward BRDF is functionally more similar to the Cook-Torrance or Blinn-Phong model, but can produce elongated specular highlights that match a common form of anisotropic reflectance.

More recent research has considered non-parametric representations of the BRDF which are often constructed directly from measured data. These range from straightforward tabulated models [12] to compressed representations obtained by projecting the measurements into either a fixed basis defined over the double hemisphere (e.g., Zernike polynomials, spherical harmonics, wavelets, radial basis functions [13]) or a specialized basis estimated from the measured data itself. In the latter case, this can be achieved using common dimensionality reduction algorithms such as Principal Component Analysis (PCA) or cast as a matrix factorization problem [14, 15]. The accuracy of these representations is greatly affected by the way the BRDF is parameterized. A particularly useful parameterization was introduced by Rusinkiewicz [16] and is based on the *half-angle* and *difference angle* (inset at right). The half-angle is simply the bisector of the incident and exitant directions $\mathbf{h} = (\omega_i + \omega_o)/\|\omega_i + \omega_o\|$, and the difference angle

(θ_d, ϕ_d) is the incident direction expressed with respect to the half-angle. This parameterization has the desirable property of aligning common BRDF features to the transformed coordinate axes – including specular peaks [6], grazing-angle effects, and retroreflective peaks [8] – and as a result, only a relatively small amount of data is needed for an accurate representation.

Acquisition

The most basic requirements of a BRDF measurement system are a light source to illuminate the surface and a photodetector to record the amount of energy reflected in a particular direction. The difficulty of measuring the BRDF of a material lies in the high dimensionality of these functions and the calibration requirements of existing setups.

Gonioreflectometers

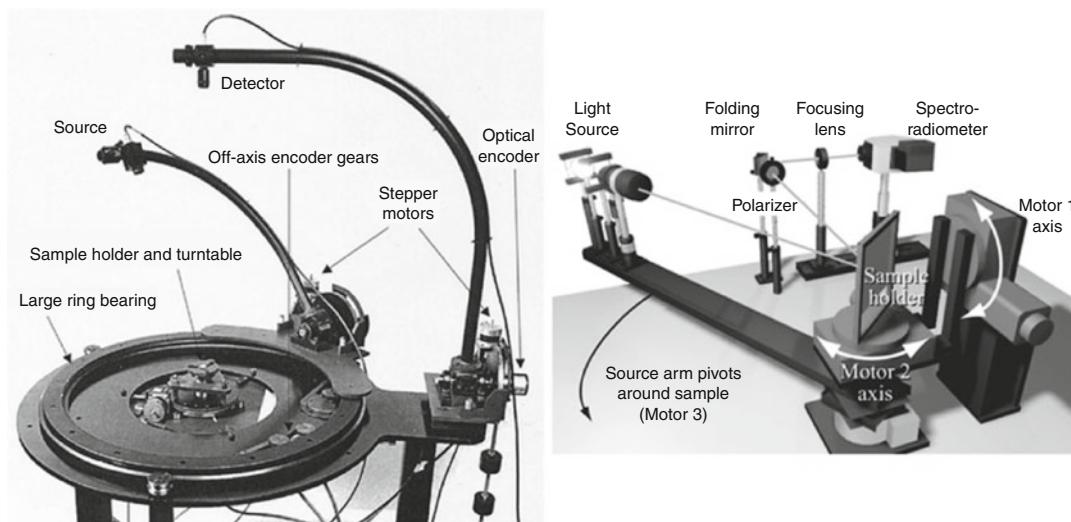

BRDFs were originally measured using a *gonioreflectometer*, a term that incorporates the Latin word for angle (*gonio*). These consist of a single photodetector and light source that can be moved to arbitrary locations on a hemisphere centered around a small planar sample (Fig. 2). Gonioreflectometers are only suitable for acquiring relatively sparse angular measurements since densely sampling the full BRDF domain would lead to infeasible acquisition times. However, they are very accurate and repeatable

and are thus still used to validate newer designs and maintain reflectance standards.

In order to use the data recorded by a gonioreflectometer in a practical system, it is often necessary to estimate the regions of the BRDF that were not directly measured. This is often done by fitting the parameters of one of the analytic BRDF models described previously to the measured data. This process involves solving a nonlinear optimization problem with many variables and is often difficult and error prone in practice [19].

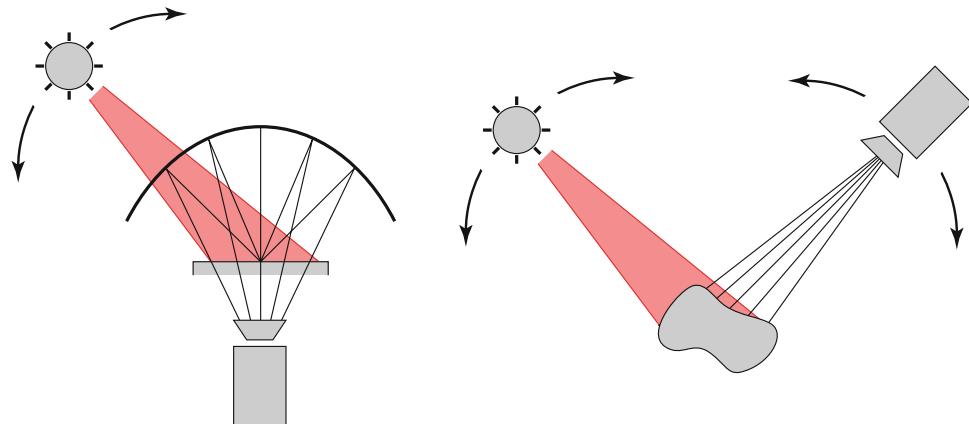

Camera-Based Systems

A seminal development was Greg Ward's use of a curved mirror and camera [11] (Fig. 3). Note that a single image recorded by the camera contains a densely sampled 2D slice of the BRDF at a fixed incident direction. Recording multiple images at different light source positions allows probing the full 4D domain. This setup enables efficiently measuring a considerably larger portion of the BRDF domain than was previously possible with gonioreflectometers and led to the development of a new anisotropic BRDF model that is still in wide use today.

Recovery of Reflectance Properties, Fig. 2 Two gonioreflectometer designs. Left: the apparatus developed by White et al. [17] has four degrees of freedom and achieves an angular resolution of approximately 0.1° and is accurate to within 0.3° . (Image reproduced from [17].)

Right: the design of Li et al. [18] has three degrees of freedom and is thus restricted to measuring isotropic material samples. Due to the use of a spectroradiometer, this system can measure the BRDF at 10 nm increments over the visible spectrum

Recovery of Reflectance Properties, Fig. 3 Two camera-based BRDF measurement systems. Left: Ward's acquisition rig used a curved half-silvered mirror and a camera to enable efficient acquisition of dense BRDF

Ghosh et al. [20] describe a related setup that uses a digital projector and multiple curved mirrors to achieve a similar acquisition process, but one that does not require any moving parts, which significantly decreases acquisition time. Dana et al. [21] also explore using a mirrored dome and camera to accelerate BRDF capture. A key aspect of their design is that it allows translating the material sample within the measurement plane in order to sample the spatial dimensions of the svBRDF.

The camera-based BRDF measurement system introduced by Marschner et al. [22] was another significant step in the field, which traded Ward's curved mirror for a curved sample to achieve a similar effect (Fig. 3 right). A unique measurement of the object's BRDF is recorded at each pixel since each pixel observes a different orientation of the surface (recall that the BRDF is defined with respect to the *local* surface frame). Assuming that the sample object's reflectance is homogeneous (i.e., no perceptible spatial variation), this provides a dense 2D slice of its BRDF, although the one that differs from the slices is acquired with Ward's setup. Matusik et al. [12] refined Marschner's design and measured the BRDFs of nearly one hundred isotropic spherical samples at unprecedented angular resolutions. Ngan et al. [19] extended this design further to allow measuring anisotropic samples that were

measurements. Right: Marschner's setup exploited the same principle through the use of a curved specimen and camera

formed into thin strips and wrapped around a cylinder.

Although camera-based systems can achieve a much higher angular resolution than traditional gonioreflectometers, the quality of the individual measurements is generally lower. This is due to the reduced quality of the individual photo-sensitive elements in a typical CCD or CMOS array, the need for more complex optical systems which can produce internal reflections, and the way wavelength is sampled using, for example, a Bayer filter [23]. However, this is beginning to change with the steady improvement in digital camera technology and the development of tunable narrowband color filters. Additionally, the high angular resolution of the data returned by these systems enables the use of non-parametric representations discussed previously. The advantage of these models is that they often provide a much more accurate fit to the measured data compared to an analytic model and require solving a linear optimization problem which is more stable.

In the aforementioned camera-based systems, the geometry of the target sample and its location with respect to the camera and light source must be known in order to properly interpret the recorded images as BRDF measurements. This calibration step is notoriously difficult and is often simplified by using samples with a specific known geometry: planar, spherical, or cylindrical.

A recent research focus has been on developing systems for measuring the BRDF or svBRDF of samples with *arbitrary geometry*. On the one hand, this task is considerably harder since existing techniques for scanning geometry often rely on assumptions about the surface reflectance. On the other hand, all that is needed is the normal direction and, for anisotropic surfaces, the tangent direction at each image pixel as opposed to a complete 3D model.

One of the first general systems for measuring the reflectance of arbitrarily shaped spatially varying opaque isotropic objects was proposed by Lensch et al. [24]. Their approach has multiple steps. First, the geometry of the target object is acquired using either a penetrative method such as a computed tomography (CT) scanner or with a standard laser scanner after first coating the object in a diffuse powder. In a second step, the object is photographed from different viewpoints under variable point lighting (Fig. 3). Third, the 3D geometry in the first step is registered to the images in the second step using a silhouette-based alignment algorithm. The extraction of BRDF data can proceed using the surface normal of the registered 3D model at each image pixel. Finally, they use the resulting BRDF data to estimate the parameters of a Lafourte model [10] at each vertex in a triangle mesh of the surface. To make this fitting process more robust, they assume that the object's reflectance can be accurately modeled with only a handful of unique *basis BRDFs* and corresponding spatial blending weights. Therefore, as opposed to storing a unique set of Lafourte parameters at each vertex, only a set of nonnegative barycentric coordinates (unity of partition) over the set of basis BRDFs is computed instead. Computing these basis BRDFs and blending weights is cast as a clustering problem.

A related system was proposed by Goldman et al. [25]. The key difference is that they *jointly* estimate the surface normal at each pixel in a fixed camera along with the coefficients of the Ward BRDF model by solving a large non-linear optimization problem. On the one hand, this avoids having to scan the geometry in a separate step and subsequently register this geometry to

the set of images, significantly simplifying the experimental setup and processing. On the other hand, this approach recovers only the normals and BRDFs for the portion of the object visible from the chosen viewpoint. This approach can be regarded as a generalization of Lambertian photometric stereo [26] since the surface BRDFs are drawn from a much larger space (i.e., the space of BRDFs expressible by the Ward model). Goldman et al. follow a similar strategy as Lensch et al. and assume that object reflectance at each pixel can be expressed as a convex combination over a small basis of homogeneous BRDFs. They demonstrate the importance of this representation of the svBRDF for achieving a stable optimization.

More recent work has extended the basic approach of Goldman et al. to avoid relying on a parametric BRDF model. The downside to using a parametric model such as the Ward BRDF is that this imposes a particular structure on the surface reflectance. Whenever the object's actual reflectance deviates from what this model can express, errors are introduced. The system presented by Alldrin et al. [27] jointly estimates the surface normal and BRDF at each pixel in a fixed camera where the BRDF is modeled using a tabulated bivariate representation. This can significantly improve the accuracy of the resulting model in many situations.

Another related approach is due to Wang et al. [28] which focuses on measuring the reflectance of anisotropic surfaces. Their system works in two steps. First, they acquire densely sampled angular measurements of the BRDF at a small number of strategically chosen points on the object surface. Second, they record sparse angular measurements sampled densely over the object surface. The sparse measurements in the second step are used to estimate a convex combination of the densely sampled BRDFs in order to recover a model of the svBRDF that is dense in both the spatial and angular dimensions. This basic strategy of combining dense angular data at a small number of surface locations with sparse angular data sampled densely over the surface represents a compelling trade-off between acquisition time and final model quality. Wang et al.

also estimate the tangent direction at each surface location as a by-product of their optimization and model the BRDF using a hybrid representation that combines a tabulated (nonparametric) normal distribution function (NDF) with analytic (parametric) expressions for the shadowing, masking, and Fresnel components [19].

A Note on Bidirectional Texture Functions

This entry has focused on methods for measuring the BRDF or svBRDF of physical objects. There is a family of related techniques that focus on the bidirectional texture function (BTF) [29]. Despite having the same domain as the svBRDF, the BTF conveys a slightly more general notion of reflectance. A BTF quantifies the amount of light that is exchanged (scattered) between pairs of angles located along the surface of a proxy geometry that does not necessarily coincide with the actual surface. As a result, the BTF couples visibility, interreflections, and local reflectance in complex ways that are perceptible at the chosen measurement scale. Technically, the difference between BTFs and svBRDFs is a matter of the degree to which this proxy geometry deviates from the actual object surface, and indeed, no real-world surface is ever perfectly smooth or exhibits exactly the microfacet structure assumed by many BRDFs. Nevertheless, some objects are more suitable than others to be represented as an svBRDF plus a surface, whereas others (e.g., cloth and other hairy or fuzzy surfaces) do not allow resolving the geometry at a fine enough resolution to isolate the local reflectance, and the BTF is perhaps the only option. Systems for measuring BTFs [29, 30] are nearly identical to those for measuring svBRDFs. The difference is a matter of how the resulting data is interpreted.

Application

Measuring and modeling the reflectance of real-world materials is a key component of most graphics and vision systems. For example, recreating a visually rich and realistic virtual 3D world

requires populating it with materials with the same variety and intricacy as those found in nature. Similarly, any vision system that attempts to infer information about the 3D structure of a natural image must reason about the way light is absorbed and reradiated by the various surfaces that compose the scene. Therefore, it is important to have efficient and accurate techniques for measuring or *scanning* the reflectance of physical samples.

Open Problems

Developing techniques for measuring and modeling BRDFs and svBRDFs is an active area of research. Much of this work focuses on expanding the set of materials that can be reliably measured to include those with anisotropic and translucent properties. Another thrust of current research focuses on the usability and operation of appearance acquisition systems themselves. Measurement systems will need to be much more efficient and easier to calibrate before they can be reliably deployed in non-laboratory conditions. Finally, extending camera-based systems to measure the spectral dimensions of BRDFs is beginning to receive serious attention. This includes resolving the spectral profiles of the incident and exitant light in addition to photoluminescence effects caused by materials that absorb energy at one wavelength and emit it at another wavelength.

Definition

A recurrent neural network is a type of neural network tailored to handle sequential data. It is

characterized by the recurrent connection in the hidden state.

Background

Sequential data, a type of data consisting of ordered homogeneous elements, appear frequently in the real world. For instance, videos captured by surveillance cameras comprise sequential data, where each video is composed of a temporal sequence of visual frames.

Let us consider sequence data \mathbf{Y} with an arbitrary length $T (\geq 2)$:

$$\mathbf{Y} = \{y_1, y_2, \dots, y_T\}. \quad (1)$$

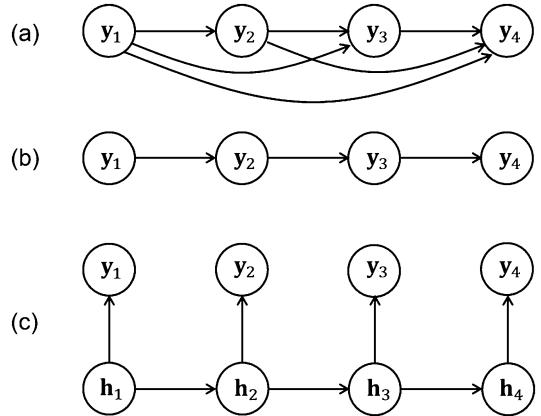

Above, the random variable y_t corresponds to the observation at the t -th step (time). Importantly, variables $\{y_t\}_{t=1}^T$ are mutually dependent as \mathbf{Y} has its own dynamics in practice. Our goal is to model the probability of \mathbf{Y} , $p(\mathbf{Y})$. Generally, $p(\mathbf{Y})$ is decomposed by means of the Bayes rule as

$$\begin{aligned} p(\mathbf{Y}) &= p(y_1, y_2, \dots, y_T) \\ &= p(y_1) \prod_{t=2}^T p(y_t | y_{t-1}, \dots, y_1). \end{aligned} \quad (2)$$

The graphical model of this process is illustrated in Fig. 1a. Theoretically, a trained model is required to output y_t based on all previous observations. However, this is very difficult in practice because an immense amount of data is necessary to fill the combinatorially large input space. Therefore, the Markov process, where the current variable is sampled conditioned only on a certain number of previous variables, is a reasonable approximation. In particular, the first-order Markov process is a frequently employed model in practice. Namely, it is assumed that

$$p(y_t | y_{t-1}, \dots, y_1) \simeq p(y_t | y_{t-1}). \quad (3)$$

Therefore, the overall probability of a sequence is approximated as

Recurrent Neural Network, Fig. 1 Graphical models for sequential data. (a) General Bayes rule, (b) first-order Markov process, and (c) hidden Markov model

$$p(y_1, y_2, \dots, y_T) \simeq p(y_1) \prod_{t=2}^T p(y_t | y_{t-1}). \quad (4)$$

In this model, the current variable y_t is dependent only on the last observation y_{t-1} (Fig. 1b). When the state space of y_t is discrete, it is called the first-order Markov chain, where the state transition probabilities $p(y_t | y_{t-1})$ are stored in the transition matrix as the model parameter.

Despite its usefulness, a vanilla Markov chain has many drawbacks. Because this is a memoryless model that only refers to the previous observation, it is impossible to capture long-term dynamics in the sequence. Moreover, basically it is difficult to apply it to nondiscrete variables. Therefore, the Markov chain has a limitation in modeling complex real-world sequential data.

The hidden Markov model (HMM) is an extension of the Markov chain that has an unobserved hidden state and is an important model that has been successfully applied in many fields such as speech recognition and action recognition [10]. As illustrated in Fig. 1c, an observed variable y_t is dependent only on a hidden state (latent variable) h_t at each step t . Meanwhile, the sequence of hidden states $\mathbf{H} = \{h_1, \dots, h_T\}$ constitutes a first-order Markov chain. Here, the probability of the

observed sequence can be obtained as

$$\begin{aligned} p(\mathbf{Y}) &= p(y_1, y_2, \dots, y_T) \\ &= p(y_1|\mathbf{h}_1)p(\mathbf{h}_1)\prod_{t=2}^T p(y_t|\mathbf{h}_t)p(\mathbf{h}_t|\mathbf{h}_{t-1}). \end{aligned} \quad (5)$$

In the HMM, the observed variable y_t no longer forms a Markov process. Also, y_t does not need to be discrete as long as $p(y_t|\mathbf{h}_t)$ is properly modeled. Theoretically, with a sufficiently large and well-defined hidden state space, HMM can memorize the information regarding the past outputs as a hidden state. However, because \mathbf{h}_t is discrete, its memory capacity is at most $\log_2 N$ bits, where N is the size of the state space. Because this is not scalable to memorize long-term dependencies, it is desirable to represent the hidden state in a continuous vector space, in other words, to use distributional representations for hidden states.

The linear dynamical system (LDS) is also an important model closely related to HMM. This is equivalent to the same stochastic process of HMM (Fig. 1c) when hidden states are defined in a continuous space, and $p(\mathbf{h}_t|\mathbf{h}_{t-1})$ and $p(y_t|\mathbf{h}_t)$ are modeled with Gaussians [9]. LDS is more commonly described by the following linear transition equations and has been frequently used in the field of control engineering:

$$\mathbf{h}_t = A\mathbf{h}_{t-1} + \mathbf{w}_t, \quad (6)$$

$$\mathbf{y}_t = C\mathbf{h}_t + \mathbf{v}_t, \quad (7)$$

$$\mathbf{w}_t \sim \mathcal{N}(\mathbf{0}, \Gamma), \quad (8)$$

$$\mathbf{v}_t \sim \mathcal{N}(\mathbf{0}, \Sigma). \quad (9)$$

Here, \mathbf{w}_t and \mathbf{v}_t are noise in the system, and A and C represent fixed linear projections. \mathcal{N} denotes a multivariate Gaussian distribution, and Γ and Σ denote the covariance matrices of the Gaussians.

In fact, LDS shares basically the same structure with a recurrent neural network (RNN). A major difference is that LDS simply repeats linear state transition and therefore, all input-output relations are eventually represented by linear models. RNN can be interpreted as a nonlinear version of LDS and has additional activation functions after each linear transformation to have a richer representational power.

Theory

Model Formulation of Recurrent Neural Network

The general formulation of RNN considers the generation process of an output sequence \mathbf{Y} conditioned on a certain input sequence \mathbf{X} , i.e., a discriminative model. Among a few variations of RNNs, let us focus on the most standard one, the Elman network [4], which is formulated as follows (Fig. 2a):

$$\tilde{\mathbf{h}}_t = V\mathbf{x}_t + U\mathbf{h}_{t-1} + \mathbf{b}_h, \quad (10)$$

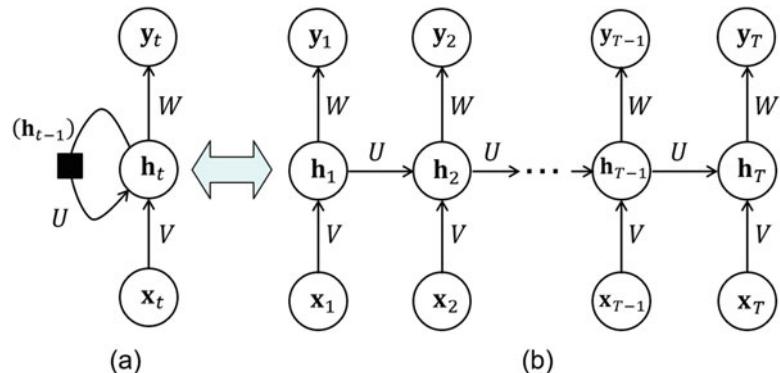

$$\mathbf{h}_t = \sigma_h(\tilde{\mathbf{h}}_t), \quad (11)$$

$$\tilde{\mathbf{y}}_t = W\mathbf{h}_t + \mathbf{b}_y, \quad (12)$$

Recurrent Neural Network, Fig. 2 (a)

Structure of a recurrent neural network. (b)

Temporally unrolled network

$$\hat{\mathbf{y}}_t = \sigma_y(\tilde{\mathbf{y}}_t). \quad (13)$$

Since the output of an RNN is decisive, it is referred to as $\hat{\mathbf{y}}_t$ to be distinguished from \mathbf{y}_t which is based on a stochastic process. V , U , and W are weight matrices and \mathbf{b}_h and \mathbf{b}_y are bias vectors. σ_h and σ_y are the activation functions at the hidden layer and the output layer, respectively. The tangent hyperbolic (tanh) function is usually used as σ_h which is applied to each element of an input vector independently (i.e., elementwise function). The selection of σ_y is dependent on the task. For example, if classification is performed at each step, the softmax function is an appropriate choice.

RNN repeats the updating of the hidden state \mathbf{h}_t at each step t using the input \mathbf{x}_t and the previous hidden state \mathbf{h}_{t-1} . This is basically the same structure as that of LDS. As is obvious from the recursive structure of Eq. 10, the output $\hat{\mathbf{y}}_t$ is influenced by all past inputs and the current input, $\{\mathbf{x}_1, \dots, \mathbf{x}_t\}$. In this sense, theoretically, RNN is expected to be able to represent dynamic relationships between inputs and outputs in arbitrary time scales.

While the recurrent structure of RNN might seem somewhat complicated, it can be represented by a static network by unrolling the internal loop (Fig. 2b). As this is nothing but a multilayer perceptron sharing parameters over all time steps, it can be trained by the standard backpropagation method. This methodology is called backpropagation through time (BPTT) as the error flows from future to past.

Backpropagation Through Time

Let $\mathcal{L}_t(\mathbf{x}_1, \dots, \mathbf{x}_t, \mathbf{g}_t)$ denote the loss at step t where \mathbf{g}_t represents the ground-truth output and $\mathcal{L} = \sum_{t=1}^T \mathcal{L}_t$ denote the overall loss of an output sequence. First, let us consider error propagation through the hidden states. From Eqs. 10 and 12, the derivative with respect to \mathbf{h}_{t-1} is derived as follows:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{h}_{t-1}} = U^\top \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t} + W^\top \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{y}}_{t-1}}. \quad (14)$$

As a special case, in the last step $t = T$, the gradient is obtained as $\frac{\partial \mathcal{L}}{\partial \mathbf{h}_T} = W^\top \frac{\partial \mathcal{L}_T}{\partial \tilde{\mathbf{y}}_T}$, which is the starting point of backpropagation. Since σ_h is an elementwise function, from Eq. 11, it follows that

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t} &= \frac{\partial \mathbf{h}_t}{\partial \tilde{\mathbf{h}}_t} \frac{\partial \mathcal{L}}{\partial \mathbf{h}_t} \\ &= \sigma'_h(\tilde{\mathbf{h}}_t) \odot \frac{\partial \mathcal{L}}{\partial \mathbf{h}_t}, \end{aligned} \quad (15)$$

where σ'_h denotes the derivative of σ_h , which is also an elementwise function. \odot represents the elementwise product of vectors. Similarly, from Eq. 13, it follows that

$$\frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{y}}_t} = \frac{\partial \hat{\mathbf{y}}_t}{\partial \tilde{\mathbf{y}}_t} \frac{\partial \mathcal{L}}{\partial \hat{\mathbf{y}}_t} = \frac{\partial \hat{\mathbf{y}}_t}{\partial \tilde{\mathbf{y}}_t} \frac{\partial \mathcal{L}_t}{\partial \hat{\mathbf{y}}_t}. \quad (16)$$

For a concrete example, in a classification problem, the softmax function and the cross-entropy loss are commonly used as σ_y and \mathcal{L}_t , respectively. In this case, the derivative becomes $\frac{\partial \mathcal{L}_t}{\partial \tilde{\mathbf{y}}_t} = \hat{\mathbf{y}}_t - \mathbf{g}_t$, where \mathbf{g}_t is the ground-truth one-hot vector at step t . Therefore, it is not necessary to compute the Jacobian matrix $\frac{\partial \hat{\mathbf{y}}_t}{\partial \tilde{\mathbf{y}}_t}$ explicitly.

Next, let us consider the gradients with respect to the model parameters. Since the same parameter is repeatedly applied in the network, it is necessary to distinguish its overall gradient from the local gradient at each step (i.e., each edge in the graph in Fig. 2b). For this purpose, the right shoulder suffix (t) is introduced to refer to the latter.

First, for the parameters in the output layer, the following is obtained from Eq. 12:

$$\left(\frac{\partial \mathcal{L}}{\partial W} \right)^{(t)} = \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{y}}_t} \mathbf{h}_t^\top, \quad (17)$$

$$\left(\frac{\partial \mathcal{L}}{\partial \mathbf{b}_y} \right)^{(t)} = \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{y}}_t}. \quad (18)$$

Similarly, the following is obtained from Eq. 10:

$$\left(\frac{\partial \mathcal{L}}{\partial U} \right)^{(t)} = \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t} \mathbf{h}_{t-1}^\top, \quad (19)$$

$$\left(\frac{\partial \mathcal{L}}{\partial \mathbf{b}_h}\right)^{(t)} = \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t}, \quad (20)$$

$$\left(\frac{\partial \mathcal{L}}{\partial V}\right)^{(t)} = \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t} \mathbf{x}_t^\top. \quad (21)$$

Finally, the overall gradients over the sequence are obtained as follows:

$$\frac{\partial \mathcal{L}}{\partial W} = \sum_{t=1}^T \left(\frac{\partial \mathcal{L}}{\partial W}\right)^{(t)} = \sum_{t=1}^T \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{y}}_t} \mathbf{h}_t^\top, \quad (22)$$

$$\frac{\partial \mathcal{L}}{\partial U} = \sum_{t=2}^T \left(\frac{\partial \mathcal{L}}{\partial U}\right)^{(t)} = \sum_{t=2}^T \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t} \mathbf{h}_{t-1}^\top, \quad (23)$$

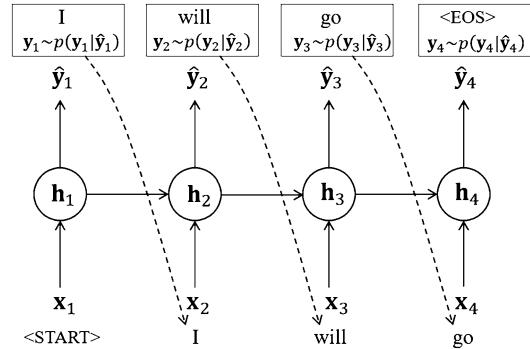

$$\frac{\partial \mathcal{L}}{\partial V} = \sum_{t=1}^T \left(\frac{\partial \mathcal{L}}{\partial V}\right)^{(t)} = \sum_{t=1}^T \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t} \mathbf{x}_t^\top, \quad (24)$$

$$\frac{\partial \mathcal{L}}{\partial \mathbf{b}_h} = \sum_{t=1}^T \left(\frac{\partial \mathcal{L}}{\partial \mathbf{b}_h}\right)^{(t)} = \sum_{t=1}^T \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{h}}_t}, \quad (25)$$

$$\frac{\partial \mathcal{L}}{\partial \mathbf{b}_y} = \sum_{t=1}^T \left(\frac{\partial \mathcal{L}}{\partial \mathbf{b}_y}\right)^{(t)} = \sum_{t=1}^T \frac{\partial \mathcal{L}}{\partial \tilde{\mathbf{y}}_t}. \quad (26)$$

Generative Mechanism and Decoding

While the discriminative model has been considered so far, RNN can also be used as a generative process. Although it is straightforward to consider a model omitting input in Eq. 10, in the current standard method, the previous output is recursively input to more explicitly store the information regarding past outputs in the sequence [5, 8]. Specifically, the final output variable \mathbf{y}_t is sampled in accordance with the conditional probability $p(\mathbf{y}_t|\hat{\mathbf{y}}_t)$ at each step t and then used as the input for the next step, i.e., $\mathbf{x}_{t+1} = \mathbf{y}_t$ (Fig. 3). $p(\mathbf{y}_t|\hat{\mathbf{y}}_t)$ should be designed carefully for each task. In the text generation task, for example, the state space of \mathbf{y}_t is discrete where each state corresponds to each word in the dictionary. Since the softmax function is used as σ_y for this task, it is possible to directly assume

Recurrent Neural Network, Fig. 3 Sequence generation with a recurrent neural network

its output to be the probability. Namely, $p(\mathbf{y}_t = \mathbf{1}^k|\hat{\mathbf{y}}_t) = \hat{y}_t^k$, where \hat{y}_t^k is the k -th element of $\hat{\mathbf{y}}_t$ and $\mathbf{1}^k$ is a one-hot vector whose k -th element is one.

In the pure generative model, the hidden state is initialized by inputting a dummy variable as the first input \mathbf{x}_1 . It is also possible to explicitly set \mathbf{h}_1 using some external mechanisms to condition the generation process accordingly. In this case, the network is often called a *decoder* as it is interpreted to be decoding information stored in vector \mathbf{h}_1 . As described later, one can realize various applications by combining a decoder with encoder networks that embed the input information into a vector.

In a decoding process, the final score (probability) of an output sequence is given by

$$p(Y) = \prod_{t=1}^T p(\mathbf{y}_t|\hat{\mathbf{y}}_t). \quad (27)$$

To generate a useful sequence, it is necessary to search over the solution space using the above criterion. The ideal goal is to find the optimal sequence that maximizes the score. However, because the solution space of sequence data expands exponentially as the number of steps increases, searching the optimal one is NP-hard. Therefore, some approximate search methods are required. Usually, an empirical method called *beam search* is used for this purpose. It basically performs a breadth-first search as the decod-

ing proceeds, keeping the best candidates in the working memory.

Sequence-to-Sequence Modeling

RNN is also often used as a sequence encoder that embeds the input sequence into a vector. An example of the encoder is illustrated in Fig. 4 (left). The input tokens are simply aggregated in the hidden state while ignoring the output at each step. Eventually, the hidden state at the final step becomes a vector representation of the whole input sequence.

By connecting this encoder with a decoder, one can easily build a *sequence-to-sequence* model [12], which can convert an input sequence to another sequence (Fig. 4). Namely, the hidden state of the decoder is initialized by the output of the encoder. This framework is more generally called the *encoder-decoder* architecture. By means of end-to-end learning in which backpropagation is performed through output to input, both decoder and encoder parameters are simultaneously optimized to achieve the overall task.

Advanced Techniques

Although RNN is a reasonable sequence model, some weaknesses are also known. First, although RNN can handle sequence dynamics at arbitrary scales in theory, in practice, it is difficult to learn long-term dependencies because of the problems of vanishing or exploding gradients [2]. This is because RNN usually becomes a very deep network whose number of layers is the length of the sequence. Therefore, in the current standard,

more powerful techniques are commonly used to represent the hidden state, such as long short-term memory (LSTM) [6], which has a gating mechanism to control information flow so that gradients are properly preserved.

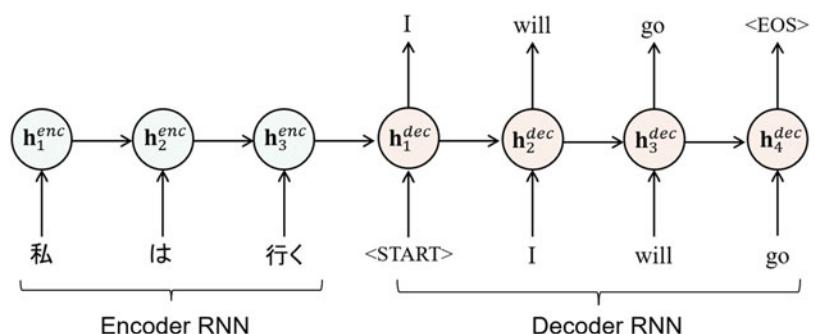

It is also known that decoding all input information from only the embedding vector given by the encoder is very difficult in practice. In particular, information regarding the order of input elements tends to be lost. To alleviate this problem, the *attention mechanism* is proposed as a powerful tool to refocus important input elements at each step of decoding [1, 7]. In the current standards, sequence-to-sequence models are commonly implemented with LSTM and attention mechanisms.

Another important issue is the enhancement of the representational power of RNN architectures. A basic RNN conveys information in only one direction, i.e., past to future. Nevertheless, it is sometimes useful to consider future information as well when it is available in the task. For example, in action recognition, there might be more noticeable visual features in somewhat future frames rather than in that of the exact moment of the action. To include such information, bidirectional RNN (BiRNN) [11] incorporates a future-to-past stream as well as the standard past-to-future stream and then combines the two streams at the output layer.

Moreover, as the original RNN has a relatively shallow structure in the input-to-output path at each step, it is also common to stack multiple RNN streams to further improve representational ability [5].

Recurrent Neural Network, Fig. 4

Sequence-to-sequence model applied to machine translation

Application

Machine Translation

The most representative application of sequence-to-sequence modeling is machine translation, which is one of the earliest successes of deep learning in natural language processing [12]. Here, the input and output are sentences (i.e., word sequences) in a source language and a target language, respectively. Merely by concatenating a source language encoder and a target language decoder, one can build the translation model and perform supervised learning (Fig. 4). Because traditional machine translation methods were based mostly on domain-specific knowledge and engineering, the success of this simple model greatly affected the community.

Image and Video Captioning

One of the important advantages of the encoder-decoder framework is its high versatility. With properly designed encoder and decoder networks, one can realize arbitrary input–output application in the same manner as in machine translation. For example, end-to-end image captioning systems can be realized by combining a CNN encoder and an RNN decoder [15], which describes the contents of input images (e.g., objects, scenes, actions) using natural language. This is known as a typical fusion task of image recognition and natural language processing.

Similarly, video captioning can be realized by aggregating visual features extracted from each frame with an encoder RNN and connecting it with a decoder RNN [14].

Open Problems

Although RNN and LSTM are established as standard tools for sequence modeling, it is important to pay attention to the progress of other approaches as well. In particular, many other powerful methods have been developed recently for sequence encoding. For example, some methods simply use pooling to aggregate input information, or apply one-dimensional CNN [3, 16], resulting in faster computation with similar or

better performance. Moreover, it has been argued whether it is really necessary to aggregate information in one hidden state. In fact, the *transformer* model [13] performs sequence encoding and decoding only by attention mechanisms and has achieved state-of-the-art performance in machine translation as of 2018. Now, the transformer is becoming a new standard of sequence embedding in place of RNN. It is essential to keep in mind that RNN is not necessarily the best choice and to carefully choose methods appropriate for the desired task.

- Plane-based camera calibration [1]
- Single-view metrology [2]
- Ground plane as a reference plane for vehicle navigation
- 3D structure recovery using a reference plane

The key observation is that an image of a plane is related to the plane in space by a homography (plane projective transformation). A point not on the plane will not be mapped by the homography, resulting the so-called plane parallax.

Definition

A *reference plane* is a plane used as a reference or a constraint to solve various computer vision problems.

Background

A reference plane, because of its known geometry, can be used in many applications:

Theory

Projective transformation is a concept used in projective geometry to describe how a set of geometric objects maps to another set of geometric objects in *projective space*. The basic intuition behind projective space is to add extra points (points at infinity) to Euclidean space, and the geometric transformation allows to move those extra points to traditional points, and vice versa.

Homogeneous coordinates are used in projective space much as Cartesian coordinates are used in Euclidean space. A point in two dimensions is described by a 3D vector. A point in three dimension is described by a 4D vector. If the homogeneous coordinates of a given point are multiplied by a nonzero scalar, the resulting homogeneous coordinates represent the same point. That is, $\lambda \mathbf{m}$ ($\lambda \neq 0$) and \mathbf{m} represent the same point. Consider a point $\mathbf{p} = [u, v]^T$ on a plane in Euclidean space; its corresponding homogeneous coordinates are $\mathbf{m} = \lambda[u, v, 1]^T$. A point at infinity on the plane is represented by $[\alpha, \beta, 0]^T$, i.e., the last element is 0. A point at infinity in 2D space can be used to describe the direction of a line on the plane. Now consider a point $\mathbf{p} = [x, y, z]^T$ in 3D Euclidean space; its corresponding homogeneous coordinates are $\mathbf{m} = \lambda[x, y, z, 1]^T$. A point at infinity in 3D space is represented by $[\alpha, \beta, \gamma, 0]^T$, i.e., the last element is 0.

Projective linear transformations do not preserve sizes and angles. They do preserve incidence (e.g., points on a line remain on a line

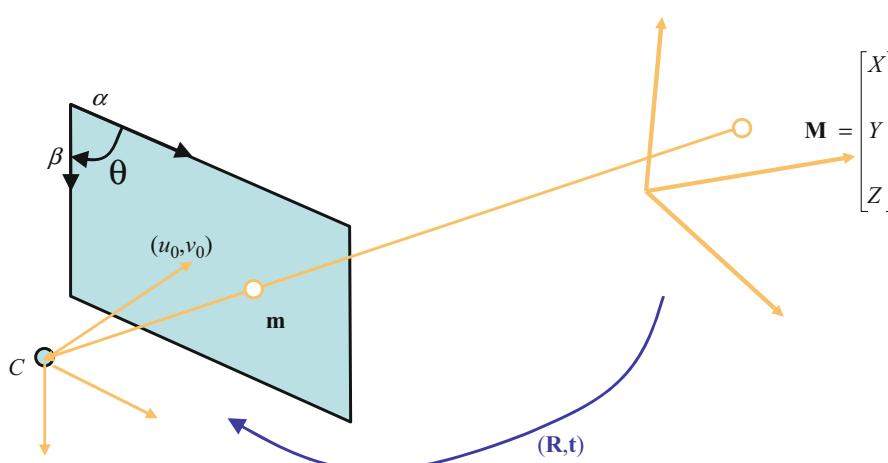

after transformation; two lines intersecting with each other will intersect after transformation) and cross ratio. A projective linear transformation are also known as a *collineation* or *projectivity*. In the case of projective plane (P^2), it is also known as a *homography* or *plane projectivity*. In computer vision, homography plays an important role because any two images of the same planar surface are related by a homography.

A camera is modeled by the usual pinhole (see Fig. 1). A 2D point is denoted by $\mathbf{m} = [u, v]^T$. A 3D point is denoted by $\mathbf{M} = [X, Y, Z]^T$. We use $\tilde{\mathbf{x}}$ to denote the augmented vector by adding 1 as the last element: $\tilde{\mathbf{m}} = [u, v, 1]^T$ and $\tilde{\mathbf{M}} = [X, Y, Z, 1]^T$. The relationship between the 3D point \mathbf{M} and its image projection \mathbf{m} is given by

$$s\tilde{\mathbf{m}} = \mathbf{A}[\mathbf{R} \ \mathbf{t}]\tilde{\mathbf{M}} \quad (1)$$

where s is a scale factor; (\mathbf{R}, \mathbf{t}) , called the extrinsic parameters, is the rotation and translation which relates the world coordinate system to the camera coordinate system; and \mathbf{A} is called the camera intrinsic matrix.

Without loss of generality, we assume the reference plane is on $Z = 0$ of the world coordinate system. Let us denote the i th column of the rotation matrix \mathbf{R} by \mathbf{r}_i . From Eq. (1), we have

Reference Plane, Fig. 1 Pinhole camera model

$$\begin{aligned} s \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} &= \mathbf{A} \begin{bmatrix} r_1 & r_2 & r_3 & t \end{bmatrix} \begin{bmatrix} X \\ Y \\ 0 \\ 1 \end{bmatrix} \\ &= \mathbf{A} \begin{bmatrix} r_1 & r_2 & t \end{bmatrix} \begin{bmatrix} X \\ Y \\ 1 \end{bmatrix}. \end{aligned}$$

By abuse of notation, we still use \mathbf{M} to denote a point on the model plane, but $\mathbf{M} = [X, Y]^T$ since Z is always equal to 0. In turn, $\tilde{\mathbf{M}} = [X, Y, 1]^T$. Therefore, a model point \mathbf{M} and its image \mathbf{m} is related by a homography \mathbf{H} :

$$s\tilde{\mathbf{m}} = \mathbf{H}\tilde{\mathbf{M}} \text{ with } \mathbf{H} = \mathbf{A} \begin{bmatrix} r_1 & r_2 & t \end{bmatrix}. \quad (2)$$

As is clear, the 3×3 matrix \mathbf{H} is defined up to a scale factor.

Furthermore, two images of the same plane are related with each other also by a homography. We use the superscript ⁽¹⁾ and ⁽²⁾ to indicate the image points related to images 1 and 2, respectively. From Eq. (2), we have

$$s^{(1)}\tilde{\mathbf{m}}^{(1)} = \mathbf{H}^{(1)}\tilde{\mathbf{M}}, \quad (3)$$

$$s^{(2)}\tilde{\mathbf{m}}^{(2)} = \mathbf{H}^{(2)}\tilde{\mathbf{M}}. \quad (4)$$

R

It is easy to see that image point $\mathbf{m}^{(2)}$ is related to image point $\mathbf{m}^{(1)}$ by

$$s^{(21)}\tilde{\mathbf{m}}^{(2)} = \mathbf{H}^{(21)}\tilde{\mathbf{m}}^{(1)} \text{ with } \mathbf{H}^{(21)} = \mathbf{H}^{(2)}\mathbf{H}^{(1)-1}. \quad (5)$$

$\mathbf{H}^{(21)}$ is the homography from images 1 to 2.

For a point not on the reference, say $\mathbf{P} = [X, Y, Z, 1]^T$, its projection onto the reference plane is $\mathbf{M} = [X, Y]$. Mapping it to the image plane with the homography gives

$$s\tilde{\mathbf{m}} = \mathbf{H}\tilde{\mathbf{M}} = \mathbf{A} [\mathbf{r}_1 \mathbf{r}_2 \mathbf{t}] \tilde{\mathbf{M}}.$$

The real image of point \mathbf{P} , however, is given by

$$t\tilde{\mathbf{p}} = \mathbf{A} [\mathbf{R} \mathbf{t}] \tilde{\mathbf{P}} = \mathbf{A} [\mathbf{r}_1 \mathbf{r}_2 \mathbf{t}] \tilde{\mathbf{M}} + \mathbf{A} \mathbf{r}_3 Z.$$

Clearly, the plane-mapped point \mathbf{m} is not the same as the real image point \mathbf{p} . The difference is the plane parallax. The farther away the point \mathbf{P} is from the reference plane, the larger the plane parallax is. Plane parallax is an important quantity in 3D structure recovery based on a reference plane.

Definition

A reflectance map is a function that gives scene radiance as a function of surface orientation.

Background

The amount of light reflected by a surface element in a given direction depends on its optical properties, on its microstructure, and on the spatial and spectral distribution of the light sources. For many materials, the fraction of the total irradiance reflected toward the viewer depends only on the surface orientation. Horn [1] introduced the reflectance map as a way to specify scene radiance as a function of surface orientation, given the following simplifying assumptions:

1. The direction toward the viewer is the same at every visible point on the surface. This holds when image projection is orthographic.
2. The direction toward the light source is the same at every visible point on the surface. This holds for point light sources at infinity and for parallel (i.e., collimated) light sources.
3. Reflectance is isotropic about the surface normal. This holds when there is no inherent directionality in surface microstructure, making reflectance invariant to rotation of the surface about the surface normal.

A reflectance map compiles the relevant information about surface material, light source dis-

tribution, and viewing geometry into a single function. It is central to *physics-based vision* including *shape from shading* and *photometric stereo*.

Work to recover height profiles from intensity measurements originated in lunar astronomy. The height variation of points on the lunar surface is small compared to the overall distance of the moon from the earth, making image projection effectively orthographic. Direct sun illumination on the lunar surface is effectively illumination of a point light source at infinity.

As originally formulated by Horn [1], the reflectance map used the gradient to represent surface orientation. Earlier, Mackworth [2] used gradient space to express geometric constraints in the interpretation of line drawings of polyhedra. Defining the reflectance map as a function of the gradient combines radiometric and geometric constraints in a common representation, the gradient space. Subsequent variants of the reflectance map have used other representations for surface orientation including the (unit) surface normal, spherical coordinates, and stereographic coordinates.

Theory

A standard geometry is assumed. Let the visible surface be given explicitly by $z = f(x, y)$ in a left-handed Euclidean coordinate system, where the viewer is looking in the positive z direction, image projection is orthographic, illumination is parallel, and the image in the xy -axes coincides with the scene in the xy -axes. The surface *gradient* (p, q) is defined by

$$p = \frac{\partial f(x, y)}{\partial x} \text{ and } q = \frac{\partial f(x, y)}{\partial y} \quad (1)$$

so that a surface normal vector is $[p, q, -1]$. The gradient (p, q) is one way to represent the two degrees of freedom of surface orientation.

The reflectance map, $R(p, q)$, determines scene radiance as a function of the gradient for a specific surface material, scene illumination, and viewing geometry. Further, if an ideal (calibrated)

camera produces image intensity proportional to scene radiance, then the image irradiance equation is

$$E(x, y) = R(p, q) \quad (2)$$

where $E(x, y)$ is image irradiance. Equation (2) is a nonlinear, first-order partial differential equation. *Shape from shading* methods determine a surface, $z = f(x, y)$, that satisfies the image irradiance equation over some domain, Ω , including any initial conditions specified on the boundary, $\partial\Omega$, or elsewhere. Sometimes, a priori constraints on the reflectance map simplify shape analysis. Three such cases are:

1. If $R(p, q)$ is symmetric about the origin in gradient space, then it is a function of $\sqrt{p^2 + q^2}$ alone and Eq. (2) is eikonal. An eikonal image irradiance equation can often be achieved by aligning a single light source direction with the viewing direction.
2. For the special case of material in the maria of the moon and other materials for which reflectance depends only on the ratio of the incident and emergent angles, $R(p, q)$ is linear in p and q .
3. For an ideal diffuse (Lambertian) reflector, Eq. (2) becomes linear if the (unit) surface normal, rather than the gradient, is used to represent surface orientation.

R

Application

Generic robot vision tasks such as object recognition, pose determination, and inspection typically assume that measured brightness depends upon surface shape. When the illumination and surface material are fixed, it becomes possible to relate measured brightness directly to shape, as the reflectance map demonstrates.

Remote sensing, on the other hand, typically assumes that (multispectral) measurements define a “spectral signature” that depends upon surface material (i.e., ground cover). Not surprisingly, difficulties arise when rugged terrain and illumination change confound the

measurements. Reflectance maps have been used to decouple geometric effects, associated with elevation, slope, and aspect, and from spectral effects, associated with surface material.

Determining the Reflectance Map

Reflectance maps are used in methods to determine shape and surface material from measured brightness and color. But, how are the appropriate reflectance maps determined? There are three approaches:

1. Reflectance can be modeled phenomenologically. That is, one imagines how an idealized material might reflect light and derives the expression for scene radiance accordingly. Ideal diffuse (Lambertian) reflection is one example of a phenomenological model. Phong shading, popular in computer graphics, is another. A reflectance map is obtained when the gradient (p, q) is used to represent surface orientation.
2. There is a standard nomenclature for reflectance [3]. The intrinsic reflectance properties of a surface material are specified by its *bidirectional reflectance distribution function* (BRDF). When the BRDF and light source distribution are known, the reflectance map can be derived analytically. Specific examples are given in [4].

Analytic modeling extends to taking simple phenomenological models, like ideal diffuse or ideal specular reflection, and applying them to a surface microstructure of known (or assumed) particle shape and distribution. For example, in reflectance spectroscopy, a technique in analytic chemistry, materials are grounded into fine powders of known particle size and shape. Analytic models are developed to relate measured reflectance of the powders to the optical properties of the material of which they are composed.

3. Finally, a reflectance map can be measured directly using a goniometer-mounted sample or indirectly from images of a calibration object of known shape, such as a sphere. Empirical measurement has the benefit of automatically compensating for the transfer

characteristics of the camera (or other sensor). Calibration results are directly applicable to the analysis of other objects of different shape but made of the same material as the calibration object and illuminated and viewed under the same conditions. In this way, a material with any reflectance characteristic can be handled, provided that the necessary calibration can be done. In some applications, it has been useful to use paint (or other coating) to match reflectance properties between a calibration object and other objects to be analyzed.

Empirical measurement over a wide range of viewpoints and illumination conditions is both data and time intensive. This has led to approaches that are best termed semiempirical. Reflectance is assumed to take on a particular functional form, typically a linear combination of certain basis reflectance functions, and empirical measurement is used to estimate the parameters associated with the assumed functional form.

Open Problems

Image irradiance equations can be generalized to accommodate perspective projection, nearby light sources, reflectance that is not isotropic about the surface normal, and optical properties of the medium through which the radiant energy is transmitted. Increasingly, the spectral dependence of reflectance also is made explicit. This adds complexity to the associated optical equations, in the case of analytic models, and to the associated calibration/storage requirements, in the case of empirical models.

Unfortunately, with empirical models, it is difficult to use measurements acquired under one condition of illumination and viewing to predict the reflectance map for other conditions of illumination and viewing. Specifically, there is no fundamental, scale-independent distinction to be made among intrinsic optical properties (i.e., the BRDF), surface microstructure, and gross surface shape.

Any reflectance map is subject to error in the presence of cast shadows and interreflection. No purely local definition can succeed since these phenomena are inherently nonlocal. Interreflection, for example, causes changes in the local illumination owing to the secondary reflections from adjacent object points.

Reflectance Models

Szymon Rusinkiewicz
Department of Computer Science, Princeton
University, Princeton, NJ, USA

Synonyms

Analytic reflectance functions; Bidirectional reflectance distribution function; BRDF models

Definition

Reflectance models are analytic functions specifying the ratio of reflected radiance to irradiance at a point.

Background

Whether for recognition or image synthesis, it is frequently necessary to have a model for how much light a surface will reflect. Though a surface may reflect a different amount of light at each position, the bidirectional reflectance distribution function (BRDF) embodies the reflectance at a single point, for every possible angle of incident and exitant light. It is defined [1] as the ratio of reflected radiance in a direction ω_o to irradiance from direction ω_i :

$$f_r(\omega_i \rightarrow \omega_o) = f_r(\theta_i, \varphi_i, \theta_o, \varphi_o) \\ = \frac{dL_o(\omega_o)}{dE_i(\omega_i)}. \quad [\text{sr}^{-1}] \quad (1)$$

Note that this equation is defined in terms of *irradiance*, which implicitly includes the famous “cosine law” of incident light. Thus, the BRDF must be multiplied by $\cos \theta_i$ in order to obtain the full variation of reflected light as a function of the angle of incidence (for a distant light source).

Though research into photorealistic image synthesis increasingly uses dense BRDF measurements (including thousands of samples across different angles of incidence and exitance) [2], the reflectance of many surfaces is adequately predicted by simple analytic functions with few free parameters. Assuming such an analytic model makes it practical to infer the complete bidirectional reflectance from a small number of measurements, fitting the function and obtaining its parameters based on the available data [3]. This function, in turn, may be used to interpret further images.

Theory

Three general classes of reflectance models have been developed in the literature. *Physically based* models attempt to model reflectance from first principles, beginning with the solution to Maxwell’s equations on surfaces of known geometry. *Microfacet* models assume a rough surface geometry, which is not known exactly but

may be characterized statistically. Finally, ad hoc, phenomenological, or *empirical* models capture some qualitative features of reflectance without necessarily striving for, or achieving, certain aspects of *physically plausible* reflectance.

Physical plausibility in reflectance typically refers to two specific properties satisfied by all actual surfaces. The first is *energy conservation*: because all incident light must be either reflected or absorbed and no light may be created during reflection, it is impossible for a surface to reflect more light than was incident on it. Mathematically, the integral of the BRDF over all outgoing directions, scaled by a cosine term to account for foreshortening, must be less than one:

$$\forall \omega_i : \int_{\Omega} f_r(\omega_i, \omega_o) \cos \theta_o d\omega_o \leq 1. \quad (2)$$

A second, more subtle, property of BRDFs is that they must be unchanged when the angles of incidence and exitance are swapped:

$$f_r(\omega_i \rightarrow \omega_o) = f_r(\omega_o \rightarrow \omega_i). \quad (3)$$

This is a condition known as *Helmholtz reciprocity* and is due to the symmetry of light transport [4]. Some systems, such as the work on Helmholtz stereopsis [5], have relied on this property, which often expressed as camera/projector duality: in many imaging systems, it is possible to interchange the roles of camera and projector, provided that cosine terms are properly accounted for.

Lambertian Reflectance

We now turn to specific reflectance models. The simplest is just a constant:

$$f_r = \text{const.} = \rho/\pi. \quad (4)$$

(It is important to keep in mind that the BRDF is defined in terms of irradiance, which has the “incident cosine law” implicitly included.) This results in a matte or diffuse appearance and is known as ideal Lambertian reflectance. This BRDF is frequently written as a constant ρ divided by π . In this case, ρ is interpreted as

the diffuse albedo: it is the fraction of light that is reflected (vs. absorbed) by the surface, and a surface with this reflectance conserves energy precisely when the albedo is less than or equal to one. Because this model is independent of the directions of incidence and exitance, it also satisfies reciprocity.

Phong and Blinn-Phong BRDFs

Another simple analytic BRDF, designed to empirically mimic the appearance of glossy (also called shiny or specular) materials, is the Phong model [6]:

$$f_r = k_s (\mathbf{r} \cdot \mathbf{v})^n, \quad (5)$$

where \mathbf{v} is the direction toward the viewer and \mathbf{r} is the mirror reflection of the light direction from the tangent plane. Note that a frequently used version of the Phong “BRDF” includes an additional $1/\cos \theta_i$ factor, which is canceled by the irradiance cosine law. The latter is therefore not a physically plausible BRDF: it does not exhibit reciprocity and does not conserve energy.

A common variant of this model is sometimes known as the Blinn-Phong model [7]:

$$f_r = k_s (\mathbf{n} \cdot \mathbf{h})^n, \quad (6)$$

though again it is often stated as a physically implausible shading model rather than a BRDF. In this equation, \mathbf{h} is the “halfway” vector, which is midway between the light direction \mathbf{l} and the viewer direction \mathbf{v} :

$$\mathbf{h} = \frac{\mathbf{l} + \mathbf{v}}{\|\mathbf{l} + \mathbf{v}\|}. \quad (7)$$

In contrast to the Lambertian BRDF, the distribution of reflected light in these models is not constant. In fact, there is a lobe centered around the direction of ideal mirror reflection for each incident angle, containing significantly more energy than the rest of the domain. This is known as the specular lobe, and its size and width (fall off) are controlled by the parameters k_s and n , respectively.

Lafortune BRDF

A popular model used for fitting analytic functions to measured BRDF data is the Lafortune model [8]:

$$f_r = (C_x l_x v_x + C_y l_y v_y + C_z l_z v_z)^n, \quad (8)$$

in which l_x , v_x , etc. represent the components of the light vector \mathbf{l} and view vector \mathbf{v} , in a coordinate system in which the surface normal is oriented along the z -axis. This model reduces to Phong by choosing $-C_x = -C_y = C_z = \sqrt[3]{k_s}$ but through suitable choice of parameters can also represent non-Lambertian diffuse reflection, off-specular reflection, anisotropy, and retro reflection. It is also common to fit a sum of multiple lobes of (Eq. 8) to measured datasets.

Ward BRDF

Another popular BRDF used in fits to measurements is the Ward model [9]:

$$f_r = k_s \frac{e^{-\tan^2 \theta_h ((\cos^2 \phi_h)/\alpha_x^2 + (\sin^2 \phi_h)/\alpha_y^2)}}{4\pi \alpha_x \alpha_y \sqrt{\cos \theta_i \cos \theta_o}}. \quad (9)$$

Compared to the Blinn-Phong BRDF, the Ward model includes a specular peak shaped by a Gaussian function (as opposed to a power-of-cosine model) but also can model anisotropic reflection by using separate Gaussian widths α_x and α_y in two perpendicular directions.

Microfacet BRDFs

Numerous BRDFs have been derived from first principles that predict the aggregate reflectance for surfaces that at a small scale consist of tiny, mirror-reflective “microfacets” oriented in random directions. An early microfacet BRDF was originally developed in the physics community by Torrance and Sparrow [10], introduced in graphics by Blinn [7], and later refined by Cook and Torrance [11]:

$$f_r = \frac{D G F}{\pi \cos \theta_i \cos \theta_o}. \quad (10)$$

There are three major terms in the model that describe the angular distribution of microfacets, how many are visible from each angle, and how light reflects from each facet.

The first term D in the Torrance-Sparrow model describes the density of facets facing in any possible direction:

$$D = \frac{e^{-(\tan^2 \theta_h)/m^2}}{4 m^2 \cos^4 \theta_h}, \quad (11)$$

where θ_h is the angle between the halfway vector \mathbf{h} and the surface normal \mathbf{n} . Notice that part of this term resembles a Gaussian, and this is not a coincidence: the Torrance-Sparrow model makes the assumption that the microfacet normals have a Gaussian distribution controlled by a “roughness” parameter m . The $\cos^4 \theta_h$ term occurring here is a change-of-basis term: it is included to properly normalize a probability distribution expressed in terms of the halfway vector.

The next term G in the Torrance-Sparrow model accounts for the fact that not all facets are visible from all directions, because they are hidden by the facets in front of them. It includes both “shadowing” and “masking” effects, representing occlusion from the point of view of the light and viewer, respectively:

$$G = \min \left\{ 1, \frac{2 \cos \theta_h \cos \theta_i}{\cos \theta_d}, \frac{2 \cos \theta_h \cos \theta_o}{\cos \theta_d} \right\}. \quad (12)$$

This formula is derived by considering a particular microgeometry: the microfacets are assumed to form V-shaped grooves in the surface, which are symmetric about the (macroscopic) surface normal.

Finally, the reflection from each facet is described by the Fresnel term F , which predicts that reflection increases toward grazing angles. This term arises from a solution to Maxwell’s equations on a surface:

$$F = \frac{1}{2} (F_{\perp} + F_{\parallel}) = \frac{1}{2} \left[\left(\frac{\sin(\theta_t - \theta_d)}{\sin(\theta_t + \theta_d)} \right)^2 + \left(\frac{\tan(\theta_d - \theta_t)}{\tan(\theta_d + \theta_t)} \right)^2 \right], \quad (13)$$

where θ_d is half the angle between the incident and exitant directions, $\theta_t = \sin^{-1}((\sin \theta_d)/\eta)$, η is the index of refraction of the surface, and the two terms represent the portion of reflected light polarized perpendicular and parallel to the plane of incidence. Note that the “difference angle” θ_d is the angle of incidence (and exitance) on a microfacet oriented to produce mirror reflection between the desired angles of incidence and reflection.

More recently, Ashikhmin et al. [12] generalized these types of microfacet BRDFs to allow expressing arbitrary half angle distributions. They demonstrate how to modify these BRDFs to replace the analytic distribution in Eq. 11 with alternative analytic forms or tabulated (sampled) functions that can express arbitrary patterns.

More Complex Analytic BRDFs

In addition to models for primarily specular surfaces, physically based BRDFs have been derived for rough diffuse surfaces (the Oren-Nayar model [13]) and for dusty surfaces (the Hapke/Lommel-Seeliger model, developed to model lunar reflectance [14]). They range in complexity from simple formulas that ignore many real-world effects to complex models that attempt to account for most actually observed surface phenomena (e.g., the He-Torrance-Sillion-Greenberg model [15]). While a detailed description of these models is beyond the scope of this entry, they are sometimes used in rendering or vision systems. The Oren-Nayar model, in particular, is often combined with the Torrance-Sparrow model (with the abbreviation TSON) to model surfaces with both a specular and non-Lambertian diffuse component. One drawback of these models, however, is that their additional complexity and many parameters can make it difficult or unstable to fit them to measured data.

Related Concepts

► Constrained Optimization

Definition

The regularization is a technique for an optimization problem with both under-constraint and over-constraint conditions. By adding a regularization term which restricts the range of variables, a penalty is imposed against the complexity or ill-posedness of the original cost function to improve the stability of the solution [1, 2]. The variable restriction is usually for smoothness and bounds of the vector space norm of variables.

The regularization is defined as, to an original cost function of $E_{\text{org}}(\mathbf{w})$ which is optimized in subject to $\mathbf{w} = (w_1, \dots, w_n)$, a regularization term (or regularizer) $R(\mathbf{w})$ is added and

$$E_{\text{reg}}(\mathbf{w}) = E_{\text{org}}(\mathbf{w}) + \lambda R(\mathbf{w}) \quad (1)$$

is totally optimized. In this form, λ is a hyper-parameter which controls the importance of the regularization term. The cost function, usually for the computer vision problem, is given as the data-fitting error to a model described by the parameter variables $\mathbf{w} = (w_1, \dots, w_n)$, and the optimization

is to find the most probable model parameters to the given image data.

The most general forms of the regularization term are with L_p norms of $\|\mathbf{w}\|_p^p$, especially in the machine learning applications. When we apply the L_1 or L_2 regularizations for the *linear regression* models, that is,

$$E_{\text{reg}} = \|Y - X\mathbf{w}\|_2 + \lambda \|\mathbf{w}\|_p^p \quad (2)$$

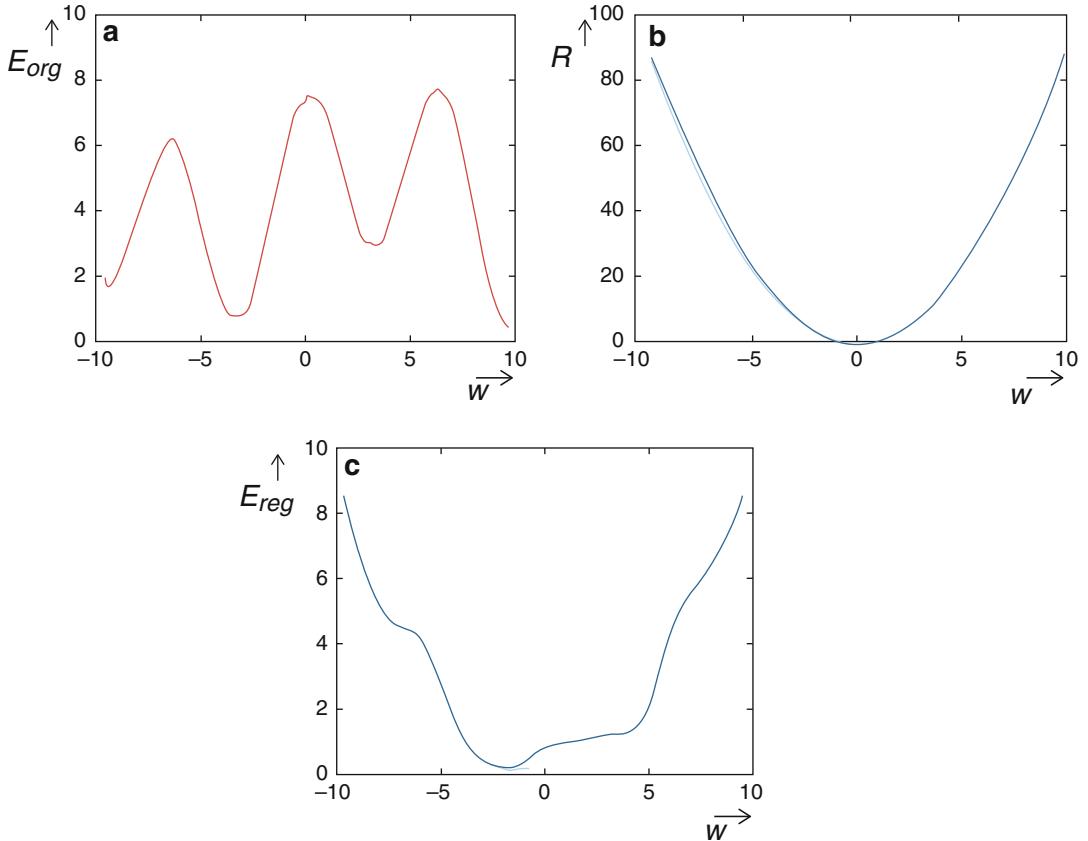

where X represents a linear weighting model with parameter variables \mathbf{w} and Y is a set of given data. The L_1 regularization ($p = 1$) is called the *Lasso* [3], and the L_2 regularization ($p = 2$) the *ridge regression* [4].

Background

The most of computer vision problem is categorized to the model fittings. The typical models are those of the perspective imaging of cameras. From the image data obtained by the camera, the problem is to reconstruct the 3D world situations of the image acquisitions. It includes camera optical parameters, camera position and poses, object 3D shapes, and other conditions represented by the parameters of \mathbf{w} in the imaging model. In other words, it must be treated as “inverse problem.”

Sometimes, we have too many image data to determine the true parameters. But, it is rather common that the data is insufficient to the parameter identification. For both cases, the regularization must work to compensate between the model fitting and reasonable parameter identification.

It is commonly believed that, if we employ the more number of parameters to describe the model, the more truly fine real-world model will be realized. However, we must compromise the number of data and reliability of the model. The regularization provides a go-between technique for them, so that sometimes it is called an *Occam's razor*.

Regularization, Fig. 1 A simple schematical example of the regularization process

Theory

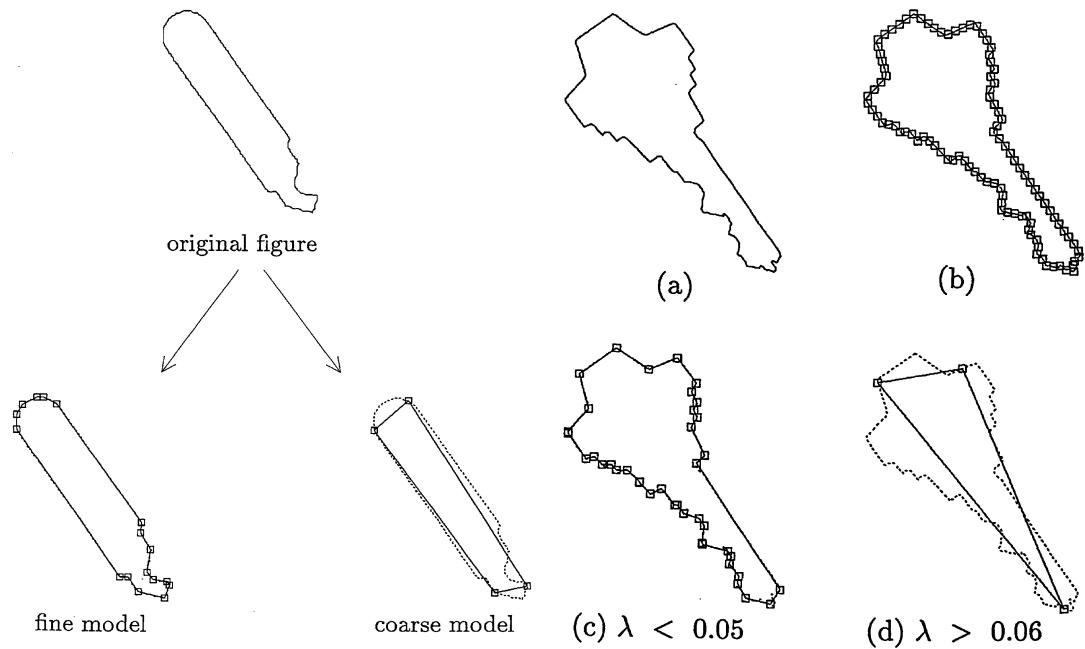

Figure 1 shows a simple schematic example of the effect of the regularization term. Assume that we are now fitting a model to a set of observed data. The problem is to determine the most probable model parameter w for this data set by evaluating the fitting error. But, the fitting error $E_{\text{org}}(w)$ is given as multiple peak and valley form with respect to w as shown in (a). Also we assume to have a prior knowledge about w that it must be near to a . Then, we introduce the regularizing term as $R(w) = (w - a)^2$ as shown in (b) (in the figure, $a = 0$), so that the optimization is to minimize $E_{\text{reg}}(w) = E_{\text{org}}(w) + \lambda(w - a)^2$ shown in (c) instead of the original error $E_{\text{org}}(w)$ only. In this case, we obtain a unique optimal “regular” solution as shown.

With the regularization term of L_p norms, the regularized cost function will be

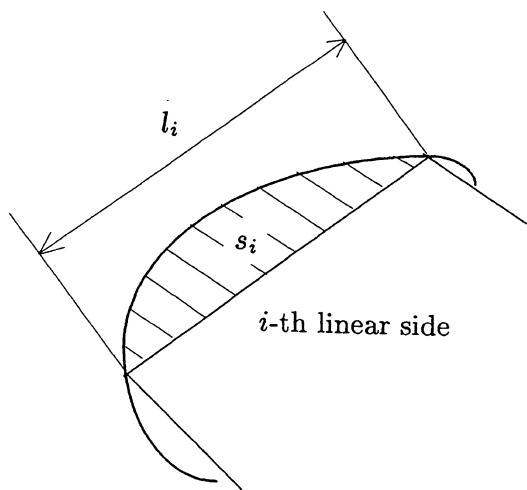

$$\begin{aligned} E_{\text{reg}}(\mathbf{w}) &= E_{\text{org}}(\mathbf{w}) + \lambda \frac{1}{p} \|\mathbf{w}\|_p^p \\ &= E_{\text{org}}(\mathbf{w}) + \lambda \frac{1}{p} \sum_i |w_i|^p \end{aligned} \quad (3)$$

For these cases, the partial differentiations of the cost function by the model parameters are given as

$$\begin{aligned} \frac{\partial E_{\text{reg}}(\mathbf{w})}{\partial w_i} &= \frac{\partial E_{\text{org}}(\mathbf{w})}{\partial w_i} + \lambda w_i && : \text{for } L_2 \quad (4) \\ &= \frac{\partial E_{\text{org}}(\mathbf{w})}{\partial w_i} + \lambda \text{sgn}(w_i) && : \text{for } L_1 \end{aligned} \quad (5)$$

Regularization, Fig. 2 Polygonal approximation of a figure with fine or coarse models

Regularization, Fig. 3 Measure of fitness of the polygonal approximation with the i th edge

These mean that, when the steepest descent method and the stochastic gradient descent are employed for the optimization, the L_2 regularization moves the solution w_i closer to 0 by an additional value proportional to the regularization parameters. The L_1 regularization does it by λ , if $|w_i|$ is greater than λ . Otherwise, $w_i = 0$.

Regularization, Fig. 4 Experimental results of proposed polygonal approximation method for a silhouette contour of (a). (b) Initial vertex settings for iterative minimization of the criterion. (c) Obtained vertices of polygon with $\lambda = 0.05$ and (d) with $\lambda = 0.09$

The latter case of L_1 regularization can be interpreted as a kind of “model selection,” because it may make some model parameters be 0 and achieves the sparsity.

Open Problems

The role of the hyper-parameter λ is an important open problem. Some important interpretation of the regularization results with the change of the λ was reported [5].

Experimental Results

Here, a typical application of the regularization technique for a polygonal fitting to a contour figure is shown [5]. A contour figure in Fig. 2 can be approximated with fine or coarse polygonal model to capture its structure. The basic idea of the approximation model fitting problem is to

optimize such the criterion function as,

$$\begin{aligned} E_{\text{reg}} &= E_{\text{org}} \text{(fitting error to the model)} \\ &+ \lambda R \text{(complexity of the model)} \end{aligned} \quad (6)$$

This is conceptually equivalent to the application of the regularization theory to model fitting problems [6, 7].

When a polygon of n line segment edge is employed to fit the contour, the criterion is given as,

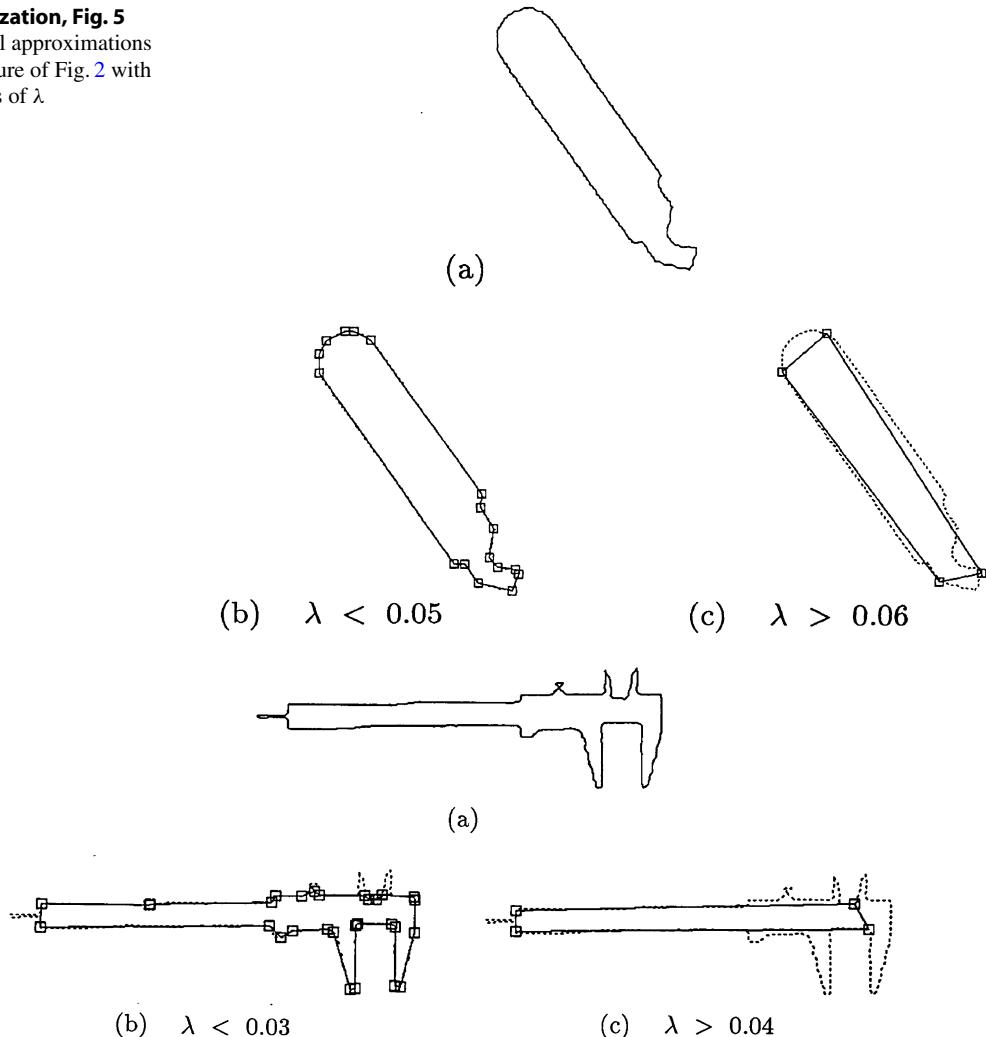

$$E_{\text{reg}} = \sum_i s_i - \lambda \frac{\sum_i l_i^2}{(\sum_i l_i)^2} \quad (7)$$

Regularization, Fig. 5

Polygonal approximations of the figure of Fig. 2 with variations of λ

where, as shown in Fig. 3, s_i is the difference area between i th linear side of the approximating polygon and the corresponding segment piece of the given contour figure and l_i is the length of the i th linear side of the polygon.

The first term is the total fitting error between the given contour and the model, and it becomes smaller when the polygonal sides run closer to the given contour. The fractional part of the second term represents the simpleness of the model. That is, it becomes greater when the number of the polygonal sides is smaller, and for the same numbers, it becomes greater when the polygon

Regularization, Fig. 6 Another example of polygonal approximations by changing the λ

includes some longer sides than when it consists of equal length sides.

These two terms are generally of trade-off and not compatible for most of contour figures. The weight λ compromises between these two terms to obtain “fit and simple” polygon minimizing the total criterion E_{reg} .

Now we discuss, when the value of λ changes, how the form of obtained approximation polygon will change.

Figure 4a shows a silhouette contour of a key consists of 830-digit chain code. For this figure approximation polygons minimizing the criterion E_{reg} with various λ are obtained. The minimization was started by firstly setting many candidate vertices of the polygon on the contour as shown in (b). Figure 4c is the final result of the optimization with $\lambda = 0.05$ which shows the vertex positions of approximation polygon on the original contour. Then, with $\lambda \geq 0.06$, the approximating pattern of (d) was obtained (The figure shown was with $\lambda = 0.09$).

This figure shows important results. That is, for various values of λ , we obtained only two types of polygons: one of which has its vertices at every sharp convex or concave point of the original contour, and the other is a simple triangle representing its global shape. Secondly, the change between these two types of approximating polygons occurs drastically when the value of λ changes across some value.

Some other experimental results are shown in Figs. 5 and 6.

Reinforcement Learning

Shin-ichi Maeda

Preferred Networks, Inc., Tokyo, Japan

Definition

Reinforcement learning (RL) is a framework that aims to optimize a decision-making rule called a *policy* to maximize the long-term cumulative reward of the agent. The policy is a map from state space to the set of actions, and an agent following the policy π is prompted to take action $\pi(s)$ at each state s . In the general setup, the action selection by the policy is stochastic. In this case, $\pi(s)$ for each s is a random variable over the set of actions. The major policy optimization methods can be grouped into two categories. The first category first estimates the action-value function that evaluates the goodness of the action at a given state and uses this function to look for the optimal policy. The second category, on the other hand, directly parametrizes the policy and seeks to optimize the policy-parameters using gradient descent-type approaches.

Background

RL originates from two academic fields, behavioral psychology and optimal control. The word *reinforce* in RL has its origin in behavioral psychology. By observing animals under various environments, behavioral psychology has studied how the animals *reinforce* their behaviors as they seek to obtain more reward and receive

less punishment. This setup is clearly different from that of supervised learning, in which the teacher signal is explicitly given to the learning agent. The word *reinforce* here is also used to make a distinction from supervised learning. As opposed to the scientific approach of behavioral psychology to understand the animals' reward-seeking behavior, optimal control theory provides an answer to a mathematical problem in which the task is to find the *control policy* that can optimize the future reward in a given environment. In the 1950s, Richard E. Bellman proved that the optimal (state) value function in a Markov decision process is given by a solution to the Bellman equation. This comes from the necessary condition the optimal policy should satisfy [4]. If the optimal value function is obtained, one can derive the optimal policy with the knowledge of the dynamics of the system. Although it is possible to compute the optimal value function numerically through dynamic programming methods, the computation cost increases exponentially with the size of the state space. Bellman called this problem the *curse of dimensionality*. Meanwhile, also in the 1950s, Marvin Minsky discussed the usefulness of the *temporal difference error* inspired by the concept of the *secondary reinforcers* in behavioral psychology [10]. Sutton and Barto later refined the idea to develop the computational model of *temporal difference learning* [17]. Chris Watkins, in his seminal 1989 paper [20], proposed the idea of Q-learning and regarded it as asynchronous dynamic programming. In contrast to the state value function, the state-action value function (a.k.a. Q-function) is a function not only of a state but also of an action. Q-function makes it possible to estimate the optimal policy without knowing the dynamics of a system (environment). In general, Q-learning can be performed without the explicit knowledge of the environmental dynamics. Instead, Q-learning is able to learn from state-action samples generated from an *arbitrary* policy. RL has attracted attention as a learning framework that may realize goal-oriented learning with limited supervision and limited prior knowledge. However, historically, there has only been a

modest number of success cases reported, such as TD-gammon. It has been shown that off-policy learning and/or nonlinear function approximation makes the learning process unstable [3, 19], leading people to believe that it might be difficult to make RL work in high-dimensional state spaces.

The turning point came in the 2010s when Google DeepMind presented the Deep Q-Network (DQN), which demonstrated human-level performance on several Atari games, by combining the power of convolutional neural networks and Q-learning [11]. Two important techniques are implemented in DQN: the first is the *fitted-Q* [6] which fixes the target of the Q-function for a certain period to avoid the instability caused by bootstrapping, and the other is the use of *experience replay* [9] that uses a replay buffer to store a large amount of samples and updates the network parameters by using samples randomly drawn from the replay buffer to decorrelate the batch of samples used for the stochastic gradient optimization. DQN opens the door to so-called deep RL where deep neural networks are used to represent the value function and/or the policy. One celebrated achievement of this new technology is AlphaGo, which succeeded in defeating one of the world's best Go players, Lee Sedol. Before the appearance of AlphaGo, there was no AI agent that had beaten a professional Go player in a regular Go game. It was widely believed that only in the far future would an AI agent beat a professional Go player. By combining DQN with Monte Carlo tree search (MCTS), AlphaGo made possible the efficient exploration of seemingly infinite state space by restricting its search to the set of promising moves.

AlphaGo is not a work of "pure" RL, as it uses methods of MCTS and supervised learning as well. However, it was shown later that AlphaGo can be eclipsed by a more pure RL approach. For example, AlphaGo Zero [16] succeeded in using *pure* RL self-training to outperform AlphaGo without relying on the knowledge of human-expert strategy. Schrittwieser et al. [12] later went even further to develop a method

that does not explicitly rely on the rules of Go itself. They also demonstrate the wide applicability of their method by defeating the top computer games agents in the board games of Chess and Shogi.

Theory

In the conventional setting of RL, the agent-environment interaction is often formulated as a Markov decision process (S, A, P, r, P_0) . In this tuple, S is the state space and A is the action space. At any time of the process, the agent is at some s in S , and it is allowed to choose an action a from A . P is state transition distribution $P : S \times S \times A \rightarrow [0, 1]$, and $P(s'|s, a)$ denotes the probability of transitioning from $s \in S$ to $s' \in S$ when the agent takes action $a \in A$. Also, $r : S \times A \times S \rightarrow \mathbb{R}$ represents the reward function, where $r(s, a, s')$ denotes the reward granted to the agent upon taking action a and transitioning from s to s' . When the reward r is stochastic, one often uses expected reward $r(s, a, s') = E[r|s, a, s']$. Finally, $P_0(s)$ is the probability of the initial state of the agent. Hereafter, let subscript t be the (relative) temporal order.

The agent starts from the initial state drawn from P_0 . At each s_t , the agent is prompted to take action from some *behavior policy*, which is a stationary distribution on A conditioned on s_t . The term *behavior policy* is often used to make distinction from '*target policy*', which is often used to represent the policy to be optimized. When the target policy is trained with the samples collected by the behavior policy, the learning is called *off-policy* learning. The celebrated Q-learning algorithm is a member of *off-policy* family.

The agent transitions to a new state and receives a reward according to the state transition distribution P and reward function r , respectively. This cycle is continuously repeated. The purpose of RL is to obtain the target policy that maximizes the expected cumulative rewards $\max_{\pi} E_{\pi}[\sum_{t=1}^T \gamma^{t-1} r_t]$. Here, T is a time horizon, and γ is a constant called the discount

factor that is allowed to take a value in $[0, 1]$. The problem setting in which $T = \infty$ is called the *infinite horizon problem* setting, and γ in this case is chosen to be $\gamma < 1$ to prevent the cumulative reward from becoming infinite. In a typical RL setting, it is often assumed that the transition distribution is not known to the agent, so that the agent cannot use knowledge of P to choose an action at each state. Thus, in a typical RL problem, one must optimize the policy using just the collection of state transitions and rewards *experienced* by the agent. This condition is different from the setting of optimal control theory where the state transition distribution and reward function are assumed to be known to the agent.

Many RL algorithms for obtaining the optimal policy have been proposed to date. Among them, the actor-critic framework is one of the basic frameworks and is a good starting point because it has connections to a wide variety of algorithms.

The actor-critic method of two steps: *policy evaluation step* where the critic evaluates the actor's current policy and the *policy improvement step* where the policy is improved based on the critic's evaluation. In the policy evaluation step, the performance of current policy is often quantified by the so-called *value function*. There are two types of value functions. A state-value function $V^{\pi}(s)$ is a function that estimates the cumulative reward over the episode in which the agent starts from the initial state s and uses the policy π to choose an action at each state. The action-value function $Q^{\pi}(s, a)$, on the other hand, is an analogue of $V^{\pi}(s)$ in which the agent's action at the initial state s is a :

$$V^{\pi}(s) = E_{\pi} \left[\sum_{t=1}^{\infty} \gamma^{t-1} r_t | s_0 = s \right], \quad (1)$$

$$Q^{\pi}(s, a) = E_{\pi} \left[\sum_{t=1}^{\infty} \gamma^{t-1} r_t | s_0 = s, a_0 = a \right]. \quad (2)$$

In the policy improvement step, the policy π' is updated so as to satisfy the following for any state,

$$E_{\pi'}[Q^\pi(s, a)|s] \geq E_\pi[Q^\pi(s, a)|s], \forall s \in S, \quad (3)$$

as long as the policy improvement is performed for all states. The condition (3) does not just guarantee that the new policy π' is better than π when evaluated using Q^π . By using the self-consistent equation known as Bellman equation,

$$Q^\pi(s_t, a_t) = E_\pi[r_{t+1} + \gamma Q^\pi(s_{t+1}, a_{t+1})|s_t, a_t], \quad (4)$$

one can also guarantee that $E_{\pi'}[Q^{\pi'}(s, a)] \geq E_\pi[Q^\pi(s, a)]$.

It is worth noting, however, that this improvement only guarantees the convergence to the local optimum unless the objective is convex, which is often not the case. An additional set of conditions is necessary to guarantee the convergence to global optimum or near-global optimum. The iteration of these two steps is also called as (generalized) policy iteration.

The problem is then how to estimate $Q^\pi(s, a)$ at every update of π for the policy evaluation. One popular way to estimate $Q^\pi(s, a)$ is to utilize the so-called Bellman operator. Bellman operator \mathcal{T}^π is an operator that receives a function F as an input and returns function $\mathcal{T}^\pi F$ as an output. $\mathcal{T}^\pi F$ is defined by the right-hand side of Bellman equation (4) as $\mathcal{T}^\pi F = E_\pi[r_{t+1} + \gamma F(s_{t+1}, a_{t+1})|s_t, a_t]$ for all (s_t, a_t) . This Bellman operator is a contraction in supremum norm when $0 < \gamma < 1$, i.e., $\|\mathcal{T}^\pi F(s, a) - \mathcal{T}^\pi G(s, a)\|_\infty \leq \gamma \|F(s, a) - G(s, a)\|$ for any function $F(s, a)$ and $G(s, a)$. By Banach's fixed point theorem, the sequence of the functions $F(s, a), \mathcal{T}^\pi F(s, a), (\mathcal{T}^\pi)^2 F(s, a), \dots$ will converge to a unique stationary function, $Q^\pi(s_t, a_t)$, irrespective of the initial function F .

In practice, the expectation in the Bellman operator is approximated by the sample average. In particular, the following update is known as Q-learning:

$$\begin{aligned} Q(s_t, a_t) &\leftarrow Q(s_t, a_t) + \\ &\alpha(\hat{\mathcal{T}}^* Q(s_t, a_t) - Q(s_t, a_t)) \end{aligned}$$

$$\begin{aligned} &= Q(s_t, a_t) \\ &+ \alpha(r_{t+1} + \gamma \max_a Q(s_{t+1}, a) \\ &- Q(s_t, a_t)), \end{aligned} \quad (5)$$

where $\hat{\mathcal{T}}^* Q(s_t, a_t)$ is a sample estimate of the optimal Bellman operator $\mathcal{T}^* Q(s_t, a_t) = E[r_{t+1} + \gamma \max_a Q(s_{t+1}, a)|s_t, a_t]$ and (s_t, a_t, s_{t+1}) is a transition sample obtained by the behavior policy and the state transition distribution. If the update (5) is repeated sufficiently many times at all state-action pairs with α that decays at a moderate rate, this iterative algorithm always converges to the optimal action value function [20]. ϵ -greedy is a popular choice for the behavior policy to cover the broad state-action space, which takes the greedy action $a^* = \arg \max_a Q(s_{t+1}, a)$ with probability $1 - \epsilon$ and takes a uniform random action with probability ϵ . The term "Q-learning" is often used to reference an algorithm that uses the policy improvement step in which the new policy is constructed using the deterministic greedy rule $a^* = \arg \max_a Q(s_{t+1}, a)$. Note this target policy always satisfies the condition (3) as it is the solution of $\max_\pi E_{\pi(a|s_{t+1})}[Q(s_{t+1}, a)]$. *Policy improvement* usually refers to this greedy way of updating based on Q . Meanwhile, there is also an important family of algorithms in which the target policy is not defined by $Q(s_{t+1}, a_{t+1})$. This family will be introduced later.

The concept of Q-learning is built on the assumption that there is a way to update Q at each (s, a) independently. This assumption, however, becomes practically impossible when the state space is too large. The cardinality of the state space can even be infinite when it is continuous! In such a case, function approximation is necessary. Suppose w is the parameter of the action value function, $Q_w(s, a)$. The mathematical analogue of (5) in the parameter space is given by

$$\begin{aligned} w &\leftarrow w + \alpha E_{\rho(s)\pi_b(a|s)}[(\hat{\mathcal{T}}^* Q_w(s, a) \\ &- Q_w(s, a))\nabla_w Q_w(s, a)], \end{aligned} \quad (6)$$

where $\rho(s)$ denotes some distribution of the state, and $\pi_b(a|s)$ is a behavior policy. Unfortunately,

however, this update does not necessarily induce a contraction about Q . By examining the Taylor expansion of (6) about w , Achiam et al. [1] showed that (6) cannot be a contraction unless α is sufficiently small and $\rho(s) > 0$ for all s in the state space. The convergence of this update rule may fail also if $Q_w(s, a)$ is very sensitive to w at states that are not involved in the estimation of the Bellman error $\hat{T}^* Q_w(s, a) - Q_w(s, a)$.

In practice, algorithms of DQN [11] often mitigate this instability problem by modifying the Bellman error into a *regression error* by using $\hat{T}^* Q_{w'}$ with a fixed parameter $w' \neq w$ as a target network over each subinterval of the training. To stabilize the training, DQN also uses experience replay [9] where the expectation in Eq.(6) is taken with respect to a uniform distribution over the pool of latest transition samples (s, a, s') called a replay buffer.

$$\begin{aligned}\Delta\theta &\propto \frac{\partial E_{\rho(s)\pi_{\theta'}(a|s)}[Q^{\pi_\theta}(s, a)]}{\partial\theta'} \Big|_{\theta'=\theta} \\ &= E_{\rho(s)\pi_\theta(a|s)} \left[\frac{\partial \log \pi_{\theta'}(a|s)}{\partial\theta'} \Big|_{\theta'=\theta} (Q^{\pi_\theta}(s, a) - b(s)) \right] \\ &= E_{\rho(s)} \left[\int \frac{\partial \pi_{\theta'}(a|s)}{\partial\theta'} \Big|_{\theta'=\theta} (Q^{\pi_\theta}(s, a) - b(s)) da \right],\end{aligned}\quad (7)$$

where $b(s)$ denotes a baseline function.

The equality in Eq.(7) is known as the policy gradient theorem [18], and the algorithms based on this theorem are often referred as policy gradient methods. It is known that the update in Eq. (7) is equivalent to gradient descent of the loss function $E_\pi \left[\sum_{t=1}^{\infty} r_t | s_0 \right]$ on the episodic task with $\gamma = 1$ if $\rho(s)$ is a distribution that represents the fraction of time spent in each state when following policy π .

Any function can be used for the baseline function $b(s)$ as it does not affect the expected value. Meanwhile, the variance of the gradient is affected by the choice of $b(s)$. Because this is generally a gradient descent optimization of a non-convex objective function, the algorithm does not necessarily converge to the optimal policy. The convergence to the global optimum, however, can be guaranteed if the policy class

So far, the target policy derived from $Q_w(s, a)$ has been used only *implicitly* in the policy improvement step, and the policy π has never appeared as an explicit variable. There is also another important family of methods that does not directly derive the target distribution from the Q-function $Q_w(s, a)$. Such cases may arise in robot control, for example, in which the space is continuous and the computation of $a^* = \arg \max_a Q(s_{t+1}, a)$ is difficult.

Suppose the target policy π_θ is parameterized by the parameter θ and θ is updated during the policy improvement step as $\theta \leftarrow \theta + \alpha \Delta\theta$ to improve the parameters in terms of $Q^\pi(s, a)$. Practically, this is done in a form of gradient method. Every time, the parameter θ is updated as $\theta \leftarrow \theta + \epsilon \Delta\theta$ instead of Eq. (3),

is appropriate, e.g., softmax policies applied to finite state and action MDPs [2].

Sometimes a reparameterized policy, such as $\pi_{\theta'}(a|s) = \int N(\epsilon|0, I) \delta(a - f_\theta(s, \epsilon)) d\epsilon$, is used to help reduce the variance of the gradient. Substituting this policy in the first expression of Eq. (7), the following policy gradient is obtained:

$$\Delta\theta \propto E_{\rho(s)N(\epsilon|0,I)}[(\nabla_\theta f_\theta(s, \epsilon)) \nabla_a Q^{\pi_\theta}(s, a)]. \quad (8)$$

Several relevant algorithms are worthy of note. To perform a policy gradient update, it is necessary to estimate $Q^{\pi_\theta}(s, a)$ at every update of π . One can estimate $Q^{\pi_\theta}(s, a)$ by using the sample estimate of the Bellman operator similar to Eq.(6). REINFORCE is an algorithm that uses the Monte Carlo method to approximate $Q^{\pi_\theta}(s, a)$. Deep Deterministic Policy Gradient

(DDPG) [8] is an algorithm that uses the version of (8) that uses deterministic f ; in other words, DDPG uses the policy gradient with $f_\theta(s, \epsilon) = f_\theta(s)$ that does not depend on the random variable ϵ . Some algorithms interpret the steepest gradient descent (7) as a solution to the optimization problem $\max_{\theta'} E_{\pi_{\theta'}}[Q^{\pi_\theta}(s, a)]$ subject to $\sqrt{\Delta\theta^T \Delta\theta} \leq \alpha$. By replacing the constraint $\sqrt{\Delta\theta^T \Delta\theta} \leq \alpha$ with $\sqrt{\Delta\theta^T F \Delta\theta} \leq \alpha$ where F is a Fisher information matrix, the corresponding update rule would become natural gradient descent, which regularizes the distributional change of the policy in terms of the Kullback-Leibler divergence. Natural Policy Gradient [7], Trust Region Policy Optimization (TRPO) [13], and Proximal Policy Optimization (PPO) [14] all belong to the family of methods that use the natural gradient, but differ in their approximation method and the model of Q-function and policy distribution.

In order to guarantee the convergence of these policy gradient algorithms, it is necessary to ensure that $\rho(s) > 0$ for a sufficiently wide range of the state space, and doing so requires extensive exploration of the state space. To encourage the exploration, a behavior policy is thus often created by adding the noise to the target policy or by adding an entropy term to the objective $\max_\pi E_{\pi(a|s_{t+1})}[Q(s_{t+1}, a) - \lambda \log \pi(a|s_{t+1})]$ where λ is a nonnegative coefficient.

Open Problems

It is believed that humans utilize some type of RL because we do not usually rely on supervised learning in many decision making problems. However, there are great differences between current RL and human learning. Current RL does not have a good generalization ability and usually overfits to the specific environment used for the training. This makes RL difficult to apply to a wide variety of real problems because it is often difficult to simulate the real environment completely. On the contrary, current RL is successful when there are little differences between the training environment and test environment such as Atari games, Go, or any

artificial simulation environments. Therefore, many researchers are interested in methods that can adapt quickly to new environments. In particular, quick adaptation from the simulation environment to real environment is called sim2real transfer. Meta-learning (or learning to learn) is sometimes applied in combination with RL to quickly adapt to the new environment. In general, improvement of generalization ability in standard context alone is often not sufficient in training an agent with quick adaptability. For example, there are similar games in Atari platform as categorized by shooting games, racing games, or action games. But current RL agents cannot adapt instantly to new games even if the RL agent is sufficiently trained on a similar game, most likely because it is overfitting to the training environment. On the other hand, a human could quickly learn to solve the similar game. It is speculated that humans learn a good prior that is applicable to different environments through learning. In other words, humans learn abstract concepts that are applicable to a wide class of environments. It has been experimentally shown that humans' quick adaptation actually relies on some prior knowledge of the visual appearance of the objects in the Atari game platform [5]. This line of research leads to hierarchical RL or the lifelong learning that aims to learn the common abstract knowledge useful for the quick adaptation or generalization. Other important problems are the efficient exploration in large state-action space and the designing of a good reward.

Definition

Retinex theory is a computational model for human color constancy. It defines a mechanism for computing lightness values from an image. Retinex theory proposes that the lightness values for each class of photoreceptors are derived independently and that this triplet of values correlates with perceived reflectance.

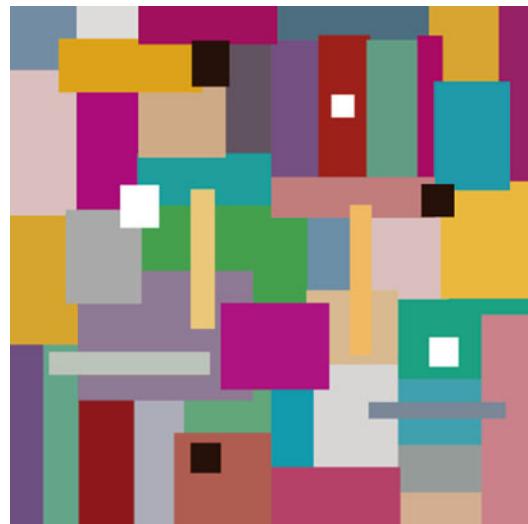

Background

The human visual system is remarkable in its ability to deal with varying illumination. Throughout the day, the visual system encounters both artificial and natural illumination, yet the appearance of the world seems stable. For example, a piece of white paper on a desk does not appear to change color when taken outside.

But anyone who has used a camera knows that the world is not as simple as it appears. Sometimes photographs captured outdoors have a blue color cast, while photographs captured indoors appear yellow. These color shifts are due to the different sources of illumination, e.g., sunlight versus an incandescent bulb. For a camera to capture the scene as it appears to the human visual system, it needs to determine, or be configured with, the color of the illumination. This setting in the camera is known as white balance.

While a camera needs to be configured for the type of illumination, the human visual system accounts for illumination changes automatically. This ability is known as color constancy. The process is fast and effortless – many people do not realize how much the measured color of an object changes under different light sources because its appearance seems stable. In a sense, the human visual system has an automatic white balance mechanism that operates without the need for a reference or knowledge of the illumination.

Land and McCann investigated color constancy under varying illumination in a

Retinex Theory, Fig. 1 An arrangement of colored rectangles similar to “Mondrian-like” stimuli used by Land and McCann [1]

series of experiments known as the “Mondrian” experiments [1]. The stimuli for the experiments consisted of a large array of rectangular colored papers that were arranged to resemble a painting by the artist Mondrian; see Fig. 1. The papers were illuminated by three projectors with filters designed to pass long waves, middle-length waves, or short waves. Focusing on one of the papers (e.g., a green paper), they adjusted the flux from each of the projectors to achieve a predetermined set of luminance values at the eye, as measured by a photometer. The subject in the study noted the color name of the paper in question. The process was repeated for other pieces of paper – first adjusting the lights to achieve the same set of luminance values, then asking the subject to note the color name. The subjects consistently reported the correct color names for the papers, despite receiving the same luminance triple at the eye from all papers. Thus, in a controlled environment, Land and McCann verified the ability of the visual system to identify correct color names under varying illumination, even when the luminance values at the eye in all cases were the same.

Theory

Retinex theory grew out of the Mondrian experiments and it defined a computational model for the color constancy of the Mondrian stimuli. Land and McCann coined the name “Retinex” to signify that, in humans, this process could involve both the retina and the cortex [1].

The main principle of Retinex theory is that images from the three classes of photoreceptors (i.e., color channels) are processed separately into three *lightness* images. The lightness values at different regions in the image correlate with the true reflectance of the region and are as independent of illumination differences as possible. Therefore, the color constancy problem is cast into a lower-dimensional problem of understanding the lightness of a single-channel image.

Retinex theory describes an algorithm for computing lightness images from intensity images. There were five main components in the original algorithm: ratio, sequential product, reset, threshold, and average [1].

Land and McCann realized the perceptual importance of edges and made the ratio of luminances across edges the fundamental unit of their algorithm. To compare areas that were not directly next to each other, they introduced the notion of a sequential product. The sequential product accumulates edge ratios along a one-dimensional path. The initial value for the sequential product is set to one, and the sequential product can become greater than one if the path crosses a region with greater reflectance than the initial region. In this case, the sequential product is reset to one to account for the highest reflectance found along the path.

Across large areas of uniform reflectance, adjacent pixels may have slightly different luminance values, leading to ratios near, but not equal to, one. The threshold component discards these small changes to make the algorithm more robust to gradual changes of illumination across the scene.

The sequential product reveals the relative reflectance of a region with respect to the highest reflectance seen along a one-dimensional path. The Retinex algorithm considers several one-

dimensional paths through the same region and averages the relative reflectances to obtain the lightness value for the region.

Through the five operations, the Retinex algorithm converts a grayscale intensity image into a lightness image. The triple of lightness values from three color channels were shown to correlate with color judgments, regardless of illumination conditions [2].

Since the original Retinex paper, there have been further studies on the roles of the different operators and modifications to these operators [3, 4]. For example, the length of the path used in the sequential product affects the ability of the algorithm to model color constancy. Short paths include little of the surrounding context, while in the limit, infinite paths result in a scaling of the image and are a poor model for human perception [5]. Later variants of the Retinex algorithm also discarded the threshold step [6], though other authors have found the threshold step to be important for separating shading and reflectance effects in images [7–9].

- ▶ Asperity Scattering
- ▶ Lambertian Reflectance
- ▶ Surface Roughness

Definition

Retroreflection is a type of reflectance which is characterized by a peak in the backward or illumination direction. Thus, materials that backscatter scatter light primarily in the direction from which it is illuminated.

Background

The reflectance of natural, opaque, rough surfaces can be described by the Bidirectional Reflectance Distribution Function (BRDF) [7]. BRDFs that are common and well known are those of Lambertian, perfectly diffusely scattering, and of specular surfaces. Such surfaces scatter light in all directions (diffuse scattering) or primarily in the mirror direction (specular reflection). However, natural surfaces can scatter light in many other ways. Retroreflection is just one such manner. Retroreflection can be caused by, for instance, hemispherical concavities in the surface [5, 8]. Even if the surface is locally Lambertian, such a “thoroughly pitted surface” shows retroreflection. Another example is the triple mirror retroreflector, which is, for instance, used in reflectors for cars and

bicycles (in small-scale versions) and in distance measurements (relatively large-scale versions). Many reflectors for outside applications (e.g., clothes of roadworkers, number plates) consist of a thin layer of small spherical particles with a refraction index of 2. Natural phenomena that are caused by retroreflection are “Heiligenschein” (the halo you can see around your head if you look at wet or dewy grass with the sun at a low angle behind you; for examples see [3]) and the Seeliger effect (reflective objects that are in opposition to the sun are brighter than in other positions).

Theory

The geometrical optical models with retroreflection lobes which were mentioned above result in quite complicated BRDFs. It is possible to fit retroreflection characteristics in a convenient, simplified formula (note that basic physical constraints should hold, e.g., nonnegativity, energy conservation, and Helmholtz reciprocity) [4]. For instance, the following BRDF model,

$$B(\mathbf{i}, \mathbf{j}, \mathbf{n}) = \frac{1}{\pi 2^k} \frac{(1 + \mathbf{i} \cdot \mathbf{j})^k}{(\mathbf{i} + \mathbf{j}) \cdot \mathbf{n}}, \quad (1)$$

is a perfect backscatterer in the sense that the BRDF equals $(2\pi(\mathbf{i} \cdot \mathbf{n}))^{-1}$ for coincident directions of incidence and viewing ($\mathbf{i} = \mathbf{j}$): When the normal irradiance is H_N , the irradiance becomes $H_N(\mathbf{i} \cdot \mathbf{n})$ and the backscattered radiance $H_N/2\pi$, i.e., independent of the slant of the surface. Thus, the full moon would appear as a featureless disk. It may well be the simplest analytical expression that leads to a pronounced backscatter lobe. The BRDF peaks at $\mathbf{i} = \mathbf{j}$; the parameter k determines the width of the peak. The albedo is a complicated function, for instance, for $k = 1$ the albedo is

$$\begin{aligned} IA_B(\vartheta_i) = & \frac{1}{2} (1 + \cos \vartheta_i - \cos 2\vartheta_i) \\ & + \frac{1}{4} (\cos \vartheta_i - \cos 3\vartheta_i) \log \frac{\cos \vartheta_i}{1 + \cos \vartheta_i}, \end{aligned} \quad (2)$$

where $\cos \vartheta_i = \mathbf{i} \cdot \mathbf{n}$. This albedo is $\frac{1}{2}$ for normal incidence and rises to 1 for grazing incidence. For $k > 1$ the expressions for the albedo become unwieldy, but numerical integration reveals that the albedo remains lower than one and approximately constant for a large range, then rises to one at grazing incidence. It is not obvious how to write down a backscatter BRDF with unit albedo throughout. Other possibilities for simplified formulations may be found in graphics as so-called backscatter shaders. However, care should be taken that many of these rendering applications do not fulfill the above-mentioned basic physical constraints.

Open Problems

BRDFs of natural surfaces can probably be categorized into about a dozen different modes. Currently only the forward, backward, diffuse, and surface scattering modes have been described by formal optical models.

Reflectance estimation from images suffers from image ambiguities. Prior knowledge on the reflectance statistics of natural materials plus formal descriptive models for the common modes of natural BRDFs can constrain this problem.

Definition

A *manifold* is a topological space that is locally Euclidean, indicating that near every point, there is a neighborhood that is topologically the same as the open unit ball in \mathbb{R}^n . A smooth manifold equipped with an inner product on each tangent space is called a *Riemannian manifold*, where various notions such as length, angles, areas (or volumes), curvature, and divergence of vector fields can be defined.

Relevance to Computer Vision

The need of using the manifold concept and Riemannian geometry arises naturally when considering the intrinsic properties of images. It is convenient to treat an image of size 64×64 as a data point in a 4096-dimensional vector space. Then we want to measure the distance or similarity between any two data points in this high-dimensional space. However, using the flat Euclidean structure in large scales seems to make little sense in this space. If you take two images that are very different, for example Arnold Schwarzenegger and Hillary Clinton, you cannot interpolate between them at all to get a facial image. (This example is from Kilian Q. Weinberger's homepage). One way is to impose some special metric in this space to make it curved, or equivalently we can transform these images into another feature space.

We can imagine an intuitive example of interpolating between digits 9 and 3. By directly doing linear interpolation in the original Euclidean space, we get blurry images. However, if following the curved manifolds of digits 9 and 3, we obtain a continuum of slowly morphing from 9 to 3. And this way, the interpolated images in the gap of two manifolds make much sense from the aspect of human eyes.

Furthermore, Riemannian geometry may play a role in the situations where a camera moves in a curved path (such as a circle) or a robot arm rotates along a given track.

Mathematical Background

The concept of a manifold is central to many parts of geometry and modern mathematical physics, because it allows complicated structures to be described and understood in terms of the simpler local topological properties of Euclidean space. Manifolds arise naturally in a variety of mathematical and physical applications as "global objects." The study of manifolds combines many important areas of mathematics: it generalizes concepts such as curves and

surfaces as well as ideas from linear algebra and topology.

In mathematics, a manifold is a topological space that locally resembles Euclidean space around each point. Precisely, each point of an n -dimensional manifold has a neighborhood that is homeomorphic to an open subset of Euclidean space \mathbb{R}^n . In other words, manifolds constitute a generalization of curves and surfaces into high-dimensional spaces. One-dimensional manifolds include lines and circles, but not figure eights "8" because they have crossing points that are not locally homeomorphic to Euclidean 1-space. Two-dimensional manifolds, also called surfaces, include the plane, the sphere, and the torus, which can all be embedded in three dimensional real space. On the other hand, the structure of three planes (e.g., the xy , yz , and zx planes in a xyz coordinate chart) intersected at the origin is an example of a non-manifold, since a neighborhood of any intersection point is neither 2D nor 3D.

Although a manifold locally resembles Euclidean space, globally it may not: manifolds in general are not homeomorphic to Euclidean space. An intuitive example is the **round/flat Earth problem**: the whole surface of the sphere is not homeomorphic to the Euclidean plane. The ancient belief is that the Earth was flat, as contrasted with the modern evidence that it is round. The discrepancy arises essentially from the fact that on the small scales, the Earth does indeed look flat, whereas on the large scales, the Earth surface is a sphere approximately. In general, any object that is nearly "flat" on small scales is a manifold. In a region it can be charted by means of map projections of the region into the Euclidean plane; in the context of manifolds, they are called *charts*. More concisely, any object that can be "charted" is a manifold.

When a region appears in two neighboring charts, the two representations may not coincide exactly, and a transformation is needed to pass from one chart to the other, called a *transition map*. *Smooth manifolds* (also called differentiable manifolds) are manifolds for which overlapping charts "relate smoothly" to each other, meaning that the inverse of one followed by the other is

an infinitely differentiable map from Euclidean space to itself. Such two charts are called “compatible.” A differentiable manifold is a type of manifold that is locally similar enough to a linear space to allow one to do calculus. One may then apply calculus while working within the individual charts, since each chart lies within a linear space to which the usual rules of calculus apply. If the charts are suitably compatible (viz., the transition from one chart to another is differentiable), then computations done in one chart are valid in any other differentiable chart. With this differentiable structure equipped on manifolds, we can define the globally differentiable tangent space, differentiable functions, and differentiable tensor and vector fields.

Differentiable manifolds are very important in physics. Special kinds of differentiable manifolds form the basis for physical theories such as classical mechanics, general relativity, and the Yang-Mills theory. It is possible to develop a calculus for differentiable manifolds, and the study of calculus on differentiable manifolds is known as *differential geometry*.

A Riemannian metric on a differentiable manifold allows distances and angles to be measured. A “Riemannian manifold” is a differentiable manifold in which each tangent space is equipped with an inner product $\langle \cdot, \cdot \rangle$ in a manner which varies smoothly from point to point. Given two tangent vectors u and v , the inner product $\langle u, v \rangle$ gives a real number. This allows one to define various notions such as length, angles, areas (or volumes), curvature, and divergence of vector fields.

Carl Friedrich Gauss (1777–1855) may have been the first to consider abstract spaces as mathematical objects in their own right. His *Theorema Egregium* (Remarkable Theorem or Totally Awesome Theorem) gives a method for computing the curvature of a surface without considering the ambient space in which the surface lies. In modern terms, the theorem proved that the Gaussian curvature $K = \kappa_1\kappa_2$ of the surface is an intrinsic property, where κ_1 and κ_2 are principal curvatures at one point. Since then, manifold theory has come to focus exclusively on these intrinsic properties (or invariants), while largely

ignoring the extrinsic properties of the ambient space.

Bernhard Riemann (1826–1866) was the first one to do extensive work generalizing the idea of intrinsic geometry to higher dimensions. The name manifold comes from Riemann’s original German term, *Mannigfaltigkeit*, which William Kingdon Clifford translated as “manifoldness.” Riemann developed his theory of higher dimensions and delivered his inaugural lecture at Göttingen in 1854 entitled “Ueber die Hypothesen welche der Geometrie zu Grunde liegen” (“On the hypotheses which underlie geometry”) [1]. Riemann found the correct way to extend to n dimensions the differential geometry of surfaces, which Gauss (as Riemann’s tutor) proved in his *Theorema Egregium*. This lecture founded the field of Riemannian geometry.

Gauss highly appreciated Riemann’s lecture “which surpassed all his expectations, in the greatest astonishment, and on the way back from the faculty meeting he spoke to Wilhelm Weber, with the greatest appreciation, and with an excitement rare for him, about the depth of the ideas presented by Riemann.” [2, Vol.2, pp.134]

Riemann’s inaugural lecture was only published 12 years later in 1868 by Dedekind, 2 years after his death. Its early reception appears to have been slow. But it is now recognized as one of the most important works in geometry and specifically set the stage for Albert Einstein’s general theory of relativity (published in 1916). Einstein used the theory of Riemannian manifolds (formally pseudo-Riemannian manifolds) to develop his general theory of relativity. General relativity generalizes special relativity and Newton’s law of universal gravitation, treating the gravity of space and time (or spacetime) as the curvature of a Riemannian space. In particular, his equations for gravitation are constraints on the curvature of space-time. As Riemann laid the foundations of the mathematics of general relativity, Riemannian geometry had received extensive attention in mathematics and theoretical physics from that time.

Theory

In the following we present formal definitions and several elementary results [3].

Definition 1 A manifold M of dimension d is a connected paracompact Hausdorff space for which every point has a neighborhood U that is homeomorphic to an open subset Ω of \mathbb{R}^d . Such a homeomorphism $x : U \mapsto \Omega$ is called a (*coordinate chart*). An *atlas* is a family $\{U_\alpha, x_\alpha\}$ of charts for which the U_α constitute an open covering of M .

Definition 2 An atlas $\{U_\alpha, x_\alpha\}$ on a manifold is called *differentiable* if all chart transitions

$$x_\beta \circ x_\alpha^{-1} : x_\alpha(U_\alpha \cap U_\beta) \mapsto x_\beta(U_\alpha \cap U_\beta)$$

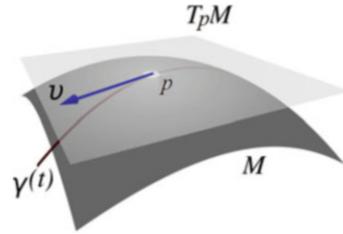

are differentiable of class C^∞ (in case $U_\alpha \cap U_\beta \neq \emptyset$). A maximal differentiable atlas is called a differentiable structure, and a *differentiable manifold* of dimension d is a manifold of dimension d with a differentiable structure.

The next key concept is called “tangent space,” which is a generalization of the tangent plane of a 2D surface. Suppose that a regular surface S is represented by $\mathbf{r}(u, v) = \{x(u, v), y(u, v), z(u, v)\}$, where $(u, v) \in \mathbb{R}^2$ and $(x, y, z) \in \mathbb{R}^3$. Thus as a main part of the functional increment, the differential

$$d\mathbf{r}(u, v) = \mathbf{r}_u(u, v)du + \mathbf{r}_v(u, v)dv$$

gives a tangent vector with (du, dv) as coordinates under the basis $\{\mathbf{r}_u, \mathbf{r}_v\}$ (generally not orthonormal). This vector space formed by basis $\{\mathbf{r}_u, \mathbf{r}_v\}$ is called a tangent space of surface S at point p , denoted by $T_p S$.

Definition 3 Let p be a point in an d -dimensional differentiable manifold M , and attach at p a copy of \mathbb{R}^d tangential to M . The

Riemannian Manifold, Fig. 1 The tangent space

resulting structure is called the tangent space of M at p , denoted by $T_p M$. If γ is a smooth curve passing through p , then the derivative of γ at p (also known as the velocity of the curve) is a tangent vector in $T_p M$.

See Fig. 1 for an illustrative example. Other definitions of the tangent space are possible. For example, a tangent vector at p may be defined as directional derivatives X of smooth functions on M that satisfies the Leibniz rule

$$X(f \cdot g)(p) = X(f(p))g(p) + f(p)X(g(p)),$$

which does not involve local coordinates.

Definition 4 Let M be a differentiable manifold of dimension d and $p \in M$. A *Riemannian metric* on M is a family of (positive definite) inner products $g_p : T_p M \times T_p M \mapsto \mathbb{R}$ such that for all differentiable vector fields X, Y on M , $p \mapsto g_p(X(p), Y(p))$ defines a smooth function $M \mapsto \mathbb{R}$. In other words, a Riemannian metric g is a symmetric $(0,2)$ -tensor that is positive definite (i.e., $g(X, X) > 0$ for all tangent vectors $X \neq 0$). A *Riemannian manifold* is a differentiable manifold equipped with a Riemannian metric.

The inner product of two tangent vector $X, Y \in T_p M$ with coordinate representations $X = \sum_i X^i \frac{\partial}{\partial x^i}$, $Y = \sum_j Y^j \frac{\partial}{\partial x^j}$ then is

$$\langle X, Y \rangle = g_p(X, Y) = g_{ij}(p)X^i Y^j.$$

In particular $\langle \frac{\partial}{\partial x^i}, \frac{\partial}{\partial x^j} \rangle = g_{ij}$. Formally, the metric tensor can be written in terms of the dual basis $\{dx^1, \dots, dx^d\}$ of the cotangent space as

$$g = \sum_{i,j} g_{ij} dx^i \otimes dx^j.$$

For a smooth parametrized curve $\gamma : [a, b] \mapsto M$, its length is defined as

$$\begin{aligned} L(\gamma) &= \int_a^b \left\| \frac{d\gamma}{dt}(t) \right\| dt \\ &= \int_a^b \sqrt{\left\langle \frac{d\gamma}{dt}(t), \frac{d\gamma}{dt}(t) \right\rangle} dt \\ &= \int_a^b \sqrt{\left\langle \sum_i \frac{\partial \gamma}{\partial x^i} \frac{dx^i}{dt}, \sum_j \frac{\partial \gamma}{\partial x^j} \frac{dx^j}{dt} \right\rangle} dt \\ &= \int_a^b \sqrt{\sum_{i,j} g\left(\frac{\partial \gamma}{\partial x^i}, \frac{\partial \gamma}{\partial x^j}\right) \frac{dx^i}{dt} \frac{dx^j}{dt}} dt \\ &= \int_a^b \sqrt{\sum_{i,j} g_{ij}(\gamma(t)) \frac{dx^i}{dt} \frac{dx^j}{dt}} dt, \end{aligned}$$

which is exactly the original starting point of Riemann.

Similarly, a *volume element* can be expressed by

$$dV = \sqrt{\det(g_{ij})} dx^1 \wedge \cdots \wedge dx^n,$$

where $\det(g_{ij})$ is the determinant of the matrix representation of the metric tensor and $\{dx^i\}$ is the dual coframe. Hence the volume of an oriented manifold M is defined to be

$$\int_M dV = \int_M \sqrt{\det(g_{ij})} dx^1 \wedge \cdots \wedge dx^n.$$

The following theorem provides a guarantee of the existence of the Riemannian metric.

Theorem 1 *Each differentiable manifold may be equipped with a Riemannian metric.*

One can read [4] for more details on Riemannian geometry and [3] for connections to geometric analysis. For those not familiar with differential geometry of curves and surfaces, please refer to [5] (without tensor analysis).

Application

Riemannian normal coordinates, introduced by Riemann in his inaugural lecture in 1854, have been used to manifold learning. Local coordinate charts can be constructed to embed data points from a high-dimensional ambient space into a low-dimensional feature space [6].

Riemannian manifolds have found successful applications for video representations in visual classification tasks, since a discriminant Riemannian metric can encode the nonlinear geometry of the underlying Riemannian manifolds. In [7] a metric learning framework was presented to learn a distance metric across a Euclidean space and a Riemannian manifold to fuse the average appearance and pattern variation of faces within one video.

Visual data often forms a special manifold structure lying on a lower dimensional space. An efficient clustering method on Riemannian manifolds was proposed in [8], and experiments over several image and video datasets demonstrated the favorable computational complexity of the proposed clustering algorithm.

In video analysis and more generally activity recognition, temporal evolutions of features can be viewed as trajectories on Riemannian manifolds. A transported square-root vector field [9] on Riemannian manifolds was used to model these trajectories, which successfully applied to visual speech recognition.

Grassmann manifold, as a special case of general Riemannian manifolds, has attracted much interests in the community of computer vision. A robust estimation approach based on Grassmann manifolds [10] was employed for chromatic noise filtering, fundamental matrix estimation, planar homography, and affine motion factorization.

The monograph [11] presents a comprehensive treatise on Riemannian geometric computations and related statistical inferences in several computer vision problems, including face recognition, activity recognition, object detection, biomedical image analysis, and structure from motion.

Recently, Riemannian geometry has been applied to the study of deep neural networks [12]. They found that neural networks are learning systems of differential equations governing the coordinate transformations that represent the data manifold. Also a closed form solution of the metric tensor on the underlying data manifold can be found by back-propagating the coordinate representations learned by neural networks.

Definition

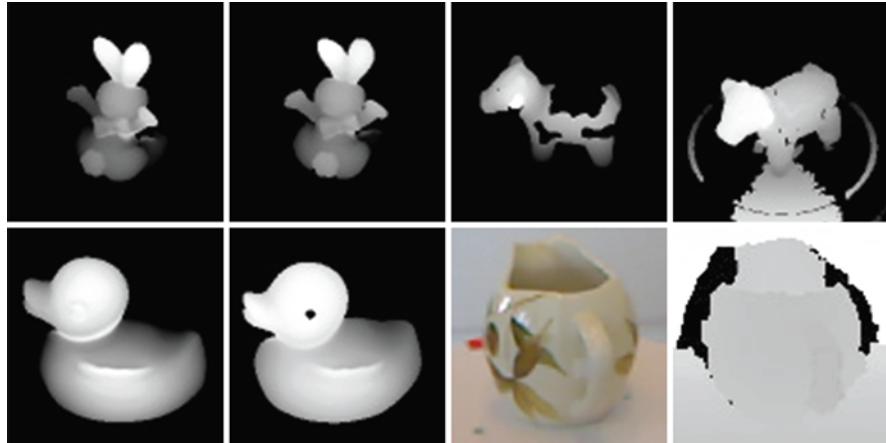

Given two copies of an object surface at different locations and orientations in space, or two parts of the surface of a single object with at least some shared overlapping area, find a translation and rigid rotation which places the two copies, or corresponding parts of the object, at the same location and orientation. This process is called rigid registration. In practice, many

approaches to rigid registration work by finding point-to-point correspondences between parts of the object surface in each dataset and use these to estimate the geometric transformation in either the least-squares or weighted least-squares sense with closed-form solution. Often, registration algorithms also output the point-to-point correspondences which can be just as useful to many applications as the transformation itself. A correspondence is such a pair of points that while described in two different coordinate systems, they represent the same point on the object surface in 3D space.

Sometimes, multiple captured datasets need to be registered either simultaneously or sequentially in a pairwise manner. Sometimes, captured data need to be registered against, say, a stored CAD model of an ideal version of the object, etc. Thus, in some cases, the “reference” shape comes from the data itself, while in other cases, there is an external reference shape.

Background

Current laser scanning technologies such as Kinect sensor released by Microsoft in 2010 enable the acquisition of both depth and intensity information from an object of interest in the form of range (depth) and RGB images as illustrated in Fig. 1. In this case, the object of interest is a pitcher and is represented as structured points. In Fig. 1, missing points can be seen in its surrounding areas, boundaries, mouth, and the areas behind the handle and the body due to inability of the scanner to capture data: occlusion, discontinuity in depth, orientation, and highly reflective surface. The occurrences and locations of such holes, occlusions, and clutter vary from one dataset to another and are usually unpredictable. While the range images describe the geometry of the object of interest, the intensity images describe its appearance. Since laser scanning systems (range cameras) have a limited field of view, and one part of the object may occlude another, a number of images have to be

Rigid Registration, Fig. 1 Real range images used. From the top left to the bottom right: the former 6, bunny0, bunny20, cow38, cow42, duck0, and duck 20

captured from different viewpoints to obtain reasonably complete coverage of the object surface; even then small gaps may remain. Each image is recorded in a local laser scanning system-centered coordinate system. If two images cover the same part of the object surface of interest, they have overlap, and the shapes represented by these two images are called overlapping shapes, in which one shape is usually called the reference shape and the other is called the data shape. To combine these images to give an overall model of the object by fusing the geometrical and/or optical information in these images, all the images have to be placed and aligned in a single global coordinate system. This process is called registration. *The ultimate goal of shape registration is to estimate the underlying transformation parameters that bring one shape into the best possible alignment with the other.* Once the underlying transformation is known, it is straightforward as a by-product to establish correspondences between two overlapping shapes. Fixing either of these two steps renders the other easier. However, they are in practice interwoven, complicating the shape registration process.

Suppose that the object of interest is rigid and represented using a set of points. Then interpoint Euclidean distances on the object surface are invariant with respect to changes in viewpoint from which the object is imaged. Let a general

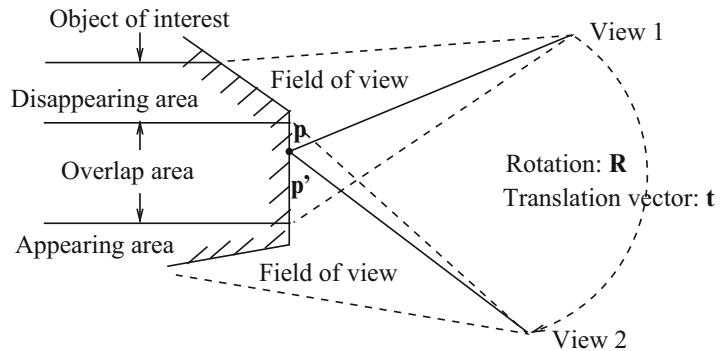

were captured using a Minolta Vivid 700 range camera [14]. The seventh and eighth are the RGB and depth images of a pitcher captured using a Kinect sensor [11]

point on the object surface belong to the overlapping area between two views. Suppose it is seen in these two views as points with coordinates $(\mathbf{p}, \mathbf{p}')$. This pair is called a correspondence between the views. These points are related by a rigid transformation (Fig. 2), which may be expressed using a rigid rotation matrix $\mathbf{R} \in \mathbb{R}^3$ and a translation vector $\mathbf{t} \in \mathbb{R}^3$: $\mathbf{p}' = \mathbf{R}\mathbf{p} + \mathbf{t}$. As a rigid rotation matrix, \mathbf{R} has to satisfy two conditions: (1) unit determinant: $\det(\mathbf{R}) = 1$ and (2) orthonormality: $\mathbf{R}^T \mathbf{R} = \mathbf{I}$. \mathbf{R} and \mathbf{t} describe the relative orientation and position, respectively, of points seen in the second view ($View_2$) in the coordinate system of the first view ($View_1$).

Automatic shape registration is a challenging problem for various reasons: (1) imaging noise, the captured data is corrupted by noise due to spatial sampling, variations in reflectance properties, depth discontinuities, mechanical control errors, signal quantization, signal detection processes, etc.; (2) occlusion, points may be absent in certain views, as one part of the object hides another; (3) limited field of view, this characteristic of scanning devices means that there is often relatively little overlap between adjacent views; (4) ambiguity between foreground and background, to facilitate data capture, a background is usually set up with different reflectance properties from the foreground to help separate the background data from the foreground data. However, this is not

Rigid Registration, Fig. 2

The relationship of a correspondence $(\mathbf{p}, \mathbf{p}')$ between two views View_1 and View_2 can be described using a rigid rotation matrix \mathbf{R} and a translation vector \mathbf{t} :

$$\mathbf{p}' = \mathbf{R}\mathbf{p} + \mathbf{t}$$

always fully successful, resulting in the former being contaminated by the latter; and (5) computational complexity, the amount of captured data is large, leading to ever more time-consuming computations as the scanner resolution and field of view increase.

Problem Statement

Firstly, we outline the rigid registration problem and briefly discuss the de facto standard method for this task: iterative closest point (ICP) algorithm [3]. In the next section, several of its representative variants will then be outlined and discussed.

Assume that the two shapes to be registered are represented as two sets of unorganized points $\mathbf{P} = \{\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_n\}$ and $\mathbf{P}' = \{\mathbf{p}'_1, \mathbf{p}'_2, \dots, \mathbf{p}'_n\}$, representing two different parts of the same free-form shape from two different nearby viewpoints with a certain amount of overlap in 3D space (Fig. 2). Here, we assume that the number of points in both point sets is identical and it is n . Generally, the 3D points are represented in d dimensional space, i.e., $\mathbf{p}_i, \mathbf{p}'_i \subset \mathbb{R}^d$. They can be a set of 3D coordinates (x, y, z) plus other measured features like color, normal vector, etc. Traditionally, only 3D coordinates are considered as input. As discussed in section “Background”, the goal is to estimate (\mathbf{R}, \mathbf{t}) . To this end, the following matching objective function $\mathcal{M}(\mathbf{R}, \mathbf{t})$ is built about the mean-squared error between the two point clouds $(\mathbf{P}, \mathbf{P}')$:

$$\mathcal{M}(\mathbf{R}, \mathbf{t}) = \mathcal{E}(\|\mathbf{RP} + \mathbf{t} - \mathbf{P}'\|^2)$$

$$= \frac{1}{n} \sum_{i=1}^n \|\mathbf{R}\mathbf{p}_i + \mathbf{t} - \mathbf{p}'_i\|^2. \quad (1)$$

Minimization of this objective function leads to a closed-form solution [22] to (\mathbf{R}, \mathbf{t}) as follows. The covariance matrix \mathcal{H} between the two point clouds is given by:

$$\mathcal{H} = \sum_{i=1}^n (\mathbf{p}_i - \mathcal{E}(\mathbf{P}))(\mathbf{p}'_i - \mathcal{E}(\mathbf{P}'))^T, \quad (2)$$

where

$$\mathcal{E}(\mathbf{P}) = \frac{1}{n} \sum_{i=1}^n \mathbf{p}_i, \quad \mathcal{E}(\mathbf{P}') = \frac{1}{n} \sum_{i=1}^n \mathbf{p}'_i, \quad (3)$$

and the superscript T denotes the transpose of a vector or a matrix.

Singular value decomposition (SVD) is employed to decompose the given covariance matrix \mathcal{H} into its orthogonal space, i.e., $\mathcal{H} = USV^T$. Using SVD, the rotation matrix \mathbf{R} and translation vector \mathbf{t} can be simply obtained with a closed-form solution from the following equations:

$$\mathbf{R} = V \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \det(VU^T) \end{pmatrix} U^T, \quad (4)$$

and

$$\mathbf{t} = \mathcal{E}(\mathbf{P}') - \mathbf{R}\mathcal{E}(\mathbf{P}) \quad (5)$$

where $\det(\cdot)$ denotes the determinant of a matrix.

Since the corresponding point pairs $(\mathbf{p}_i, \mathbf{p}'_i)$ are normally unknown, the objective function defined in Eq. 1 must be revised to account for point matching $\mathcal{F}(\mathbf{P}, \mathbf{P}')$ between $(\mathbf{P}, \mathbf{P}')$ as:

$$\mathcal{M}(\mathbf{R}, \mathbf{t}) = \mathcal{E}(||\mathbf{R}\mathbf{P} + \mathbf{t} - \mathcal{F}(\mathbf{P}, \mathbf{P}')||^2), \quad (6)$$

where a mapping \mathcal{F} from each point \mathbf{p}_i in point cloud \mathbf{P} to its corresponding point $\mathbf{p}'_{f(i)}$ in point cloud \mathbf{P}' is defined as:

$$\mathcal{F}: \mathbf{p}_i \rightarrow \mathbf{P}',$$

$$\text{where } \mathbf{p}'_{f(i)} = \underset{\mathbf{p}'_j \in \mathbf{P}'}{\operatorname{argmin}} ||\mathbf{R}\mathbf{p}_i + \mathbf{t} - \mathbf{p}'_j||, \quad (7)$$

which minimizes the Euclidean distance between the transformed point $\mathbf{R}\mathbf{p}_i + \mathbf{t}$ and any point \mathbf{p}'_j in \mathbf{P}' . Equations 6 and 7 are recursively updated until (1) the mapping objective function $\mathcal{M}(\mathbf{R}, \mathbf{t})$ in Eq. 1 has reached its local optimal value, or (2) the maximum number MaxIter of iterations has been reached. The tentative correspondences $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ are finally employed in the covariance matrix to yield through Eqs. 2, 3, 4, and 5 the desired rotation matrix \mathbf{R} and the translation vector \mathbf{t} .

ICP is a simple yet effective algorithm to align two overlapping point clouds subject to relatively small transformations. When this is not the case, the feature extraction and matching method such as the signatures of the histograms of orientations (SHOT) method [20] can be employed to estimate the underlying transformation for its initialization. ICP has a particular advantage in that it is robust to false-positive matches (outliers). Its key step is to find the point matches $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ between $(\mathbf{P}, \mathbf{P}')$, whose brute force search and evaluation has a computational complexity of $O(n^2)$ [7]. When n is small, fewer than thousands, for example, then it is efficient. Otherwise, effective data structures such as k-D tree should be used to accelerate the search for the closest points, whose computational complexity can then be reduced to $O(n \log n)$. Note that ICP [3] assumes that \mathbf{P} represents a subset of \mathbf{P}' in 3D space. This assumption seldom holds in practice. Thus, the evaluation of the established

point matches $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ to what extent they are correct is key for successful registration of the given partially overlapping shapes. To address these issues, many variants [2, 4, 13, 15, 19, 21] have been proposed. Unfortunately, these ICP variants have caused some confusion or bias in subsequent publications and comparative studies in the literature, since it is not always clear which ICP variants they refer to and whether the selected ICP variants are applicable to the given data.

Theory

The conventional ICP algorithm [3] is a de facto method for the registration of overlapping 3D shapes; it has attracted intensive attention from the community, leading many variants [2, 13, 15, 19, 23] to be proposed for the improvement of its performance. In this section, we select four representative ICP variants [2, 4, 19, 23] and describe their main differences from those outlined in the preceding section.

Iteratively Re-weighted

Least-Squares-Based ICP (IRLS-ICP)

After the tentative correspondences $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ have been established using Eq. 7, it is critical to evaluate to what extent they are correct. Iteratively re-weighted least-squares-based ICP (IRLS-ICP) is proposed in [2]. Firstly, the error e_i of each tentative correspondence $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ is calculated as $e_i = ||\mathbf{p}'_{f(i)} - \mathbf{R}\mathbf{p}_i - \mathbf{t}||$. Then these errors are scaled with the parameter τ : $E_i = e_i/\tau$ where τ is a function about the standard deviation σ of the errors of all such tentative correspondences $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$: $\tau = 7.0589\sigma$ where σ is an optimal estimation of the standard deviation of the errors of these tentative correspondences: $\sigma = 1.9e_m$. If $\sigma < 0.000001e_{\max}$, then $\sigma = 0.3e_{\max}$; if $e_m = 0$, then $\sigma = 1$ where $e_m = \text{median}_i e_i$ and $e_{\max} = \max_i e_i$. Finally, the weight w_i of each tentative correspondence $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ is estimated using the Tukey's function as: if $e_i < \tau$, then $w_i = (1 - E_i^2)^2$; otherwise, $w_i = 0$.

Due to the introduction of the weights of the tentative correspondences $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$, Eqs. 2 and 3 have to be updated accordingly as:

$$\mathcal{H} = \sum_{i=1}^n w_i (\mathbf{p}_i - \mathcal{E}(\mathbf{P})) (\mathbf{p}'_{f(i)} - \mathcal{E}(\mathbf{P}'))^T, \quad (8)$$

where

$$\mathcal{E}(\mathbf{P}) = \frac{\sum_{i=1}^n w_i \mathbf{p}_i}{\sum_{i=1}^n w_i}, \quad \mathcal{E}(\mathbf{P}') = \frac{\sum_{i=1}^n w_i \mathbf{p}'_{f(i)}}{\sum_{i=1}^n w_i}. \quad (9)$$

The condition for the objective function in Eq. 1 to reach its local optimal value is that the relative difference of the averages of the errors of the tentative correspondences that are smaller than 1.5σ between two successive iterations must be smaller than a predetermined threshold, 0.00001.

Point-to-Plane ICP (PtP-ICP)

While the IRLS-ICP algorithm outlined above minimizes the point-to-point distances and usually converges slowly, it is proposed in [4] to minimize the point-to-plane distances between the established tentative correspondences $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ instead. In this case, Eq. 1 has to be modified as:

$$\mathcal{M}(\mathbf{R}, \mathbf{t}) = \frac{1}{n} \sum_{i=1}^n ((\mathbf{R}\mathbf{p}_i + \mathbf{t} - \mathbf{p}'_{f(i)})^T \mathbf{n}'_{f(i)})^2, \quad (10)$$

where \mathbf{n}'_j is the normal vector at point \mathbf{p}'_j . This essentially minimizes the squared distances from the transformed points $\mathbf{R}\mathbf{p}_i + \mathbf{t}$ to the tangent planes passing through, or of the correspondence vectors $\mathbf{R}\mathbf{p}_i + \mathbf{t} - \mathbf{p}'_{f(i)}$ along the normal vectors at, the correspondents $\mathbf{p}'_{f(i)}$. This is a nonlinear function about the Euler rotation angles α, β , and γ around the x , y , and z axes of the rotation matrix \mathbf{R} :

$$\mathbf{R} = \begin{bmatrix} \cos(\gamma) \cos(\beta) - \sin(\gamma) \cos(\alpha) + \cos(\gamma) \sin(\beta) \sin(\alpha) & \sin(\gamma) \sin(\alpha) + \cos(\gamma) \sin(\beta) \cos(\alpha) \\ \sin(\gamma) \cos(\beta) & \cos(\gamma) \cos(\alpha) + \sin(\gamma) \sin(\beta) \sin(\alpha) \\ -\sin(\beta) & \cos(\beta) \sin(\alpha) \\ & \cos(\beta) \cos(\alpha) \end{bmatrix} \quad (11)$$

and thus is more challenging to optimize and no closed-form solution exists. Since the transformation is relatively small, using the approximations of $\sin(\alpha) = \alpha$, $\alpha\beta = 0$, and $\cos(\alpha) = 1$, this objective function can then be linearized as:

$$\begin{aligned} \mathcal{M}(\mathbf{R}, \mathbf{t}) = \frac{1}{n} \sum_{i=1}^n & \left((\mathbf{p}_i \times \mathbf{n}'_{f(i)}, \mathbf{n}'_{f(i)})^T \mathbf{x} \right. \\ & \left. + (\mathbf{p}_i - \mathbf{p}'_{f(i)})^T \mathbf{n}'_{f(i)} \right)^2 \end{aligned} \quad (12)$$

where $\mathbf{x} = (\alpha, \beta, \gamma, t_x, t_y, t_z)^T$. This is a linear least-squares problem in \mathbf{x} which can be easily solved as $\mathbf{x} = (A^T A)^{-1} b$ where $A = \{a_i\}$, $b = \{b_i\}$, $a_i = (\mathbf{p}_i \times \mathbf{n}'_{f(i)}, \mathbf{n}'_{f(i)})^T$ and $b_i = (\mathbf{p}'_{f(i)} - \mathbf{p}_i)^T \mathbf{n}'_{f(i)}$.

Suppose the existing transformation is $(\mathbf{R}_0, \mathbf{t}_0)$ and the incremental transformation (\mathbf{R}, \mathbf{t}) is

estimated above, then the former will be updated as $\mathbf{R}_0 \leftarrow \mathbf{R}\mathbf{R}_0$ and $\mathbf{t}_0 \leftarrow \mathbf{R}\mathbf{t}_0 + \mathbf{t}$, due to the fact that the relationship between $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ is represented as: $\mathbf{R}(\mathbf{R}_0 \mathbf{p}_i + \mathbf{t}_0) + \mathbf{t} = \mathbf{p}'_{f(i)}$. Thus the total concatenated transformation is then the updated $(\mathbf{R}_0, \mathbf{t}_0)$.

Different conditions can be defined to judge whether the objective function in Eq. 1 has reached its local optimal value. In this case, it is defined as both the relative differences of the rotation vector $(\alpha, \beta, \gamma)^T$ and the translation vector $(t_x, t_y, t_z)^T$ between two successive iterations being smaller than a threshold, 0.001.

Symmetric Point-to-Plane ICP (SPtP-ICP)

From Eq. 12, it can be seen that the objective function is not symmetric with regard to the order of $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ or their normal vectors $(\mathbf{n}_i, \mathbf{n}'_{f(i)})$. To address this issue, and it is also proposed in [19], to transform the tentative correspondences

$(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ toward each other to meet in between, instead of always transforming \mathbf{P} toward and to meet at \mathbf{P}' , it is modified as:

$$\mathcal{M}(\mathbf{R}, \mathbf{t}) = \frac{1}{n} \sum_{i=1}^n \left(\left(\mathbf{R}\mathbf{p}_i + \mathbf{t} - \mathbf{R}^{-1}\mathbf{p}'_{f(i)} \right)^T \left(\mathbf{n}_i + \mathbf{n}'_{f(i)} \right) \right)^2. \quad (13)$$

To further improve the robustness of the method, it is proposed to center the tentative correspondences $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ to their barycenters, respectively, as $(\bar{\mathbf{p}}_i, \bar{\mathbf{p}}'_{f(i)})$ where $\bar{\mathbf{p}}_i = \mathbf{p}_i - \mathcal{E}(\mathbf{P})$, $\bar{\mathbf{p}}'_{f(i)} = \mathbf{p}'_{f(i)} - \mathcal{E}(\mathbf{P}')$, $\mathcal{E}(\mathbf{P}) = \frac{1}{n} \sum_{i=1}^n \mathbf{p}_i$, and $\mathcal{E}(\mathbf{P}') = \frac{1}{n} \sum_{i=1}^n \mathbf{p}'_{f(i)}$. Thus, Eq. 13 can be rewritten as:

$$\mathcal{M}(\mathbf{R}, \mathbf{t}) = \frac{1}{n} \sum_{i=1}^n \left(\left(\mathbf{R}\bar{\mathbf{p}}_i + \mathbf{t} - \mathbf{R}^{-1}\bar{\mathbf{p}}'_{f(i)} \right)^T \left(\mathbf{n}_i + \mathbf{n}'_{f(i)} \right) \right)^2. \quad (14)$$

Assume that the rotation matrix is represented in rotation axis \mathbf{h} and rotation angle θ and the latter is relatively small, then this objective function can be linearized as:

$$\begin{aligned} \mathcal{M}(\mathbf{R}, \mathbf{t}) &= \frac{1}{n} \sum_{i=1}^n \left((\bar{\mathbf{p}}_i + \bar{\mathbf{p}}'_{f(i)}) \times \mathbf{N}_i, \mathbf{N}_i \right)^T \mathbf{x} \\ &\quad + (\bar{\mathbf{p}}_i - \bar{\mathbf{p}}'_{f(i)})^T \mathbf{N}_i)^2 \end{aligned} \quad (15)$$

where $\mathbf{x} = (a_x, a_y, a_z, b_x, b_y, b_z)^T$ and $\mathbf{N}_i = \mathbf{n}_i + \mathbf{n}'_{f(i)}$. This is again a linear least-squares problem in \mathbf{x} which can be solved using the method outlined above.

Then the transformation parameters rotation axis \mathbf{h} , rotation angle θ , and translation vector \mathbf{t} can be derived from \mathbf{x} as $\mathbf{h} = (a_x/\rho, a_y/\rho, a_z/\rho)^T$, $\theta = \tan^{-1}(\rho)$, and $\mathbf{t} = \cos(\theta)(b_x, b_y, b_z)^T$ where $\rho = \sqrt{a_x^2 + a_y^2 + a_z^2}$. The rotation matrix \mathbf{R} is derived as $\mathbf{R} = \mathbf{I} + \sin(\theta)\mathbf{H} + (1 - \cos(\theta))\mathbf{H}^2$ where $\mathbf{H} = \begin{bmatrix} 0 & -h_z & h_y \\ h_z & 0 & -h_x \\ -h_y & h_x & 0 \end{bmatrix}$ and \mathbf{I} is the 3 by 3 identity

matrix. The final total transformation $(\mathbf{R}_0, \mathbf{t}_0)$ is derived from Eq. 14 as: $\mathbf{R}_0 = \mathbf{R}\mathbf{R}$ and $\mathbf{t}_0 = \mathbf{R}\mathbf{t} + \mathcal{E}(\mathbf{P}') - \mathbf{R}_0\mathcal{E}(\mathbf{P})$. It is interesting to note that while \mathbf{R}_0 has the same rotation axis as \mathbf{R} , the rotation angle of \mathbf{R}_0 is twice that of \mathbf{R} . This means that the estimated rotation angle can be half that of the ground truth, and this is likely to mitigate the requirement of the initial transformation.

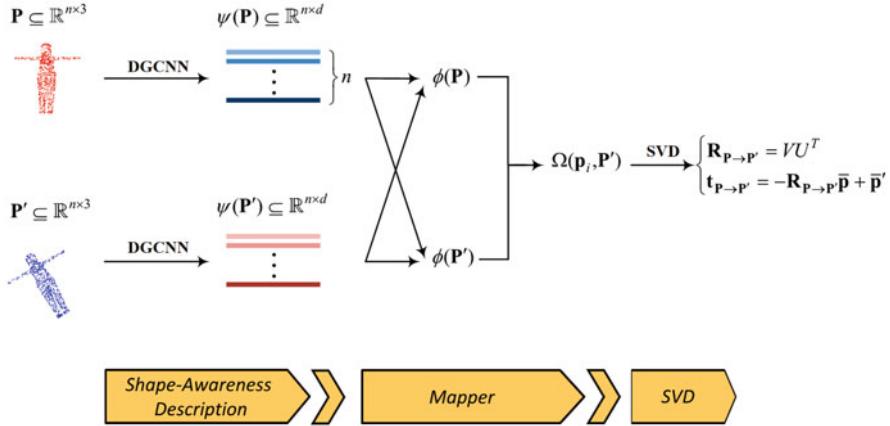

The termination condition of SPtP-ICP is the same as that for PtP-ICP above.

Deep Closest Point (DCP) Algorithm

Inspired by the recent success of convolutional neural networks (CNNs) [6, 17, 24] in solving highly complicated problems, Wang and Solomon [23] proposed a learning-based method, named deep closest point (DCP), that estimates a rigid transformation between two overlapping point clouds.

The DCP algorithm is elegant, since (1) it combines the feature extraction and matching step with the transformation estimation step in an end-to-end manner and (2) it embeds the conventional ICP algorithm in the framework of deep learning and does show that the deep learning methods can be developed for the registration of overlapping rigid shapes. While it has great potential for the registration of overlapping shapes, its requirement of training data limits its applicability. In this case, we just outline its main ideas and will not go into the details for re-implementation in this section. While its architecture is presented in Fig. 3, it consists of the following three main steps:

- (i) Use the dynamic graph CNN [24] to map input point cloud data from 3D space into a higher-dimensional feature space, through extracting and convolving the edges between the point of interest and its neighbors;
- (ii) Form attention models f_i and f'_j through adding necessary changes about the global context to the extracted local features and then match these features probabilistically with weights w_{ij} for tentative correspondences $(\mathbf{p}_i, \mathbf{p}'_j)$; and

Rigid Registration, Fig. 3 Network architecture of DCP. Ψ is a mapping function $\psi(\cdot) : \mathbb{R}^{n \times 3} \mapsto \mathbb{R}^{n \times d}$ and $\phi : \mathbb{R}^{n \times d} \times \mathbb{R}^{n \times d} \mapsto \mathbb{R}^{n \times d}$ is an attention function

- (iii) Estimate the rigid transformation using SVD over the tentative correspondences $(\mathbf{p}_i, \mathbf{p}''_i)$ where $\mathbf{p}''_i = \frac{\sum_{j=1}^n w_{ij} \mathbf{p}'_j}{\sum_{j=1}^n w_{ij}}$.

During the training, the estimated rigid transformation (\mathbf{R}, \mathbf{t}) is refined with regard to the ground truth ($\mathbf{R}_G, \mathbf{t}_G$). The loss function in DCP is defined as:

$$\mathcal{L} = ||\mathbf{R}^T \mathbf{R}_G - \mathbf{I}||^2 + ||\mathbf{t} - \mathbf{t}_G||^2 + \lambda ||\Psi||^2, \quad (16)$$

where the third term denotes Tikhonov regularization of the DCP parameters Ψ for reducing the complexity of the network.

From the outline above, it can be seen that DCP follows the assumption of the traditional ICP algorithm [3] that every point \mathbf{p}_i in \mathbf{P} can find a correspondent in \mathbf{P}' . This is a strict assumption that limits its applicability in the real world. Even though the idea is elegant, it has to be developed further to handle typical imaging conditions and produce accurate and stable registration results.

Application

Rigid registration of overlapping free form shapes finds numerous applications in digital shape reconstruction, map building, robot

navigation, object recognition, and inspection, to just name a few. These applications can be classified into three main categories according to the information sought:

- *Merging information from different views for shape modeling.* Rigid registration is applied in [9] to the complementary data captured using a terrestrial laser scanner (TLS) and an unmanned aerial vehicle (UAV) from the ground and top of a site in different viewpoints. Registration allows redundant points in the overlapping areas to be fused and the complementary points to be integrated, leading to a full digital 3D model. This has been used to create a digital shape archive documenting the Magoksa Temple, located in Gonju, Republic of Korea. A UAV-assisted laser scanning system has been described in [10] for the modeling of an unstructured terrain and environments. It includes four steps: (1) a UAV is used to capture the data from 30 m above the ground and employs the structure from motion technique to construct a coarse map of the environment; (2) the scanning locations are planned through maximization of the coverage area and visible voxels with enough distances between each other; (3) the object detection-based potential vector field method is employed for path planning; and finally

- (4) an existing simultaneous localization and map (SLAM) building method is employed to build a dense color map of the environment through registering the scanned point clouds from the laser scanner at different locations to the coarse map with appearance information.
- *Using underlying transformations for localization and loop closure.* A pose graph SLAM system is described in [18] for a quadruped robot to navigate indoor and outdoor environments over a long distance. To construct the map, the existing point clouds are registered with an existing auto-tuned ICP algorithm to the current point cloud, captured using a LiDAR scanner without being affected by existing illumination conditions in the environment. To facilitate the registration, the kinematic-forward odometry is employed to initialize the ICP algorithm. From the movement of the robot, a factor graph is built. To correct the drift of the odometry, the closure of the loops is detected in two scenarios: (1) small environment, through the current pose and poses in the factor graph, and (2) large environment, through a learning approach to detect, represent, and match planar segments in different point clouds. To make sure the reliability of the robot navigation, all the registrations of the point clouds are verified so that they have similar normal vectors. The path for the robot to return is finally selected using Dijkstra's algorithm.
 - *Making comparisons between an original view or a CAD model and a new view of a scene/object for recognition and inspection.* The multi-view depth (MVD) features are extracted from given point clouds in [8] for object recognition. To this end, the robust local reference frames are firstly extracted, based on which the local depths of the neighboring points are then projected onto $x - y$, $y - z$, and $x - z$ planes and their distributions are represented as histograms, respectively. All these histograms are finally concatenated as the MVD feature. These MVD features from a model and a scene are matched, from which the hypothesis is set

up and verified that the scene was generated from this model. A complete system has been described in [12] for scanning and inspecting industrial parts. An industrial part is firstly scanned through a laser line scanner with the original signal denoised. Then the scanned point cloud and the CAD model point cloud are registered using the 4-points congruent sets method [1] whose results are further refined with the conventional ICP algorithm. The registration results show that most of the deviations of the points are within the range of $\pm 50 \mu\text{m}$. The method is effective and efficient.

Open Problems

Automatic registration of overlapping free form shapes is challenging, and the following issues remain open:

- *Point sampling.* When a scanner is used to image an object of interest, it essentially samples the object surface. In this case, the points sampled in different views of the surface are sampled at different locations. The nature of this imaging process implies that no exact point will be sampled from two different viewpoints. The variation in location of the sampled points is determined mainly by the resolution of the scanner. The higher the resolution, the smaller the variation. Even though the sampling resolution can be increased, it has a limit. Consequently, no matter how good the scanner is, typically, the correspondences are never fully correct and must have some errors.

DCP essentially maps each 3D point to a high 1024-dimensional feature space. To facilitate the implementation without requiring too much storage space and computational time, a small number of 1024 points have been sampled as input. Such a small number of 1024 points creates further issues: (1) how to sample such 1024 points. Normally, a uniform sampling is performed; and (2) such a small number of 1024 points can hardly represent

the geometry, topology, and details of the object surface of interest, especially when it is relatively complex such as an aeroplane. This also explains why the registration results are usually not as good as expected.

- *Computational efficiency.* In theory, only three correct correspondences are needed for the estimation of the underlying rigid transformation. In practice, since the correspondences are usually contaminated by noise, more correspondences must be used instead to obtain a consensus. On the other hand, the more measured points there are for each shape to be registered, the more candidates that must be considered in the search for correct correspondences. DCP and generally deep learning algorithms require GPU devices for feasible computation. These mean that computational complexity plays an important role in the quality of registration, especially for dense models. For instance, DGCNN needs about 310,000 parameters for the feature extraction of 1024 points! In practice, many point clouds have more than 500K 3D points, and it is almost impossible to apply them all directly to the current DCP. Furthermore, real-time applications like mobile robotics and autonomous driving need lightweight networks. Developing lightweight yet effective deep learning algorithms seems more appealing.
- *Robustness.* When the shapes of testing and training datasets are similar to each other, ICP variants work well. However, 3D scanned shapes in the real world usually contain out-of-distribution samples and are subject to different samplings, noises, and distortions that significantly influence the captured datasets. Outliers/clutters are another big problem in the scanned data. They come from either background, other parts of the same surface, other objects, or artifacts from the scanning process. In practice, the number and distribution of the outliers usually vary, and they can be clustered rather than spread uniformly through the data. Robust algorithms need to take such issues into account. The unpredictable proportion, distribution, and location of the outliers render it difficult to evaluate the relative quality of the

established correspondences. These failures have two main causes: (1) ICP variants depend upon some parameters and assumptions, many of which are data dependent, and (2) since ICP variants usually consider just 3D coordinates, no prior knowledge is available about such factors as distribution of points, colors, normal vectors, occlusion, appearance and disappearance of points, imaging noise, and the magnitude of the transformation. If such knowledge is available, expected locations of overlapping and nonoverlapping points can be used to guide the registration process. To tackle these problems, the future works must focus on robustness.

- *Performance measurement.* Various methods have been developed in the literature to assess the performance of registration algorithms: the root-mean-squared-distance (RMSD) [15], mean squared error (MSE) [21], or the average of registration errors of reciprocal correspondences [13]. However, no single parameter can always successfully measure the performance of different algorithms with different data. All these methods measure different aspects of the success of registration algorithms. A further problem arises when the underlying rigid transformation is modeled as nonrigid [5], using, e.g., thin-plate splines (TPS). In such cases, these performance measures may indicate low errors, but this does not necessarily mean that the registration is accurate. This can happen because the TPS has $n+4$ degrees of freedom and often overfits noisy points and outliers in the data.

R

Experimental Results

In this section, we show some typical results from three selected ICP variants with an advantage of easy implementation and no need of training: iteratively re-weighted least-squares-based ICP (IRLS-ICP) [2], point-to-plane ICP (PtP-ICP) [4], and the symmetric point-to-plane ICP (SPtP-ICP) [19]. The initial transformation is the pure translational transformation $\mathbf{R}_0 = \mathbf{I}$ and $\mathbf{t}_0 = \mathcal{E}(\mathbf{P}') - \mathcal{E}(\mathbf{P})$. While the IRLS-ICP algo-

rithm directly handles the outliers (wrong correspondences), both the PtP-ICP and SPtP-ICP algorithms use the following two rules to reject wrong correspondences for easy implementation: (1) e_i must be smaller than 2.5 times the standard deviation of all e_i , which is optimally estimated as 1.4826 times e_m ; and (2) the normal vectors at the tentative correspondences must point in the same direction and thus their dot product must be positive. The maximum number $MaxIter$ of iterations was set as 100.

Three pairs of range images, bunny0-20, cow38-42, and duck0-20 (Fig. 1), captured using a Minolta Vivid 700 range camera were selected for the experiments. These images have a resolution of 200×200 . Unless the rotation angle of the rigid transformation is known from the naming of the image files, the other parameters are unknown. The k-D tree was used to speed up the search of tentative correspondences for the sake of computational efficiency.

The following parameters are of interest for validating the performance of different techniques: the estimated rotation axis $\hat{\mathbf{h}}$, rotation angle $\hat{\theta}$ and translation vector $\hat{\mathbf{t}}$ of the underlying transformation, the number N of reciprocal correspondences (RCs), the average e_μ and standard deviation e_σ of the errors of the RCs, and the number It of iterations and time in seconds used for convergence:

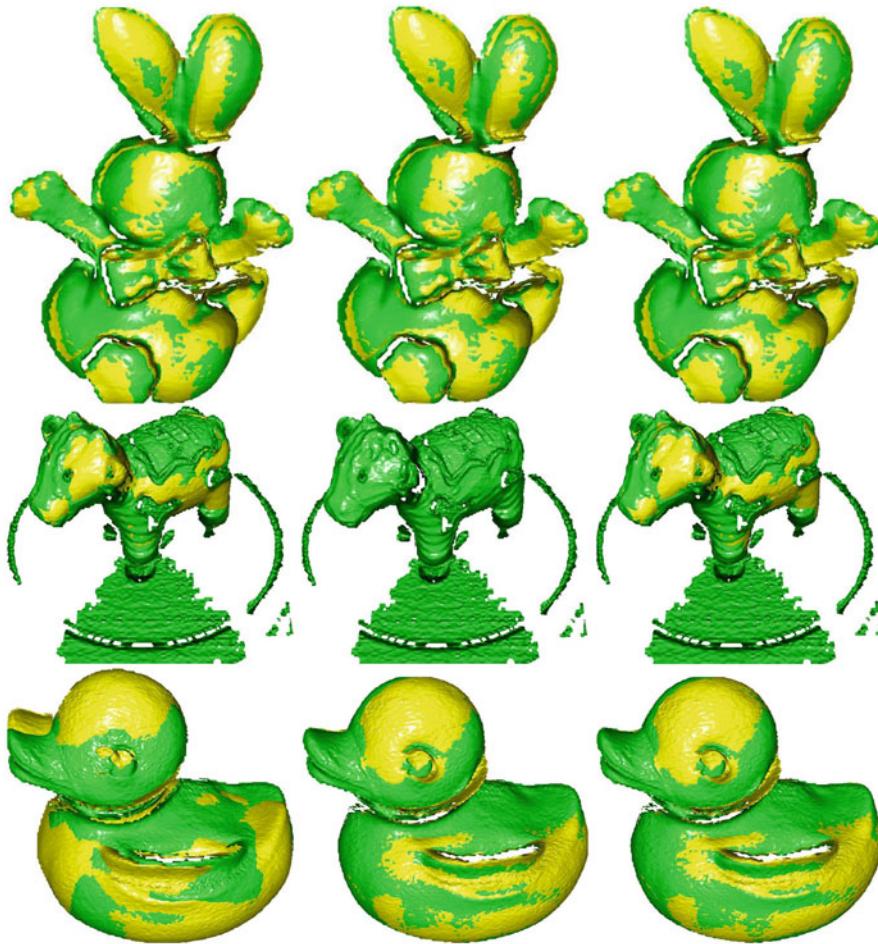

- *Rotation axis and angle:* Given the estimated rotation matrix $\hat{\mathbf{R}} = \begin{bmatrix} r_{11} & r_{12} & r_{13} \\ r_{21} & r_{22} & r_{23} \\ r_{31} & r_{32} & r_{33} \end{bmatrix}$, its rotation angle $\hat{\theta}$ and rotation axis $\hat{\mathbf{h}}$ are estimated, respectively, as $\hat{\theta} = \cos^{-1}((r_{11} + r_{22} + r_{33} - 1)/2)$, $\hat{\mathbf{h}} \leftarrow \hat{\mathbf{h}}/\|\hat{\mathbf{h}}\|$, and $\hat{\mathbf{h}} = (r_{32} - r_{23}, r_{13} - r_{31}, r_{21} - r_{12})^T / \sin \hat{\theta}$, where $\hat{\theta}$ cannot be zero.
- *Registration errors:* We also report the average e_μ and standard deviation e_σ of registration errors of the finally established reciprocal correspondences (RCs): $e_\mu = \frac{1}{N} \sum_{i=1}^N e_i$ and $e_\sigma = \sqrt{\frac{1}{N} \sum_{i=1}^N (e_i - e_\mu)^2}$, where $e_i = \|\mathbf{p}'_{f(i)} - \hat{\mathbf{R}}\mathbf{p}_i - \hat{\mathbf{t}}\|$ and a RC $(\mathbf{p}_i, \mathbf{p}'_{f(i)})$ is such a correspondence that \mathbf{p}_i in \mathbf{P} finds $\mathbf{p}'_{f(i)}$ in \mathbf{P}' as its match and $\mathbf{p}'_{f(i)}$ in \mathbf{P}' also finds \mathbf{p}_i in \mathbf{P} as its match. The determination of RCs has an advantage of easy implementation as they do not involve any threshold.

- *The number It of iterations:* While the maximum number $MaxIter$ of iterations allowed is set to 100, an ICP variant may converge early, and thus It should be smaller than 100.
- *Computational time in seconds:* All the experiments were carried out on a 64-bits computer with Intel(R) Core(TM) i7-8750H CPU @ 2.20 GHz processors and 16 GB RAM.

The experimental results are presented Table 1 and Fig. 4. In the figure, the yellow color represents the transformed first data shape \mathbf{P} , and the green color represents the second reference shape \mathbf{P}' .

Figure 4 shows that the bunny0-20 shapes have all been properly aligned by three ICP variants with a large amount of interpenetration between the transformed bunny0 and the reference bunny20 shapes. However, the PtP-ICP failed to register the cow38-42 shapes which are more challenging to register due to two main factors: relatively large transformations underlying the shapes with a rotation angle as large as 40° and the reference cow42 shape that includes a cluttered background. While the former may violate the assumption that the underlying transformation is relatively small for the establishment of tentative correspondences and linearizing the objective function with a least-squares solution, the latter makes it more difficult to distinguish the correct matches from the wrong ones. The bill of the duck in the transformed duck0 shape has been clearly displaced by the IRLS-ICP algorithm with regard to that in the reference duck20 shape. Both PtP-ICP and SPtP-ICP algorithms aligned the duck0-20 shapes properly.

These results have been verified by Table 1. Both the IRLS-ICP and SPtP-ICP algorithms aligned the cow38-42 shapes properly; however, the former did not converge within the maximum number $MaxIter$ of iterations allowed, resulting in a slightly higher average registration error e_μ . While the IRLS-ICP algorithm converges

prematurely and the PtP-ICP algorithms did not converge for the registration of the duck0-20 shapes, the convergence speed of the former is slow but that of the latter is faster with the estimated rotation angle close to the ground truth of 20° , and the former increases e_μ of the latter by 40%. These results confirm the observations made in the community of 3D imaging that the point-to-point-based ICP algorithm usually converges slowly with local linear convergence, the point-to-plane-based PtP-ICP algorithm converges faster with superlinear convergence, and the SPtP-ICP algorithm is the fastest with quadratic convergence [19]. The PtP-ICP algorithm is not as stable as the latest SPtP-ICP algorithm. This is because while the former minimizes approximately the local point-to-plane distances or the local quadratic approximants to the squared point-to-point distances [16], it allows one shape to slide on the other at locally flat patches with zero residual at optimal alignment for faster convergence. In contrast, the latter essentially minimizes the difference between the second-order (constant curvature) properties of the local surface patches; it thus allows one shape to slide on the other as long as their local surface patches have constant curvatures.

Robust Estimation Techniques

Peter Meer
 Department of Electrical and Computer Engineering, Rutgers University, Piscataway, NJ, USA

Synonyms

[Robust clustering](#); [Robust regression](#)

Definition

The goal of robust algorithms in computer vision is to extract all the information necessary to solve a vision task while discarding everything unrelated. The algorithms can be nonparametric, returning cluster centers, or parametric implementing regression estimations. In real-life applications, a robust procedure is always required. Deep learning methods, returning complex objects without a mathematical description, are not discussed in this entry.

Background

A data point can be an *inlier* or an *outlier*. If for a given task there are several inlier structures, the outliers are either on another inlier structure (structured outliers) or completely unstructured. If more than one type of inlier structure exist in the data, e.g., regression of planes and spheres, post-processing is required with all the inliers found in the estimations processes together.

R

Nonparametric Estimation

Known also as *location* estimation. The data points in the original space are transformed into clusters in the feature space. An algorithm finds the cluster centers, associates the points with their centers, and leaves out the outliers.

The k-nearest neighbor (k-NN) method is not considered robust since the user has to specify correctly several constants each time. The kernel density estimation is used today in computer vision with the 2D image segmentation being an example. The *mean shift* algorithm [1] computes

Robust Estimation Techniques, Fig. 1 2D Image segmentation. *Left:* Original. 321×481 pixels. *Right:* Mean shift segmentation. Spatial bandwidth 100, very large. Range bandwidth 8

over each small regions of the data the kernel density in both the xy , spatial space, and the color $L^*u^*v^*$, range space. See the *Color Spaces* entry. The modes of this five dimensional density are found iteratively and correspond to the cluster centers. All the points converging to a center define a cluster. There are no limitations in the shape of the clusters. The mean shift automatically returns the number of clusters. The spatial and range bandwidths are the only two parameters and can be loosely defined. In fact, instead of the given spatial bandwidth, the spatial limits can be extracted from the spatial borders of the range bandwidth. The segmentation results do not change much (Fig. 1). Mean shift can be used in other nonparametric estimations too.

Regression Estimation

The parametric *regression* estimation is defined by nonlinear relations in 2D, between 2D to 2D, 2D to 3D or in 3D. For example, epipolar geometry defines pairs of corresponding homogeneous points between two 2D images satisfying the fundamental matrix constraint $\mathbf{y}_2^T \mathbf{F} \mathbf{y}_1 = 0$. See

the *Epipolar Geometry* entry. A pair is an outlier when the two points do not correspond. The robust estimation returns the correct 3×3 matrix \mathbf{F} . See the *Fundamental Matrix* entry.

A robust estimator rewrites the nonlinear relation at the input into a higher dimensional linear relation. The new variables in the linearized space are \mathbf{x} , containing the original variables \mathbf{y} and the pairwise products of the components $y_j y_k$. For fundamental matrix, the linear relation has eight variables $\boldsymbol{\theta}$. The four original variables and the four products formed by multiplying the two coordinates from the first image with the two coordinates from the second.

The n points of \mathbf{y} at the input are assumed to have the same independent additive noise, which is true only for the inliers. A linear relation satisfied by $n_1 < n$ inliers is

$$\mathbf{x}_i^T \boldsymbol{\theta} - \alpha \approx 0 \quad i = 1, \dots, n_1 \quad (1)$$

where the m -dimensional vector $\hat{\boldsymbol{\theta}}$ and the scalar intercept $\hat{\alpha}$ have to be estimated. Which \mathbf{x}_i -s are the inliers in (1) is selected by the n_1 samples

returned by the estimation. Most robust algorithms don't take into account the heteroscedasticity of the covariance matrix of \mathbf{x}_i , depending of the original point \mathbf{y}_i .

There are $n - n_1$ outlier points in (1). If structured outliers exist, the n_1 points are removed, and a new inlier structure estimation starts. The procedure ends when no significant inlier structure remains. Most estimators also take into account the constraint $\hat{\boldsymbol{\theta}}^T \hat{\boldsymbol{\theta}} = 1$, which reduces the ambiguity of $\hat{\boldsymbol{\theta}}$ to an orthonormal gauge matrix [2].

The nonlinearities at the input disappear when it is rewritten into the linear relation. If additional constraints related to \mathbf{y} exist, it should be transformed together with the main problem.

The user must supply the threshold between the detected inlier structures and the outliers. If the inlier noise is significant, more than four/five inlier structures are difficult to recover.

The majority of the robust estimators are unbiased, converging toward the theoretical values of the estimates. Only a few problems, like ellipse estimation, are biased [3]. See the *Ellipse Fitting* entry.

When the relation (1) is extended to $\boldsymbol{\Theta}^T \mathbf{x} - \boldsymbol{\alpha}$, the $m \times k$ matrix $\boldsymbol{\Theta}$ and the k -dimensional intercept $\hat{\boldsymbol{\alpha}}$ have to be estimated. The constraint $\hat{\boldsymbol{\Theta}}^T \hat{\boldsymbol{\Theta}} = \mathbf{I}_{k \times k}$ defines a k -dimensional Grassmann manifold in m -dimensions. See the *Riemannian Manifold* entry. After $\hat{\boldsymbol{\Theta}}$ and $\hat{\boldsymbol{\alpha}}$ were obtained, if the estimation is applied again in the Grassmann manifold, it can improve the estimates [4].

Important Regression Methods

Robust regression appeared about the same time around 1960 both in statistics and computer vision independently.

Hough Transform

The Hough transform was proposed in 1959 [5] and patented in 1962 for the detection of linear trajectories of subatomic particles in a bubble chamber. The book of Rosenfeld [6] introduced

it to computer vision. In the Hough transform, a 2D data point draws a sinusoid with angles from 0° to 180° on the abscissa and the corresponding signed distances on the ordinate. Points belonging to a line in the xy space intersect in a single location in this polar representation. Several lines could be detected. The amount of the noise and the type of the noise distribution strongly influence the dimensions of the bin quantizing the transformed space. The Hough transform was extended to planes, circles, ellipses, and analytical and nonanalytical shapes, but does not generalize beyond curve detection. Today the Hough transform is only rarely used.

M-Estimator

The first robust estimator in statistics, the M-estimator, was proposed in 1964 by Huber [7]. The user has to provide, before the estimation s , the scale of the inlier noise. The M-estimator generally recovers only a single inlier structure and is not considered a robust estimator for vision problems. Often is part of a more complex procedure.

In computer vision the M-estimator has the loss function

$$0 \leq \rho(u) \leq 1 \quad |u| \leq 1 \quad \rho(u) = 1 \quad |u| > 1 \quad (2)$$

where $\rho(0) = 0$, is even symmetric $\rho(-u) = \rho(u)$ and nondecreasing with increasing $|u|$. The derivative $\psi(u)$ being redescending, the objection function $\sum \rho(u)$ is nonconvex, and the M-estimator converges only to a local optimum. Examples of loss functions can be found in [7] and [8]. The scale s being given, $u = e/s$ where e is the residual. The inliers are $|e| \leq s$, while the outliers are $|e| > s$.

To solve the simplest M-estimation, an original variable $y_{[k]} = z$ is moved to the left side $z = \mathbf{x}^T \boldsymbol{\theta} - \boldsymbol{\alpha}$. The residual for z_i is

$$e_i = z_i - [\mathbf{x}_i^T \hat{\boldsymbol{\theta}} - \hat{\boldsymbol{\alpha}}] \quad i = 1, \dots, n \quad (3)$$

and the M-estimator minimizes

$$\underset{\alpha, \theta}{\operatorname{argmin}} \frac{1}{n} \sum_{i=1}^n \rho\left(\frac{e_i}{s}\right) \quad (4)$$

where the m -dimensional vector $\hat{\theta}$ and the scalar intercept $\hat{\alpha}$ have to be estimated. The number of inliers $n_1 < n$ emerges from the estimation and $m \ll n_1$.

Using all the n points, the nonrobust total least squares (TLS) initialize the estimate. The M-estimator is an *iteratively reweighted least squares* (IRLS). In each iteration, the sum of the gradients of $\rho(e_i/s)$ in θ and α is equal to zero. The relation was multiplied and divides with the residual e_i .

$$\sum_{i=1}^n \begin{pmatrix} \mathbf{x}_i \\ 1 \end{pmatrix} \left[z_i - (\mathbf{x}_i^T \hat{\theta} - \hat{\alpha}) \right] \frac{1}{e_i} \frac{d\rho(e_i/s)}{de} = \mathbf{0}. \quad (5)$$

The nonnegative weights are computed from $\psi(u)/e = \rho'(u)/e$ as

$$w(e_i) = w_{ii} = \frac{1}{e_i} \psi(e_i/s) \geq 0 \quad i = 1, \dots, n \quad (6)$$

and the $n \times n$ diagonal weight matrix \mathbf{W} can be defined. A data point is either an inlier with $|e_i| \leq s$ and $w_{ii} > 0$ ($w_{ii} = 0$ for $|e_i| = s$) or an outlier with $|e_j| > s$ and $w_{jj} = 0$. The outliers do not participate in the estimation.

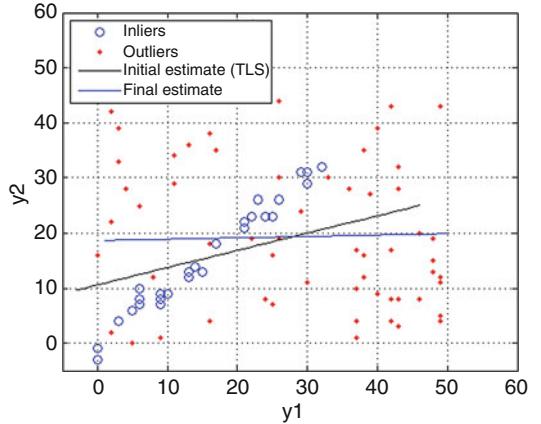

The $n \times (m+1)$ matrix \mathbf{A} and the column vector \mathbf{z} are

$$\mathbf{A} = \begin{pmatrix} \mathbf{x}_1^T & 1 \\ \cdot & \cdot \\ \mathbf{x}_n^T & 1 \end{pmatrix} \quad \mathbf{z} = \begin{pmatrix} z_1 \\ \cdot \\ z_n \end{pmatrix} \quad (7)$$

and the matrices \mathbf{A} and \mathbf{W} have full rank. Each iteration $l = 1, 2, \dots$ returns

$$\begin{pmatrix} \hat{\theta}^{(l)} \\ \hat{\alpha}^{(l)} \end{pmatrix} = [\mathbf{A}^T \mathbf{W}^{[l-1]} \mathbf{A}]^{-1} \mathbf{A}^T \mathbf{W}^{[l-1]} \mathbf{z}. \quad (8)$$

The procedure converges after a few iterations at $l = t$. To reduce the ambiguity, $\hat{\theta}$ has to satisfy $\hat{\theta}^T \hat{\theta} = 1$. From $\hat{\theta}^{(t)}/\|\hat{\theta}^{(t)}\|$ and $\hat{\alpha}^{(t)}/\|\hat{\theta}^{(t)}\|$, the original estimates can be computed.

Robust Estimation Techniques, Fig. 2 The M-estimator may not recover the correct 2D estimate even with the correct s

The correct scale estimate often is difficult to find beforehand. If the estimation is performed over a sequence, the scale may change significantly. If the initial estimate with TLS was completely wrong, even with the correct s , to recover the true estimate may not be possible (Fig. 2).

The *least median of squares* (LMedS), introduced in statistics in 1984 by Rousseeuw [9], were used in computer vision at the end of 1980s [10]. The LMedS recovered a single inlier structure which contained more than 50 percent of the points as inliers. A survey of M-estimators and LMedS, including their limitations, can be found in [8]. The special issue of Computer Vision and Image Understanding [11] gave an overview of the robust procedures at the 1990s.

RANSAC

Today almost everybody uses the *RANdom SAmple Consensus* (RANSAC) estimator. The RANSAC was introduced by Fischler and Bolles in 1980 and in 1981 was published [12]. See [13, Sec. 4.7] for a more recent description.

The estimation in RANSAC is based on hypotheses drawn with *elemental subsets*. An elemental subset is the smallest number of data points required to estimate all the unknowns, which for nonlinear inputs is from (1). The 3×3 matrix in 2D homography needs four-point correspondences since each point pair

corresponds to two unknowns. See the *Wide Baseline Matching* entry. The fundamental matrix needs eight points because the 3×3 matrix \mathbf{F} introduces eight unknowns in the linearized equation. See the *Eight-Point Algorithm* entry.

The user have to provide beforehand the scale s of the inlier noise. RANSAC cannot achieve the global optimum being based on elemental subsets.

RANSAC has a binary loss function $\rho_{zo}(u)$

$$\rho_{zo}(u) = 0 \quad |u| \leq 1 \quad \rho_{zo}(u) = 1 \quad |u| > 1. \quad (9)$$

The residual $e_i = \mathbf{x}_i^T \boldsymbol{\theta} - \alpha$ is zero when \mathbf{x}_i is on the estimate. Inliers have $|e_i| \leq s$, and outliers have $|e_j| > s$.

The algorithm minimizes the number of outliers in N elemental subset trials and returns the RANSAC estimates $\hat{\boldsymbol{\theta}}$ and $\hat{\alpha}$

$$\operatorname{argmin}_{\alpha, \boldsymbol{\theta}} \sum_{i=1}^n \rho_{zo} \left(\frac{\mathbf{x}_i^T \boldsymbol{\theta} - \alpha}{s} \right) \quad \text{in } N \text{ trials.} \quad (10)$$

The value of N can be up to a few thousands, generally larger if the elemental subset needs more points. When the estimate does not change significantly for larger N , the given N is enough.

- Repeat N times:
 - Choose an elemental subset by random sampling *without* replacement.
 - Find the linear model candidates $\boldsymbol{\theta}, \alpha$.
 - Assume these estimates are valid for all n points.
 - Compute the distance for each point from the linear model.
 - Distances less than the scale s , called the consensus set, are inliers.
- The candidate having the largest consensus set, smallest set of outliers, returns the RANSAC estimates $\hat{\boldsymbol{\theta}}$ and $\hat{\alpha}$.
- Perform total least squares (TLS) for the inlier points. Normalize the solution with $\hat{\boldsymbol{\theta}}_{tls}^T \hat{\boldsymbol{\theta}}_{tls} = 1$. Compute the original estimates.

Figure 3 shows an elemental subset processing. If RANSAC is successful, a good inlier/outlier

separation is obtained. While the scale s is always present, now often is no longer explicitly given in the papers.

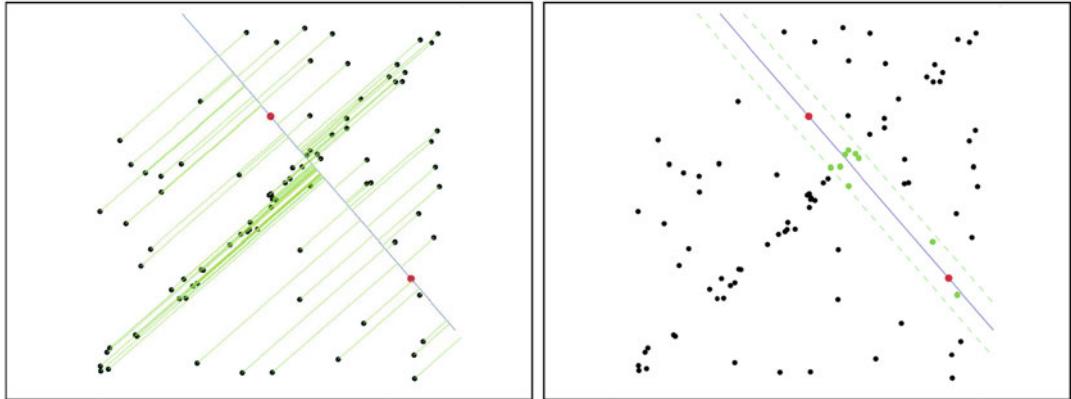

The RANSAC can fail if there are multiple inlier structures, if an image is resized but the scale did not change, and if in a sequence of images the scale changed significantly. Even if the correct scale is given, for asymmetric outliers RANSAC may not work (Fig. 4).

Robust methods are applied to all nonparametric and parametric models, both in 2D and 3D. Regression estimations mainly use RANSAC. The other methods are more complicated and may not work for a given application. At least in the industry, the emphasis is on the final product and not on how to get there. Tuned to a specific task, if RANSAC does the job, it is enough.

Beyond RANSAC

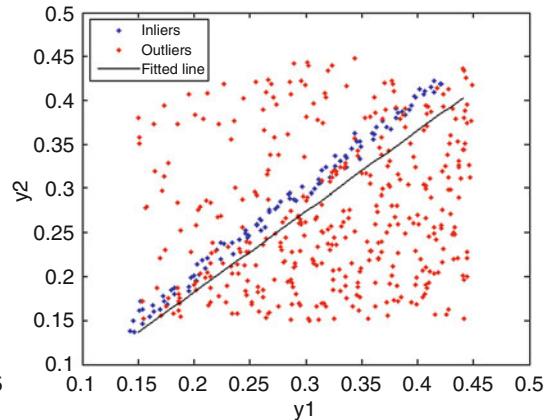

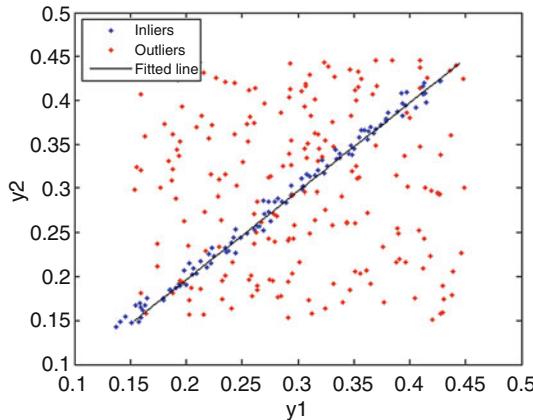

The literature for robust estimation is very large, and many estimators, most related to RANSAC, were proposed. They try to improve RANSAC by the scale coming from the data, the sampling is guided, the model verification is hierarchical, etc. Even today papers appear about binomial constraints, maximum consensus, graph-cut RANSAC, latent RANSAC, and parametric robustness by deep learning. Each of them, using a small set of other estimators, tries to prove that the described new estimator is better. However, no breakthrough happened in the last 40 years. A few algorithms are presented below which achieved some success. Most of the references are in [14].

In *progressive sample consensus* (PROSAC), Chum and Matas used similarity scores to build recurrence relations for sampling the data nonuniformly. The correspondences could lead to degenerate configurations. Torr and Zisserman maximized the likelihood through *maximum likelihood estimation sample consensus* (MLESAC) [11]. It was extended by Tordoff and Murray to guided sampling. In *locally optimized RANSAC* (Lo-RANSAC), Chum et al. were based on an inner RANSAC having the currently best subset of inliers, updated if a larger number of inliers were detected. In *preemptive RANSAC*, Nister scored a fixed number of the

Robust Estimation Techniques, Fig. 3 *Left:* The two red points define an elemental subset for 2D line fitting with RANSAC. The distances of the points from the

model are in green. *Right:* Only a few points are inliers for the given scale s

Robust Estimation Techniques, Fig. 4 2D line fitting with the correct s in RANSAC. *Left:* The symmetrical outliers are filtered out. *Right:* For asymmetric outliers RANSAC failed

hypotheses for the i -s point and retained only the bests for the $(i + 1)$ -s point. The process continued till only one hypothesis remained. Frahm and Pollefeys used RANSAC for quasi-degenerate data (QDEGSAC) by first detecting the degeneracy.

In *Generalized Principal Component Analysis* (GPCA), Vidal et al. [15] estimated the inlier subspaces by analyzing the derivatives of polynomials derived from the data. The subspaces could have different dimensions, but in the presence of unstructured outliers, the estimator failed. In *Propose Expand and Re-estimate Labels* (PEARL), Isack and Boykov [16] started with RANSAC and applied energy minimization with alternative

steps of expansion for inlier classification and reestimation of the errors. Several other laboratories did similar PEARL-type procedures.

All the above cited methods recovered parametric inlier structures, but the inlier estimations were not completely independent. The scale was unique and generally not estimated from the data. The estimations stop when it is assumed that no significant inlier structure still exists, which is not always true.

MISRE

The *Multiple Input Structures with Robust Estimator* (MISRE) [17] eliminates the problems described in the previous paragraph. The MISRE

Robust Estimation Techniques, Fig. 5 *Left:* A 2D image from the *toy* sequence. *Right:* The segmented 3D planes and 3D spheres with MISRE. See text

independently processes each structure without labelling as inliers or outliers, and only the classification puts the significant inlier structures first. At the end of the estimation, a straightforward inlier/outlier threshold is the only role the user has.

The Mahalanobis distances measure how far is from α the projection $z_i = \mathbf{x}_i^\top \boldsymbol{\theta}$, normalized by the standard deviation of z_i without σ . The n distances in an elemental subset trial are sorted in increasing order. After N trials, the working sequence is the sequence which has the *minimum sum* of Mahalanobis distances for the first 5% of the data. If significant inlier structures still exist, with high probability the working sequence will contain one of them.

The scale estimate is computed from many independent expansions. Each expansion has segments of Mahalanobis distances starting at 5% of the data until no expansion is possible. Every expansion ends when the average of the processed points is larger than twice the number of points in the next segment. The largest scale in the region of interest is the scale estimate. Mean shift [1] refines the structure, and the structures density is computed.

The classification is based on decreasing density. The significant inlier structures at the top because the outliers have large scales and small densities. The structures being estimated

independently, if the amount of outliers increase only the weakest inlier structure, may disappear at the beginning.

In Fig. 5a 2D image is shown from the 36 images in the *toy* sequence. The professional ReMake software program returned 10854 points in 3D. For spheres estimation, the first two inlier structures were spheres, and about 7300 points are deleted. For planes estimation, the first three inlier structures were planes, and several thousand points are deleted. The post-processing reallocated some of the points between the planes and the spheres (Fig. 5b). The results could be improved with stronger preprocessing, the dark plane in the background practically don't appear, and post-processing.

R

Open Problems

The performance of a machine is ultimately judged by the human observer performing the same task. The human visual system is much more sophisticated than any machine today meaning that robust estimation can grow a lot. The MISRE introduced above applied to images with several thousand pixels in each dimension can be further improved. Increasing the importance of the preprocessing, the number of outliers can be reduced without significantly

reducing the number of inliers. The estimation starts from a “better input,” and more inlier structures can be recovered. However, this also means that all the low-level algorithms have to be reexamined.

► Radiometric Response Function

Definition

In imaging, saturation is a type of distortion where the recorded image is limited to some maximum value, interfering with the measurement of bright regions of the scene.

Background

The role of a sensor element is to measure incident irradiance and record that quantity as an image intensity value. However, physical constraints limit the maximum irradiance that can be measured for a given camera setting. In the absence of noise, the mapping from irradiance to image intensity is fully described by the

radiometric response function, a monotonically increasing function whose range is restricted by the maximum irradiance. Pixels whose intensity corresponds to this maximum are known as saturated.

Saturated pixels contain less information about the scene than other pixels. While non-saturated pixels can be related to the incident irradiance by applying the inverse of the radiometric response function, saturated pixels provide only a lower bound on irradiance. Therefore, estimating the irradiance of saturated pixels is similar to other image “hallucination” tasks such as inpainting [2].

Since many computer vision algorithms assume a linear relationship between sensor irradiance and the measured image intensity, it is important to identify saturated pixels and handle them appropriately. In practice, saturated pixels are often treated as missing values or otherwise ignored.

Theory

In the idealized noise-free case, the image intensity M of a pixel can be described as mapping the incident irradiance I according to the radiometric response function $f(\cdot)$, limited by the maximum irradiance I_{\max} ,

$$M = f(\min(I, I_{\max})). \quad (1)$$

For an irradiance of I_{\max} or higher, the image intensity will saturate at its maximum value of $M_{\max} = f(I_{\max})$. Since saturated pixels do not have unique corresponding irradiance values, they provide no direct information about incident irradiance beyond imposing a lower bound of I_{\max} .

Identifying saturated pixels is straightforward in practice, since many saturated pixels have the nominal maximum pixel value of M_{\max} . Sensor noise and other on-camera processing introduce the minor complication that saturated pixels may have values slightly less than this maximum. This effect is easily addressed, however, by using a lower, more conservative threshold to detect saturation [6, 8].

Saturation is caused by underlying physical characteristics of the sensor which limit the highest irradiance that can be measured for the given settings of the camera. In a digital sensor, where incident photoelectrons are recorded as electric charge, each sensor element can store a maximum amount of charge known as the *full well capacity*. Together with the exposure time and amplifier gain, the full well capacity imposes a limit on the maximum irradiance that can be measured before saturation. Film-based sensors are subject to saturation as well, but the mechanism limiting their photosensitivity is chemical [9].

While modern digital sensors are designed to dissipate excess charge above the full well capacity, for very bright parts of the scene, excess charge from a saturated pixel can spill over to adjacent regions. This artifact, known as *blooming*, can lead to saturation in pixels that would not otherwise be saturated.

Application

Saturation can pose problems for computer vision algorithms that assume linearity unless saturated pixels are identified and handled appropriately. For example, methods operating in the Fourier domain require special attention to saturation [1, 18], because the global nature of the transform means that even isolated saturated

pixels can corrupt the whole image. The two main approaches to dealing with saturated pixels are explicitly treating them as missing values and interpolating them from surrounding pixels.

The effect of saturation should also be taken into account when estimating the parameters of sensor noise from an image [5, 11]. Pixels near saturation will demonstrate reduced variance in general, since the maximum value imposed by saturation will make their samples closer on average.

From the standpoint of photography, camera settings should be chosen to avoid saturation in regions of interest, otherwise important detail or color information may be lost. Photographers describe saturated images as being *overexposed* or as having clipped or blown highlights. Although ill-posed, a problem of great practical interest to photographers is recovering detail in saturated regions of the scene or at least hallucinating plausible detail.

Under mild overexposure, only partial color information may be lost due to saturation. Partial saturation results from the different spectral sensitivities of each color channel, leading one channel to saturate before the others. In this setting, the main approach for restoring detail is to represent the correlation between color channels, using either global [19] or spatially varying [7, 12] color distribution models, then using this correlation to transfer information from the non-saturated color channels.

With greater overexposure, pixels become saturated in all color channels. The most common approach for restoring detail in this setting is to blindly extrapolate smooth peaks within saturated regions [7, 15, 17]. In fact, saturated regions can sometimes provide quantitative evidence about the underlying irradiance. Provided that overexposure is moderate and the scene is sufficiently smooth, the band-limitation of irradiance [1] or the resulting noise distribution [4] can be exploited to recover detail in fully saturated regions. For more severe overexposure or larger saturated regions, none of these methods are generally sufficient. In such cases, user guidance

may be enlisted to help transfer plausible high-frequency detail from other sources [17].

In general, choosing the exposure setting for a photo requires balancing competing goals. While overexposure causes loss of detail in the highlights due to saturation, underexposure leads to higher relative noise. The relationship between noise and saturation defines the *dynamic range* of the sensor and determines the range of irradiances that can be captured acceptably in a single shot. When restricted to a single shot, one should generally choose the exposure setting so that the brightest region of interest falls just below the saturation point [14].

For scenes with large dynamic range, such considerations have motivated *high dynamic range imaging* methods based on capturing multiple photos with different exposure times [3], each of which saturates at a different irradiance. There is also an ongoing effort to develop new kinds of high dynamic range sensors offering higher effective saturation levels [10]. A broad range of new designs have been proposed, including sensors that record the precise length of exposure time needed to reach saturation and sensors with a logarithm-like response. Each of these designs presents unique tradeoffs, including different noise characteristics over their operating range [10]. An orthogonal imaging approach is to use spatial multiplexing to incorporate multiple types of sensor elements, each having different sensitivities [13, 18] or sizes [16].

- ▶ Edge Detection

Definition

The notion of scale selection refers to methods for estimating characteristic scales in image data and for automatically determining locally appropriate scales in a scale-space representation, so as to adapt subsequent processing to the local image structure and compute scale-invariant image features and image descriptors.

An essential aspect of the approach is that it allows for a bottom-up determination of inherent scales of features and objects without first recognizing them or delimiting, alternatively segmenting, them from their surroundings.

Scale selection methods have also been developed from other viewpoints of performing noise suppression and exploring top-down information.

Background

The concept of *scale* is essential when computing features and descriptors from image data. Real-world objects may contain different types of structures at different scales and may therefore appear in different ways depending on the scale of observation. When observing objects by a

camera or an eye, there is an additional scale problem due to perspective effects, implying that distant objects will appear smaller than nearby objects. A vision system intended to operate autonomously on image data acquired from a complex environment must therefore be able to handle and be robust to such scale variations.

For a vision system that observes an unknown scene, there is usually no way to a priori know what scales are appropriate for extracting the relevant information. Hence, a multi-scale representation of the image data is essential, whereby the original signal is embedded into a *one-parameter family* of signals using scale as the parameter. Given an N -dimensional signal $f: \mathbb{R}^N \rightarrow \mathbb{R}$ and with the notation $x = (x_1, \dots, x_N) \in \mathbb{R}^N$, the *scale-space representation* [1–3] of f is defined by the convolution operation

$$L(x; t) = \int_{\xi \in \mathbb{R}^N} f(x - \xi) g(\xi; t) d\xi, \quad (1)$$

where $g: \mathbb{R}^N \times \mathbb{R}_+ \rightarrow \mathbb{R}$ denotes the *Gaussian kernel*

$$g(x; t) = \frac{1}{(2\pi t)^{N/2}} e^{-|x|^2/2t} \quad (2)$$

and the variance $t = \sigma^2$ of this kernel is referred to as the *scale parameter*. Based on this representation, *Gaussian derivatives*, or *scale-space derivatives*, at any scale t can then be computed by differentiating the scale-space representation or equivalently by convolving the original image with Gaussian derivative kernels

$$L_{x^\alpha}(\cdot; t) = \partial_{x^\alpha} L(\cdot; t) = (\partial_{x^\alpha} g(\cdot; t)) * f(\cdot) \quad (3)$$

(with multi-index notation $\alpha = (\alpha_1, \dots, \alpha_N)$ for $\partial_{x^\alpha} = \partial_{x_1^{\alpha_1}} \dots \partial_{x_N^{\alpha_N}}$). Such Gaussian derivatives can be used as a basis for expressing a large number of visual modules including feature detection, feature classification, image matching, motion, shape cues, and image-based recognition [4].

Theory

The notion of scale selection complements traditional *scale-space theory* by providing explicit mechanisms for generating hypotheses about interesting scales.

Scale Selection from γ -Normalized Derivatives

A particularly useful methodology for computing estimates of *characteristic scales* is by detecting *local extrema over scales* of differential expressions in terms of γ -normalized derivatives [5, 6] defined by

$$\partial_\xi = t^{\gamma/2} \partial_x. \quad (4)$$

A general and very useful property of this construction is that if two signals f and f' are related by a scaling transformation

$$f'(x') = f(x) \quad \text{with} \quad x' = s x, \quad (5)$$

and if there is a local extremum over scales at $(x_0; t_0)$ in a differential expression $\mathcal{D}_{\gamma-\text{norm}} L$ defined as a homogeneous polynomial of Gaussian derivatives computed from the scale-space representation L of the original signal f , then there will be a corresponding local extremum over scales at $(x'_0; t'_0) = (s x_0; s^2 t_0)$ in the corresponding differential expression $\mathcal{D}_{\gamma-\text{norm}} L'$ computed from the scale-space representation L' of the rescaled signal f' [5, Sect. 4.1].

This scaling result holds for all homogeneous polynomial differential expressions, including rotationally invariant differential invariants, and implies that local extrema over scales of γ -normalized derivatives are preserved under scaling transformations. Thereby, such local extrema over scales provide a theoretically well-founded way to automatically adapt the scale levels to local scale variations.

Specifically, scale-normalized scale-space derivatives of order $|\alpha| = \alpha_1 + \dots + \alpha_N$ at corresponding points will then be related according to

$$L'_{\xi^\alpha}(x'; t') = s^{|\alpha|(\gamma-1)} L_{\xi^\alpha}(x; t), \quad (6)$$

which means that $\gamma = 1$ implies perfect scale invariance in the sense that the γ -normalized derivatives at corresponding points will be equal. If $\gamma \neq 1$, the difference in magnitude can on the other hand be easily compensated for using the scale values of corresponding scale-adaptive image features.

These results imply that detection of image features and computation of image descriptors at scale levels equal to or proportional to the scales at which there are local extrema over scales constitutes a very general methodology for obtaining *scale-invariant image features* and *scale-invariant image descriptors*.

Indeed, it can also be axiomatically shown that the notion of γ -normalized derivatives arises by necessity, given the condition that local extrema over scales of scale-normalized derivatives should be preserved under scaling transformations [5, Appendix A.1].

Relation to Frequency Estimation

There is a conceptual similarity between this principle and local frequency estimation from peaks in the Fourier transform. For a one-dimensional sine wave

$$f(x) = \sin(\omega x), \quad (7)$$

it can be shown [5, Sect. 3] that there will be a peak in the magnitude of the m th order γ -normalized derivative at a scale

$$\sigma_{\max} = \frac{\sqrt{\gamma m}}{2\pi} \lambda \quad (8)$$

proportional to the wavelength $\lambda = 2\pi/|\omega|$ of the signal. Two conceptual differences compared to Fourier-based frequency estimation, however, are that (i) no window size is needed for computing the Fourier transform and (ii) this approach applies also to nonlinear differential expressions.

Relations to Image Statistics

It can be shown [5, Sect. 9.1] that the notion of γ -normalized derivatives corresponds to normalizing the m th order N -dimensional Gaussian derivatives to constant L_p -norms over scale with

$$p = \frac{1}{1 + \frac{m}{N}(1 - \gamma)}, \quad (9)$$

where the perfectly scale-invariant case $\gamma = 1$ corresponds to L_1 -normalization for all orders m .

It can also be shown [5, Sect. 9.2] that the γ -normalized derivatives are *neutral* with respect to *self-similar* power spectra of the form

$$S_f(\omega) = |\omega|^{-N-2m(1-\gamma)}. \quad (10)$$

Natural images often show a qualitative behavior similar to this [7].

Scale-Space Signatures

Figure 1 illustrates the basic idea, by showing the so-called *scale-space signatures* accumulated in the two-dimensional case (In the specific 2-D case, the simplifying notation $(x, y) \in \mathbb{R}^2$ is used instead of $x = (x_1, x_2) \in \mathbb{R}_2$, implying that $L_{x_1 x_1} = L_{xx}$, $L_{x_1 x_2} = L_{xy}$, $L_{x_2 x_2} = L_{yy}$, etc.) for two generally applicable differential entities for scale selection: the *scale-normalized Laplacian* [3, Sect. 13.3] [5, Sect. 5] (with $\gamma = 1$)

$$\nabla^2 L_{\text{norm}} = t(L_{xx} + L_{yy}) \quad (11)$$

and the *scale-normalized determinant of the Hessian* [3, 5] (also with $\gamma = 1$)

$$\det \mathcal{H}_{\text{norm}} L = t^2 (L_{xx} L_{yy} - L_{xy}^2). \quad (12)$$

In the scene in Fig. 1, there are strong perspective scaling effects due to differences in depth between similar objects in the world. These scale variations are reflected in the scale-space signatures in the respect that the local extrema over scales are assumed at finer scales for distant objects and at coarser scales for nearby objects. If one computes the ratio between the scale values in terms of a scale parameter $\sigma = \sqrt{t}$ of dimension [length], then the ratio between the scale values is in very good agreement with the ratio between the sizes of the objects in the image

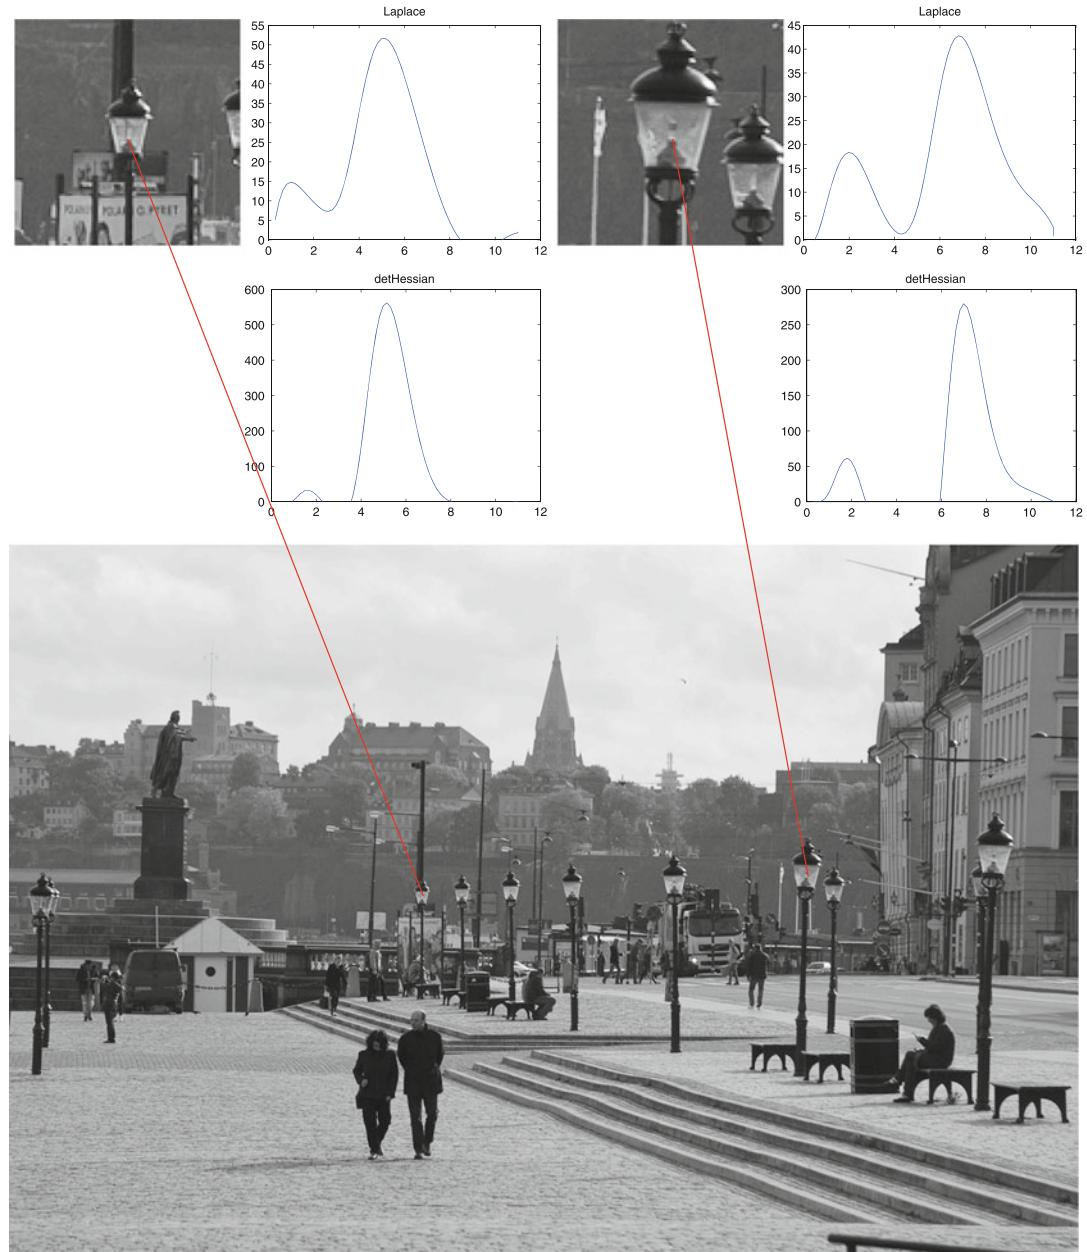

domain as measured by a ruler. This property illustrates one of the scale-invariant properties of the scale selection mechanism.

General Framework for Defining Scale-Invariant Image Descriptors

By computing an image descriptor at a scale proportional to the detection scale \hat{t} of a scale-invariant image feature or by normalizing an image patch by a corresponding scaling factor $\hat{\sigma} = \sqrt{\hat{t}}$, provides two very general scale normalization mechanisms that can be used for defining much wider classes of *scale-invariant image descriptors* [5, 9] (see the “Application” section below for two specific examples regarding image-based recognition). The scale-invariant properties of these descriptors originate from the general scale-invariant property of local extrema over scales of differential expressions in terms of γ -normalized derivatives.

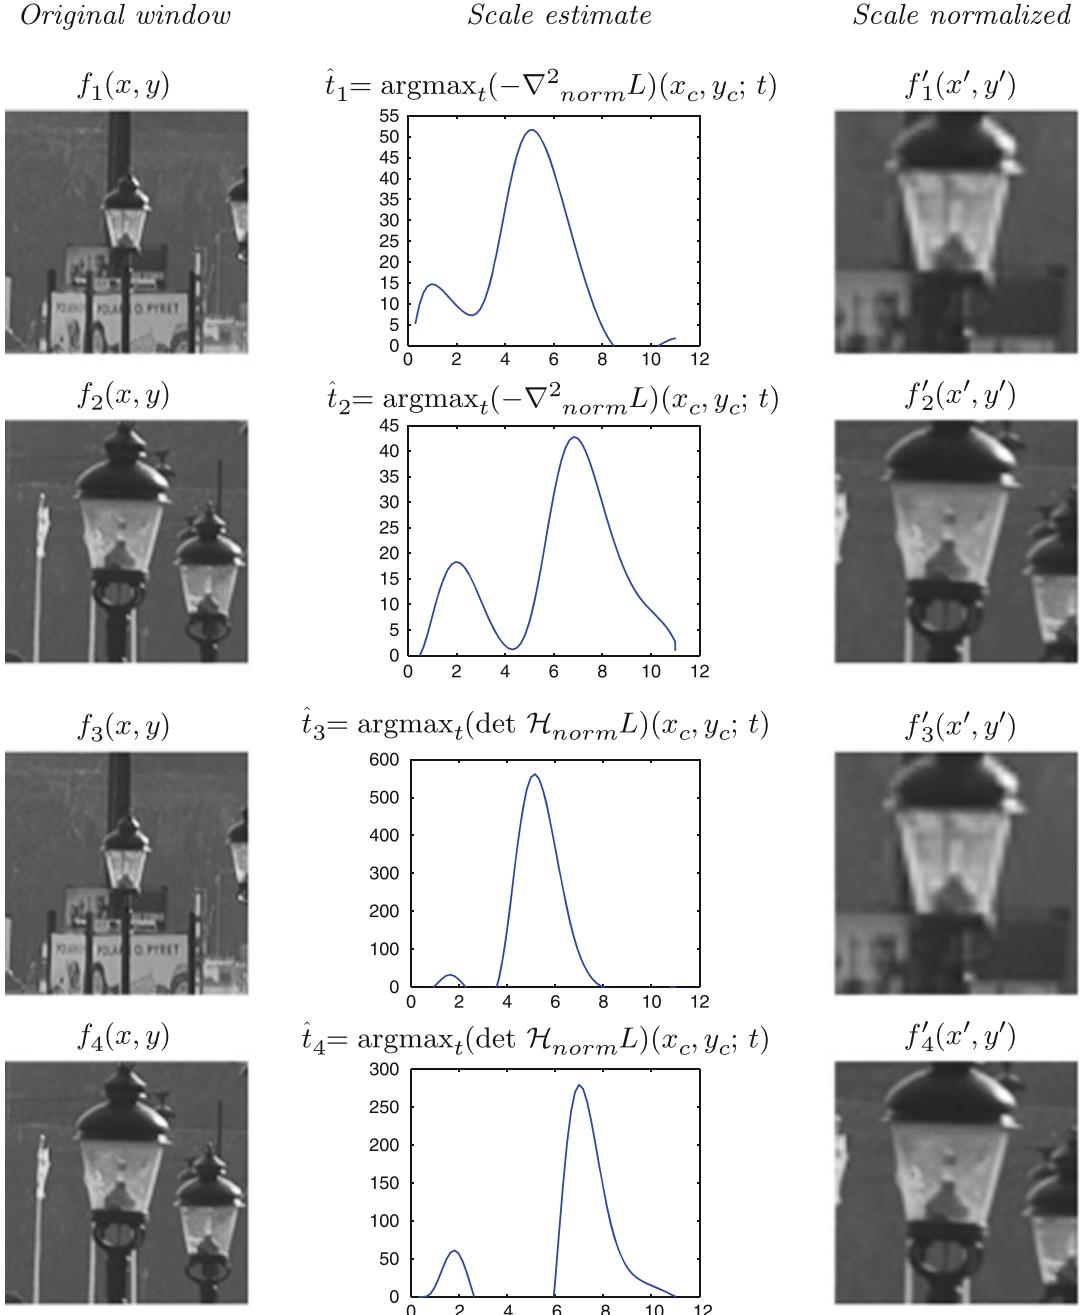

Figure 2 illustrates how scale normalization can be performed in this way by rescaling the local image patches around the two details in Fig. 1 using the scale values $\hat{\sigma} = \sqrt{\hat{t}}$ at which the Laplacian $\nabla_{\text{norm}}^2 L$ and the determinant of the Hessian, respectively, assumed their strongest local extrema over scales. In this sense, scale normalization from the detection scales \hat{t} constitutes a general mechanism for establishing a *common scale-invariant reference frame* with regard to scaling transformations [8].

It should be noted, however, that multiple extrema over scales may in general be found in the scale-space signature, as can be seen in Figs. 1 and 2, where two significant local extrema over scales are obtained in each scale-space signature, with the coarser-scale response corresponding to the lamp as a whole and the finer-scale response corresponding to the light bulb inside. Because of this inherent multi-scale nature of real-world objects, a vision system intended to interpret images from a natural environment must in general be able to handle *multiple scale hypotheses over scales*.

Scale Selection, Fig. 1 Scale-space signatures accumulated for image structures of different size in the image domain. The *upper part* of the illustration shows windows around two details from the image at the *bottom*, with corresponding scale-space signatures of the scale-normalized Laplacian $\nabla_{\text{norm}}^2 L$ and the scale-normalized determinant of the Hessian $\det \mathcal{H}_{\text{norm}} L$ accumulated at the central point in each window. As can be seen from the graphs,

the local extrema over scales are assumed at coarser scales for the larger-size object than for the smaller-size object. Specifically, the ratio between the scale values at which the local extrema are assumed provides an estimate of the relative amount of scaling, when measured in dimension [length] (In the graphs, the *horizontal axis* represents effective scale [3, pp 180–182] approximated by $\tau \approx \log_2(1+t)$). (Reprinted from [8] with permission)

Scale Selection, Fig. 2 In this illustration, local windows around two of the lamps in Fig. 1 (shown in the *left column*) have been rescaled by scaling factors $\hat{s} = \sqrt{\hat{t}}$ obtained from the dominant response over scales of the Laplacian $\nabla^2_{norm} L$ and the determinant of the Hessian

$\det \mathcal{H}_{norm} L$ (shown in the *middle column*) to compute a *scale-normalized window* (shown in the *right column*) around each detail. In this way, scale selection can be used for defining a *scale-normalized reference frame* for subsequent computation of *scale-invariant image descriptors*. (Reprinted from [8] with permission)

Scale-Space Extrema

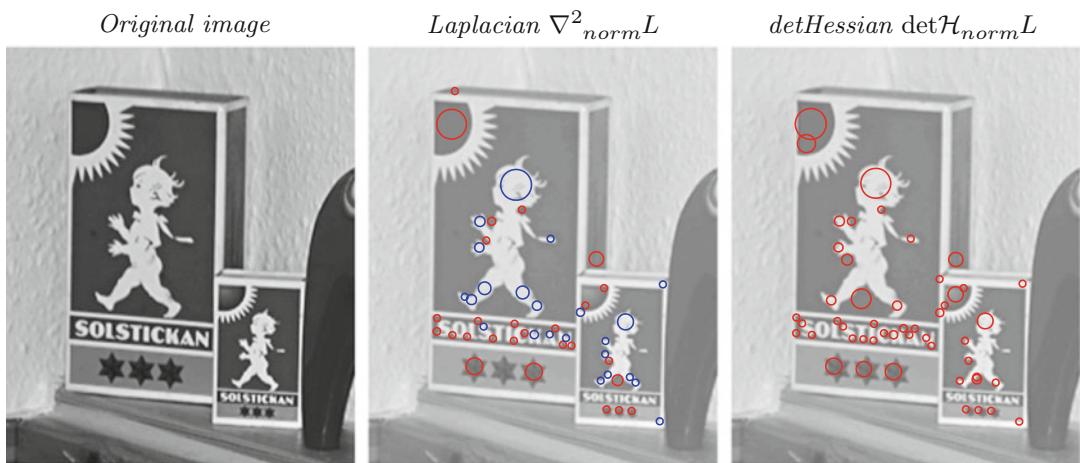

The notion of scale selection from scale-normalized derivatives can be complemented by *spatial selection* by detecting points in scale space that assume *local extrema with respect to both space x and scale t* . Such points are referred to as *scale-space extrema*. Specifically, detection of scale-space extrema of rotationally invariant differential invariants provides a general, effective, and robust methodology for detecting *interest points with built-in scale selection* [3, 5, 9]. Thus, given a scale-normalized differential expression $\mathcal{D}_{\gamma-\text{norm}}L$, one simultaneously obtains spatial positions \hat{x} and scale estimates \hat{t} according to

$$(\hat{x}; \hat{t}) = \operatorname{argmaxminlocal}_{(x; t)} (\mathcal{D}_{\gamma-\text{norm}}L)(x; t). \quad (13)$$

Figure 3 shows the result of detecting the 50 strongest scale-space extrema of the scale-normalized Laplacian $\nabla_{\text{norm}}^2 L$ and the scale-normalized determinant of the Hessian $\det \mathcal{H}_{\text{norm}}L$ from an image that contains two objects of different sizes. Each scale-space

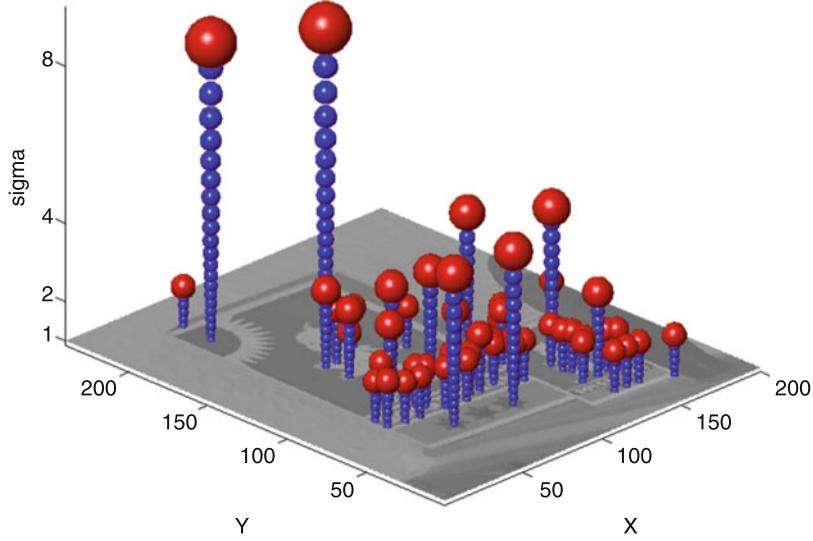

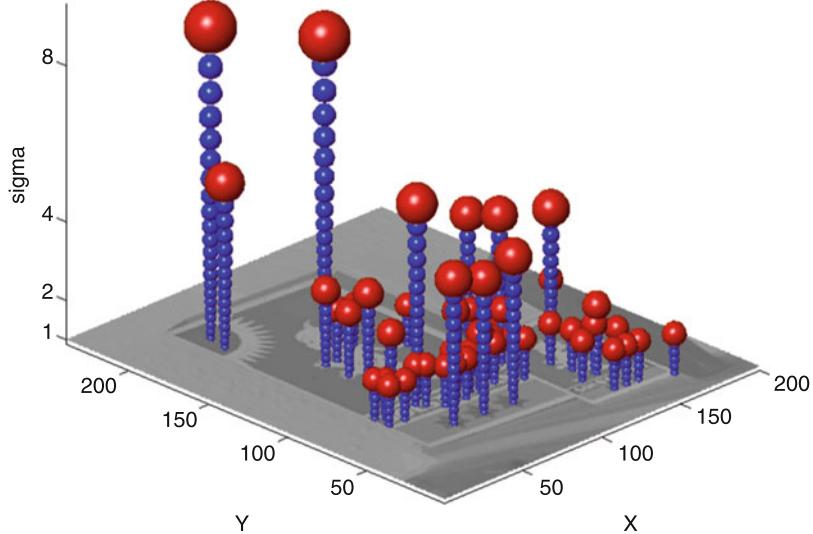

extremum has been illustrated by a circle with the radius proportional to the detection scale $\hat{\sigma} = \sqrt{\hat{t}}$. In Fig. 4, each feature has been visualized by a sphere in the 3-D scale-space volume of the 2-D image, with the radius of the sphere increasing with the detection scale. As can be seen from this illustration, the notion of scale-space extrema can effectively reveal interest points and characteristic scales of those (see the “Application” section below for more details about scale-invariant interest point detectors). Specifically, the differences in the radii of the circles in the 2-D illustration and in the heights over the image plane in the 3-D graphics reveal the scale differences between corresponding image features from the two objects.

The differential operators $\nabla_{\text{norm}}^2 L$ and $\det \mathcal{H}_{\text{norm}}L$ in general both produce strong responses at the centers of blob-like structures that are either brighter or darker than their surrounding, provided that these differential entities are computed at scale levels that roughly match the size of the corresponding image structures. For this reason, they constitute very useful differential entities for *blob detection*.

Scale Selection, Fig. 3 2-D illustration of the 50 strongest *scale-space extrema* of the Laplacian $\nabla_{\text{norm}}^2 L$ and the determinant of the Hessian $\det \mathcal{H}_{\text{norm}}L$ computed from an image with two similar objects of different physical sizes. Each feature is illustrated by a circle centered at

the position (\hat{x}, \hat{y}) of the scale-space extremum and with the radius proportional to the detection scale $\hat{\sigma} = \sqrt{\hat{t}}$. Red circles represent scale-space maxima, while blue circles

Scale-space extrema of the Laplacian $\nabla_{\text{norm}}^2 L$ Scale-space extrema of the determinant of the Hessian $\det \mathcal{H}_{\text{norm}} L$ 

Scale Selection, Fig. 4 3-D illustration of the 50 strongest scale-space extrema of the Laplacian $\nabla_{\text{norm}}^2 L$ and the determinant of the Hessian $\det \mathcal{H}_{\text{norm}} L$ computed from the image in Fig. 4. Here, each feature is illustrated

by a *red sphere* centered at the position $(\hat{x}_0, \hat{y}_0; \hat{t}_0)$ of the scale-space extremum and with the radius increasing with the detection scale \hat{t}_0 . The *blue spheres* have been inserted to simplify visual interpretation

Discrete Implementation

Detection of scale-space extrema from an N -dimensional discrete image can be performed by nearest-neighbor comparisons in the $N + 1$ -dimensional scale-space volume. For a 2-D

image, this implies that nearest-neighbor comparisons are performed by local comparisons with the 26 neighbors in a $3 \times 3 \times 3$ neighborhood over space and scale [3] [5, footnote 16] [10]. Scale estimates and position estimates of higher accu-

racy can then be obtained by fitting a parabola to the data around any scale-space extremum [10, 11].

Discrete analogues of γ -normalized derivatives can be obtained either by (i) *variance-based normalization* which implies that the discrete derivative approximations $\delta_{x^\alpha} L$ are multiplied by an appropriate power of the scale parameter

$$\begin{aligned} L_{\xi^\alpha}(\cdot; t) &= L_{\xi_1^{\alpha_1} \dots \xi_N^{\alpha_N}}(\cdot; t) \\ &= (t^{\gamma/2})^{|\alpha|} (\delta_{x^\alpha} L)(\cdot; t) \end{aligned} \quad (14)$$

or by using the notion of (ii) l_p -normalization [5, Appendix A.4.2]

$$L_{\xi^\alpha}(\cdot; t) = L_{\xi_1^{\alpha_1} \dots \xi_N^{\alpha_N}}(\cdot; t) = C_\alpha (\delta_{x^\alpha} L)(\cdot; t), \quad (15)$$

where the discrete normalization constants C_α are determined such that the l_p -norms of the scale-normalized discrete derivative approximation kernels $\delta_{x^\alpha} T$ [3, Chap. 5] are to be equal to the L_p -norms of the corresponding γ -normalized Gaussian derivative kernels $\partial_{x^\alpha} g$

$$\begin{aligned} C_\alpha \left(\sum_{n \in \mathbb{R}^N} |(\delta_{x^\alpha} T)(n; t)|^p \right)^{1/p} &= \\ (t^{\gamma/2})^{|\alpha|} \left(\int_{x \in \mathbb{R}^N} |(\partial_{x^\alpha} g)(x; t)|^p dx \right)^{1/p}. \end{aligned} \quad (16)$$

Experiments in [11] show that the notion of l_p -normalization gives more accurate scale estimates in situations where discretization effects become important.

A particularly convenient way of implementing scale-space smoothing in this context is by convolution with the *discrete analogue of the Gaussian kernel* [3, pp 84–87]

$$T(n; t) = e^{-t} I_n(t), \quad (17)$$

which implies that the semigroup property of the Gaussian scale space holds exactly also for the discrete scale-space kernels $T(\cdot; t_1) * T(\cdot; t_2) = T(\cdot; t_1 + t_2)$ and the *cascade smoothing property*

$$L(\cdot; t_2) = T(\cdot; t_2 - t_1) * L(\cdot; t_1), \quad (18)$$

for $t_2 \geq t_1 \geq 0$ implies that one can perform a set of incremental convolutions with kernels of smaller support instead of computing each scale level from the original signal f independently.

The notion of scale selection from scale-normalized derivatives can also be transferred to a *pyramid* representation to allow for real-time implementation on standard processors [10–12].

Alternative Approaches to Scale Selection

A number of other mechanisms for scale selection have also been developed based on ideas of:

- Detecting peaks over scales in weighted entropy measures [13] or Lyapunov functionals [14],
- Minimizing normalized error measures over scales in order to compute more accurate localization estimates for coarser-scale corner features [5, Sect. 7.2] or for coarse-to-fine matching of highly noisy image data [15],
- Determining minimum reliable scales for feature detection according to an a priori determined noise suppression model [16],
- Determining optimal stopping times in nonlinear diffusion-based image restoration methods using similarity measurements relative to the original data [17],
- Performing image segmentation from the scales at which a supervised classifier delivers class labels with the highest posterior [18, 19],
- Considering subspaces generated by local image descriptors computed over multiple scales to improve the performance of stereo matching [20, 21].

Relations Between the Different Approaches to Scale Selection

The different approaches to scale selection may have quite different properties, depending on the types of data they are applied to. For noise-free data, an adaptive noise suppression scheme optimized for suppressing high-frequency noise can be expected to not smooth the data at all,

thus implying the selection of a zero scale, whereas scale selection based on local extrema over scales will always select a scale level reflecting a characteristic length in the image data.

Provided that the characteristic lengths of the relevant image features are greater than the typical characteristic lengths in the noise, scale selection based on scale-normalized derivatives will therefore lead to scale-invariant image features. Smoothing approaches that are optimized for suppressing superimposed high-frequency noise will on the other hand lead to an amount of smoothing that is primarily determined by the noise level and therefore not necessarily corresponding to scale-invariant image descriptors. In this respect, these two types of scale determination approaches can lead to fundamentally different results.

If the task is to detect fine-scale details with amplitude and/or characteristic scales comparable to the noise, it does, however, not seem unlikely that the two types of approaches could possibly benefit from each other.

Application

Interest Point Detectors with Built-In Scale Selection

Below, four different interest point detectors with automatic scale selection will be presented. A more general set of scale-invariant interest point detectors defined according to a similar methodology can be found in [9] with an in-depth theoretical analysis of their scale selection properties in [22].

Blob Detection

Based on the notion of scale-space extrema, straightforward methods for blob detection can be obtained by detecting scale-space extrema of either (i) the scale-normalized Laplacian $\nabla_{\text{norm}}^2 L = t(L_{xx} + L_{yy})$ or (ii) the scale-normalized determinant of the Hessian $\det \mathcal{H}_{\text{norm}} L = t^2(L_{xx}L_{yy} - L_{xy}^2)$ [3, 5]. Specifically, using the *Laplacian* operator one can detect:

- Bright blobs from negative scale-space minima of $\nabla_{\text{norm}}^2 L$
- Dark blobs from positive scale-space maxima of $\nabla_{\text{norm}}^2 L$

Using *the determinant of the Hessian*, one can on the other hand detect:

- Bright blobs from positive scale-space maxima of $\det \mathcal{H}_{\text{norm}} L$ that satisfy $\nabla^2 L < 0$
- Dark blobs from positive scale-space maxima of $\det \mathcal{H}_{\text{norm}} L$ that satisfy $\nabla^2 L > 0$
- Saddle-like image features from negative scale-space minima of $\det \mathcal{H}_{\text{norm}} L$

These two blob detection approaches do both satisfy the basic scale selection property that if the scale-adaptive blob detector is applied to a two-dimensional Gaussian blob with scale value t_0 , i.e., $f(x, y) = g(x, y; t_0)$, then the selected scale \hat{t} will be equal to the scale of the blob in the input data, i.e., $\hat{t} = t_0$.

In comparison, the image features obtained from the determinant of the Hessian blob detector do often have better repeatability properties under affine image deformations than Laplacian image features [5, 9, 22].

Figure 5 shows the result of applying these interest point detectors to a gray-level image. Please note how the variations in the detection scales of the blob responses reflect the perspective scaling effects in the scene.

Corner Detection

A straightforward method for scale-invariant corner detection can be obtained by detecting positive scale-space maxima and negative scale-space minima of the scale-normalized *rescaled level curve curvature* measure

$$\begin{aligned} \tilde{\kappa}(L) &= t^{2\gamma} |\nabla L|^2 \kappa(L) \\ &= t^{2\gamma} \left(L_x^2 L_{yy} + L_y^2 L_{xx} - 2L_x L_y L_{xy} \right), \end{aligned} \quad (19)$$

where $\kappa(L)$ denotes the curvature of the level curves of the Gaussian smoothed image at any

Scale Selection, Fig. 5

Scale-invariant interest points obtained from the 1,000 strongest scale-space extrema of the Laplacian $\nabla^2_{\text{norm}} L$ and the determinant of the Hessian $\det \mathcal{H}_{\text{norm}} L$ with the size of each circle reflecting the detection scale of the corresponding feature. Red circles represent local maxima of the operator response, while blue circles indicate local minima

scale and $\gamma = 7/8$ turns out to be a good choice [5, Sect. 6] [22]; see Fig. 6a for an illustration.

The *Harris-Laplace* operator [23] is structurally different in the respect that it uses different entities for spatial selection (the Harris measure) and scale selection ($\nabla^2_{\text{norm}} L$); see Fig. 6b.

Edge Detection

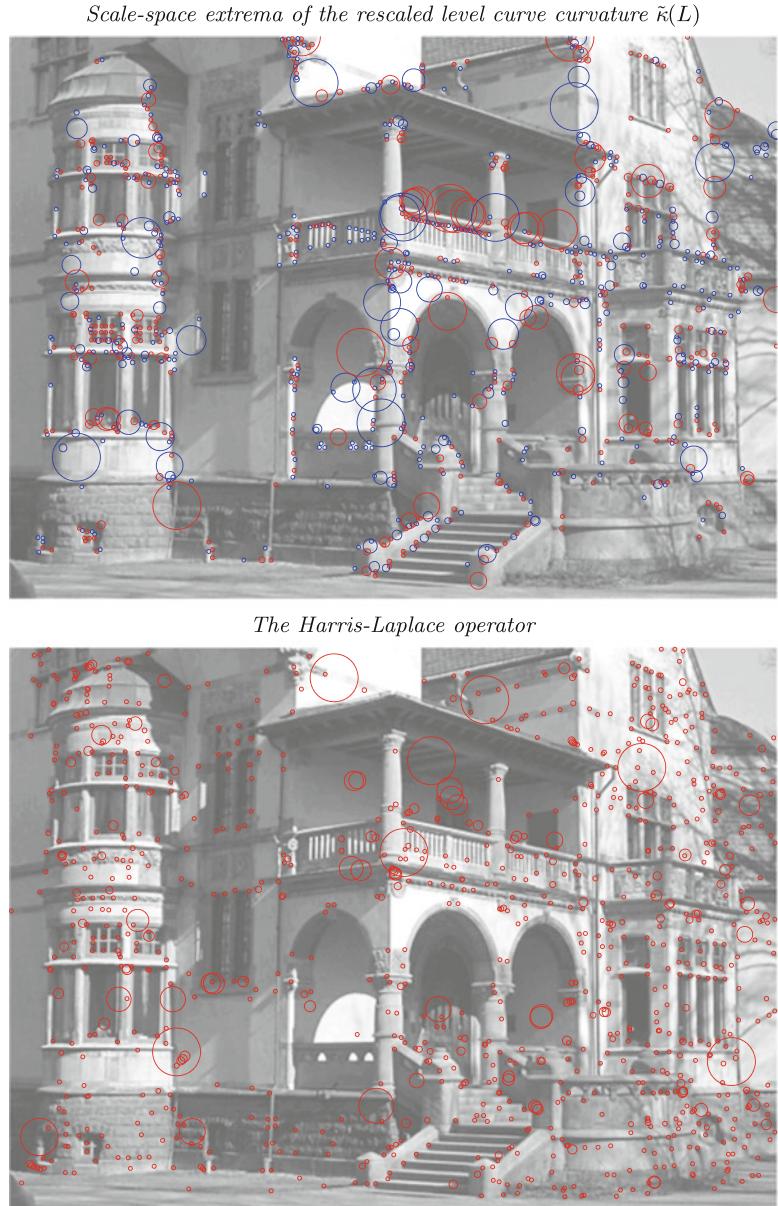

With regard to edge detection, the evolution properties over scales of the *scale-normalized gradient magnitude*

$$|\nabla L|_{\text{norm}} = t^{\gamma/2} \sqrt{L_x^2 + L_y^2} \quad (20)$$

can be shown to reveal local characteristics of the type of edge [6, Sect. 4]. Specifically, by choosing $\gamma = 1/2$, a local maximum over scales will be assumed at a scale corresponding to the diffuseness of a one-dimensional diffuse step edge

Scale Selection, Fig. 6

Scale-invariant interest points obtained from the 1,000 strongest scale-space extrema of the rescaled level curve curvature $\tilde{\kappa}(L)$ and the Harris-Laplace operator. The size of each circle reflects the detection scale of the corresponding feature. For the rescaled level curve curvature operator $\tilde{\kappa}(L)$, the color of the circles show the sign of the curvature; red circles represent a local maxima of the operator response, while blue circles indicate local minima

$$\Phi(x; t_0) = \int_{u=-\infty}^x g(u; t_0) du \quad (21)$$

and may then provide cues to, e.g., focus blur, shadow edges, or diffuse edges.

Ridge and Valley Detection

Let e_p and e_q denote the eigendirections of the Hessian matrix $\mathcal{H}L$ such that the mixed second-order derivative in this coordinate frame is zero

$L_{pq} = 0$ and denote the eigenvalues of the Hessian matrix by L_{pp} and L_{qq} . These eigenvalues are also referred to as *principal curvatures*, and these directions are assumed to be ordered such that $L_{pp} < L_{qq}$.

Then, a differential geometric definition of the *ridges* in the image at any scale can be expressed as the set of points that satisfy [6, Sect. 5.2]

$$L_p = 0, \quad L_{pp} \leq 0, \quad |L_{pp}| \geq |L_{qq}|. \quad (22)$$

Similarly, the *valleys* at any scale can be defined from [4]

$$L_q = 0, \quad L_{qq} \geq 0, \quad |L_{qq}| \geq |L_{pp}|. \quad (23)$$

With $R_{\gamma-\text{norm}}$ denoting a scale-normalized measure of *ridge strength* (or valley strength) defined from the principal curvatures L_{pp} and L_{qq} , one can also express ridge and valley detection methods with automatic scale selection by detecting *scale-space ridges* using the definition

$$\begin{aligned} L_p &= 0, \quad L_{pp} \leq 0, \quad \partial_t(R_{\gamma-\text{norm}}) = 0, \\ \partial_{tt}(R_{\gamma-\text{norm}}) &\leq 0 \end{aligned} \quad (24)$$

and *scale-space valleys* according to

$$\begin{aligned} L_q &= 0, \quad L_{qq} \geq 0, \quad \partial_t(R_{\gamma-\text{norm}}) = 0, \\ \partial_{tt}(R_{\gamma-\text{norm}}) &\leq 0. \end{aligned} \quad (25)$$

Specifically, it can be shown that for natural measures of ridge or valley strength, the choice $\gamma = 3/4$ implies that the selected scale will reflect the width of a Gaussian ridge (or valley) [6]. For generalizations to 3-D images, see [24–26].

Feature Tracking

By adapting the scales for feature detection by a local scale selection mechanism, the resulting image features will be robust to scale changes, which means that they can be matched over substantial size variations [27]. Indeed, the variations over time in the characteristic scale estimates obtained during feature tracking can, if appropriately implemented, be robust enough for computing estimates of *time to collision* [11,34].

Image-Based Matching and Recognition

The SIFT descriptor [10] comprises a bottom-up keypoint detection stage with scale-space extrema detection in a differences-of-Gaussians (DoG) pyramid. The scale-invariant properties of the SIFT descriptor can be explained as follows.

From the way that the DoG operator is implemented in the pyramid in [10], it follows that

the normalization will be similar to the scale-normalized Laplacian. Using the fact that the scale-space representation satisfies the diffusion equation, it follows that the Laplacian operator can be approximated from the difference between two levels in the scale-space representation:

$$\begin{aligned} \frac{1}{2}\nabla^2 L(x, y; t) &= \partial_t L(x, y; t) \\ &\approx \frac{L(x, y; t + \Delta t) - L(x, y; t)}{\Delta t} \\ &= \frac{DOG(x, y; t, \Delta t)}{\Delta t}, \end{aligned} \quad (26)$$

i.e., from the difference of two Gaussian smoothed images.

With the scale levels distributed such that the ratio between successive scale levels is k when measured in terms of $\sigma = \sqrt{t}$, (i.e., $\sigma_{i+1} = k \sigma_i$ and $t_{i+1} = k^2 t_i$ which implies that $\Delta t_i = (k^2 - 1) t_i$), it follows that [9]

$$\begin{aligned} DOG(x, y; t) &= L(x, y; k^2 t) - L(x, y; t) \\ &\approx (k^2 - 1) t (\partial_t L(x, y; t)) \\ &= (k^2 - 1) t \frac{1}{2} \nabla^2 L(x, y; t) \\ &= \frac{(k^2 - 1)}{2} t \nabla^2 L(x, y; t) \\ &= \frac{(k^2 - 1)}{2} \nabla_{\text{norm}}^2 L(x, y; t). \end{aligned} \quad (27)$$

Hence, with self-similar sampling of the scale levels, the pyramid-implemented DoG interest point operator can be interpreted as an approximation of the scale-adapted Laplacian operator in Eq. (11).

In the SURF descriptor [28], local feature detection is performed by detecting local extrema over space and scale of an approximation of the determinant of the Hessian operator in terms of Haar wavelets, with the filters normalized to constant l_1 - or Frobenius norm over scales. According to Eq. (9), the γ -normalized derivative concept corresponds to normalization of the Gaussian derivative operators to unit L_p -norm

over scales. Furthermore, it was shown in [11] that normalizing the filter responses to constant l_p -norm over scales gives better accuracy in a practical implementation than normalization of the discrete filters by multiplication with the scale parameter raised to a power of $m\gamma/2$, where m denotes the order of differentiation. Hence, the initial feature detection step in the SURF descriptor can be seen as an approximation of the scale-normalized determinant of the Hessian operator in Eq. (12).

The scale-invariant property of the actual image descriptors in the SIFT and SURF descriptors does in turn follow from the scale-invariant properties of the initial feature detection step, in line with the general framework for computing scale-invariant image descriptors from scale estimates obtained from local extrema over scales of scale-normalized differential expressions, as described in the “[Theory](#)” section above.

In these ways, the notion of scale selection constitutes a general mechanism for computing scale-invariant image descriptors for image-based matching and recognition.

Extensions of this (spatial) scale selection methodology to temporal and spatio-temporal scale selection are given in [29–32]. Extensions of these (sparse) scale selection methodologies to dense scale selection, where local estimates of spatial and/or temporal scales are obtained at every point and/or temporal moment in space, time, or space-time, are presented in [33].

Definition

Scene classification is the process of identifying the semantic category of the place (e.g., a living room, a coast, a rainforest) where a given photograph is taken.

Background

Scene classification has been one of the hallmark tasks of computer vision, allowing the definition of context for object recognition. This task is challenging due to the large variation in the spatial structure and the occurrence of different objects across scene categories. The key step toward achieving human-level scene recognition capability is designing the categorical representations that are able to summarize the properties of various scene categories as well as distinguish among the image samples from different scene categories. Some image samples of Places dataset [1, 2] are shown in Fig. 1. We can see there is a large variation in their spatial properties such as

Scene Classification, Fig. 1 Scene image examples from the Places dataset [2]

openness and naturalness, as well as the different objects occurred.

Theory

The early cognition studies have demonstrated that human perception systems integrate enough information about the meaning of a scene in less than 200 ms [3]. This suggested the recognition of real-world scenes may be initiated from the encoding of the global spatial configuration, ignoring the most detailed information about the objects in a scene [4]. Inspired by the human scene recognition studies, the field of scene classification in computer vision follows a succession of designing scene representations by extracting the holistic properties, rather than focusing on the underlying objects.

The commonly used models for scene classification consider the scene image as whole for feature extraction and bypass the segmentation or detection of the objects. For example, one of the earliest scene models is the gist of the scene [5]. It defines various global scene properties such as naturalness, openness, and depth to describe the given photos. Such semantic properties create a low-dimensional feature for classification. Meanwhile, the bag-of-words models, which are commonly used in text clas-

sification, have been extended by modeling the image regions as the visual words for classifying scenes [6, 7]. Furthermore, to better capture the geometric correspondence in scene representation, a scene model improves the orderless bag-of-features image representation with spatial pyramid match kernels [8]. Most of these traditional scene representations only work for image datasets with a few thousand samples.

Recently with the rise of million-sized scene dataset Places [1, 2], the data-driven deep learning models such as deep convolutional neural networks (CNNs) [9, 10] have greatly improved the state of the art for the large-scale scene classification. After training on 1.8 million images from 365 scene categories from the Places, the Places365-ResNet is able to achieve more than 85% top-5 accuracy on its validation set, outperforming the traditional scene classification models with more than 10% margin. The deep features from the CNN trained on Places also show a great generalization ability to improve other scene-centric tasks such as scene attribute prediction [2] and scene parsing [11].

The CNN models trained on large-scale image datasets benefit from the end-to-end training for learning the representation and classifier jointly. However, given the millions of model parameters and the outstanding performance on scene classification for the Places CNNs, it

was unclear what has been learned inside the deep representation for classifying scenes. The study of comparing the deep representations trained on ImageNet [9] and Places [1] shows that object detection emerges inside a CNN trained to recognize scenes, even more than when trained with ImageNet [12]. The result was surprising because many internal convolutional filters emerge as object detectors, in a supervised setting tuned to scene classification rather than object classification. It reveals that the CNN can support the recognition at several levels of abstraction (e.g., edges, texture, objects, and scenes).

In the real world, objects never occur in isolation. Thus recognizing scenes provides the contextual information to be exploited by the object recognition and detection [13, 14]. A better integration of scene classification and object recognition will lead to a new generation of computer vision systems. Furthermore, there are other scene understanding tasks closely relevant to scene classification, such as scene layout estimation [15], scene attribute prediction [16], scene parsing [11], as well as the recent topic on embodied AI where an agent or a robot actively explores the real environment or inside a realistic virtual environment to understand the surroundings [17]. Automated scene classification systems have the potential to make a significant impact to those relevant topics.

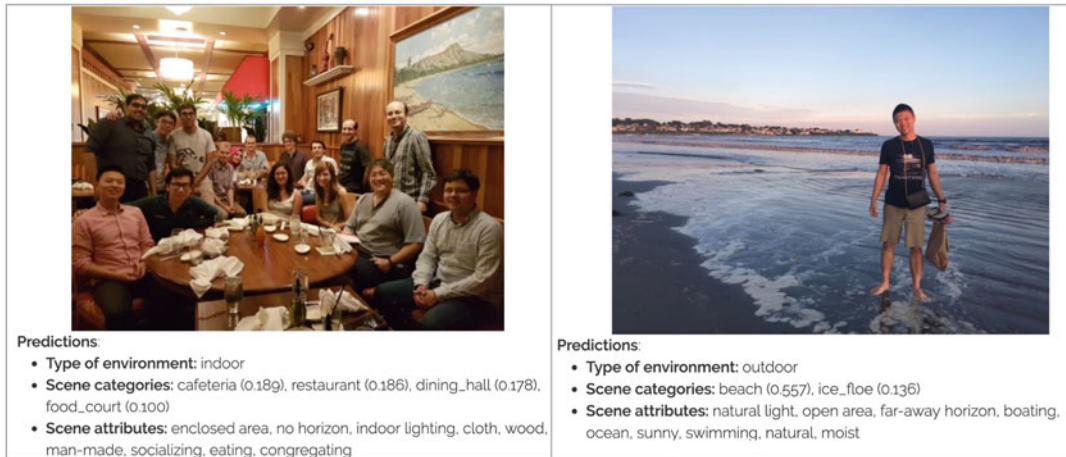

Open Problems

Because of the recent progress in deep neural network models and the emergence of large-scale image dataset such as Places [2], the accuracy of scene classification has been greatly improved close to the human-level recognition. However, the performance is measured on the predefined scene categories of a dataset. Given the wide variation of scenes we encounter in the real world, designing scene recognition systems that are able to generalize to other unseen scenes and environments in an open-ended setting is still very challenging. Meanwhile, though deep neural net-

works have greatly advanced the state of the art for visual recognition, there still lacks enough understanding on what has been learned in deep models. It leads to the broader and more general interest toward developing interpretable and human understandable machine learning models. Finally it remains an open problem on making the scene recognition and object recognition mutually benefit each other.

Experimental Results

The progress of scene recognition is closely tied with the development of scene recognition benchmarks. The first benchmark for scene recognition was the Scene15 database [8], extended from the 8 scene dataset in [5]. This dataset contains only 15 scene categories with a few hundred images per class, and current classifiers are saturated, reaching near human performance with more than 95% accuracy. The MIT Indoor67 database [18] with 67 indoor categories and the SUN (Scene UNderstanding, with 397 categories and 130,519 images) database [19] provided a larger coverage of place categories, but still ran short in data samples for training deep neural networks. Recent Places dataset [2] with 10 million images from 434 scene categories has facilitated the development of deep neural networks for scene classification. The deep neural network models trained on Places already achieve close to human-level scene recognition accuracy. Besides, the scene classification web demo [20] powered by the pretrained Places scene recognition models allows users to take a photo and upload it for scene recognition. Noticeably from the 9,925 anonymous feedback collected from the web demo, the top-5 recognition accuracy of the recognition web demo in the wild reaches about 72%, which is impressive given that people uploaded all kinds of photos from real life and not necessarily scenes-like photos. Screenshots of the scene classification demo are shown in Fig. 2. Improving the scene classification in such an open-ended setting is one of the future works.

Scene Classification, Fig. 2 Scene classification demo by Places model [20]. Both the scene categories and the scene attributes are accurately predicted for the two uploaded photos

Definition

Semantic image segmentation describes the task of partitioning an image into regions that delineate meaningful objects and labeling those regions with an object category label. Some example semantic segmentations are given in Fig. 1. It can be seen as a generalization of figure-ground segmentation [1] where one segments a particular object, say a horse, from the background.

- ▶ Interactive Segmentation

Background

Images typically contain multiple objects, including *things* such as people, cars, and cows and *stuff* such as grass, sky, and water. The imaging process composites the appearances of these objects, leaving (at most) an intensity edge between one object and the next. Semantic image segmentation aims to recover the image regions corresponding directly to objects, as well as labeling those regions with the relevant object category.

The task is usually approached as supervised or semi-supervised machine learning, using a set of training images that are manually segmented and labeled. The learning algorithm then discovers relevant image features that help discriminate regions belonging to different categories in unseen test images. Other cues such as layout and context further help resolve ambiguities;

Semantic Image Segmentation: Traditional Approach, Fig. 1 Top row: three input images. Bottom row: the corresponding semantic segmentations where colors represent object categories

for example, a pixel that neighbors a car pixel is likely to have the same label, and a region containing a cow is likely to be above a region containing grass.

Semantic image segmentation has been of interest since at least 1989 [2], but only fairly recently [3, 4] have processor speeds started to allow the rich models for high accuracy across many object categories.

Theory

Problem Formulations In essence, the semantic segmentation task can be treated as a pixel-labeling problem. The different methods proposed for solving this problem can be categorized based on the relationships they encode between different pixels (see Fig. 2). Some methods for semantic segmentation solve the pixel-labeling problem by classifying each pixel independently [5, 6]. Another class of methods works by grouping pixels into segments (or super-pixels) and assigning a single label to each group [7]. Superpixels are computed from the image in a bottom-up fashion [8–10] and can aid computational efficiency but may lead to a final incorrect labeling.

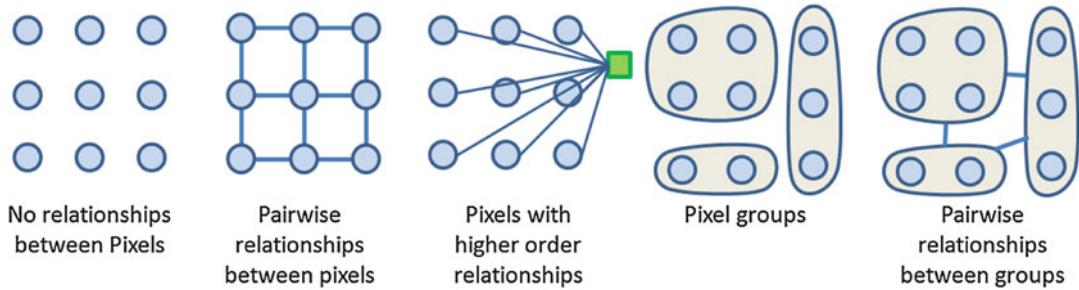

Many semantic segmentation algorithms are based on the pairwise Markov Random Field (MRF) [11] or Conditional Random Field (CRF) models [12, 13] which enforce

relationships between pairs of neighboring pixels [5]. They encourage adjacent pixels that are similar in appearance to take the same semantic label, and lead to segmentation results with smooth boundaries. A related notion of layout consistency was explored in [14].

Some methods go beyond pairwise interactions between pixels and enforce higher-order relationships between groups of (or even all) pixels in the image. For instance, they encourage groups of pixels to take the same semantic label [15], or make sure that some semantic label is taken by at least one pixel in the image [16]. These models also allow the use of top-down object detection results to prime the segmentation [6, 17]. In related work, data-driven Markov Chain Monte Carlo (DDMCMC) was used to parse images with a rich generative model [18]. A nonparametric approach to semantic segmentation was proposed in [19], where labels were transferred between nearest-neighbor images matched using SIFT flow features.

Features Used for Pixel/Super-Pixel Classification

There are many informative image cues that can be used for semantic segmentation, including intensity, color, texture, context, motion, and 3D structure. Dense interest point descriptors can be used, for example, [20–22], or light-weight

Semantic Image Segmentation: Traditional Approach, Fig. 2 Different approaches for semantic segmentation

region integrals of textons [5,6], or even features based on histogram of gradients [16]. Motion-derived 3D structure was used in [23] to segment images from a video sequence. Range images or depth cameras have been used for semantic segmentation in [24].

Incorporating Context

Context can be incorporated in several ways: (i) *appearance* context [5] captures the notion that a sheep might typically stand on something green, (ii) *semantic* context [6, 25–27] captures the notion that a sheep might typically stand on grass, and (iii) *auto-context* [6, 28] describes a recursive classification procedure whereby the classification uses contextual features from a previous stage of classification, capturing the notion that this pixel might belong to sheep because a nearby pixel was classified as sheep at the previous stage.

Datasets

To a large extent, the quality of the semantic segmentation algorithm is related to the quality of the training dataset. Most techniques require fully pixel-wise labeled images which are expensive to obtain. Other approaches reduce this requirement in various ways, including multiple over-segmentations [29], co-segmenting several images at once [30], incorporating image or region labels [6, 17, 31], and exploiting probabilistic aspect models [32].

Early datasets for semantic segmentation include Corel and Sowerby [33] and the MSRC dataset [5]. Recently, more challenging dataset have been proposed that dramatically increase

the variability in the images and thus bring us much closer to solving semantic segmentation as a real-world problem. LabelMe [34] used a web interface to capture a large number of image labels. The Pascal VOC Segmentation Challenge [35] runs yearly and deliberately tries to remove contextual clues in the data to foster the best object detection algorithms. The SUN 09 dataset [36] goes to the other extreme of labeling many objects per image to include as much context as possible. LabelMe, Pascal VOC, and SUN 09 for the most part only provide labels for things and not stuff, often leaving the background a single heterogenous category.

Application

Accurately segmenting and recognizing what those objects are opens up many potential applications. Not only does it tell us what things are in an image but also where they are and how they look. This information can be used in, for example, image search, image editing, augmented reality, robot navigation, and medical image analysis.

Semidefinite Programming

Chunhua Shen and Anton van den Hengel
School of Computer Science, The University of Adelaide, Adelaide, SA, Australia

Synonyms

Convex minimization; Semidefinite optimization

Definition

Semidefinite programming is a subtopic of convex optimization. Convex optimization refers to minimization of a convex function subject to a set of convex constraints. Semidefinite programming involves minimization of a linear objective function over the intersection of linear constraints and the cone of positive semidefinite matrices. Clearly, semidefinite programming is a special case of convex optimization.

Background

Many computer vision problems can be formulated as convex optimization problems. The main advantage of convex optimization is that if a local minimum exists, then it is also a global minimum. In other words, the convexity guarantees to attain the global optimum if it exists.

In a semidefinite programming problem, one minimizes a linear function subject to the constraint that an affine combination of symmetric matrices is positive semidefinite. Semidefinite programming unifies a few standard problems such as linear programming, quadratic programming, and second-order cone programming. Semidefinite programming has many applications in computer vision.

Theory

Mathematically, semidefinite programming solves the following problem:

$$\begin{aligned} \min_X & \langle C, X \rangle, \text{ s.t. } \langle A_k, X \rangle \\ & = b_k, (k = 1, \dots, m), X \succcurlyeq 0. \end{aligned} \quad (1)$$

Here, the optimization variable $X \in \mathbb{R}^{D \times D}$ is a symmetric and positive semidefinite matrix. The operator $\langle A, B \rangle = \sum_{ij} A_{ij} B_{ij}$ calculates the inner product of two matrices (or vectors). The last constraint $X \succcurlyeq 0$ means X is positive semidefinite. Such a constraint is nonlinear and nonsmooth

but convex. The following statements about a semidefinite matrix are equivalent: (1) $X \succcurlyeq 0$; (2) All eigenvalues of X are nonnegative; and (3) $\forall \mathbf{u} \in r^D, \mathbf{u}^\top X \mathbf{u} \geq 0$.

We can easily write the dual problem of (Eq. 1) by finding the saddle point of its Lagrangian:

$$\max_{\mathbf{y}} \langle \mathbf{b}, \mathbf{y} \rangle, \text{s.t. } \sum_{i=1}^m y_k A_k \succcurlyeq C. \quad (2)$$

Here, $\mathbf{y} \in r^m$ is the variable to optimize. The notation $A \preccurlyeq B$ means $B - A \succcurlyeq 0$. Weak duality and strong duality hold for the primal problem (Eq. 1) and dual problem (Eq. 2) under mild conditions. In particular, strong duality means that optimal values of the primal and dual problems are the same. Strong duality follows from Slater's condition for constraint qualification [1], which is stated as follows. If (Eq. 1) and (Eq. 2) both are feasible and there is a strictly interior point for either (Eq. 1) or (Eq. 2), then optimal primal and dual solutions exist and the corresponding optimal values are the same.

Semidefinite programming can be viewed as an extension of linear programming where the element-wise inequalities between vectors become linear matrix inequalities (LMIs). An LMI takes the form of $\sum_{k=0}^m y_k A_k \geq 0$, with $\mathbf{y} = [y_0 \dots y_m]$ being a vector and matrices A_k being symmetric matrices. An LMI enforces a convex constraint on the vector \mathbf{y} . Indeed, the interior-point methods for linear programming can be generalized to semidefinite programming. In fact, as shown by Nesterov and Nemirovsky [2], in principle interior-point methods for linear programming can be generalized to all convex optimization problems. Significantly, interior-point methods enable semidefinite programs to be solved very efficiently. It is theoretically guaranteed that the effort needed to solve a semidefinite program to a prescribed accuracy grows no faster than a polynomial of the problem size. Off-the-shelf solvers include CSDP [3], SDPT3 [4], and SeDuMi [5]. One can also use optimization modeling languages such as CVX [6] and YALMIP [7] to greatly simplify the problem modeling process.

Although interior-point methods are polynomial-time algorithms, they do not scale well. If the number of constraints m is of order $O(D^2)$ with the semidefinite matrix being $D \times D$, at each iteration, the computational time is of order $O(D^6)$. This high computational complexity makes interior-point methods impractical for large-scale problems. Recently, first-order augmented Lagrangian approaches have been proposed for solving large problems. In particular, as shown in [8], the alternating direction method is applied to solve the dual augmented Lagrangian problem of the standard semidefinite problem. This method is much more scalable than the conventional interior-point methods.

Application

Semidefinite programming has attracted extensive research interests in computer vision and machine learning due to its many applications in these fields.

Max-cut approximation and image segmentation. It is well known that semidefinite programming can be used to approximately solve some difficult combinatorial optimization problems. It is a useful tool for approximating NP-hard problems. Such an example is the Max-cut problem, which can be described as follows. Given a graph $G = (V, E)$, output a partition of the vertices V so as to maximize the number of edges crossing from one side to the other. This problem can be expressed as an integer quadratic problem:

$$\max_{\mathbf{u}} \sum_{(i,j) \in E} \frac{1-u_i u_j}{2}, \text{s.t. } u_i \in \{-1, 1\}, \forall i = 1, \dots, n. \quad (3)$$

This problem is NP-hard due to the discrete constraints. To obtain a semidefinite relaxation, we lift each scalar variable u_i to a higher dimension $\mathbf{u}_i \in r^n$ and $\|\mathbf{u}\|_2 = 1$. We introduce another variable substitution $U_{ij} = \mathbf{u}_i^\top \mathbf{u}_j$ to bring (Eq. 3) into a semidefinite program:

$$\max_U \sum_{(i,j) \in E} \frac{1 - U_{ij}}{2}, \text{s.t. } U_{ii} = 1, \quad (4)$$

$$\forall i = 1, \dots, n; U \succcurlyeq 0.$$

The constraint $U \succcurlyeq 0$ is due to the fact $U_{ij} = \mathbf{u}_i^\top \mathbf{u}_j$. The optimal value of (Eq. 4) is an upper bound of the original problem (Eq. 3). It is easy to see that (Eq. 4) is a semidefinite problem. Hence, the global solution of (Eq. 4) is guaranteed. Approximate solutions to the original problem can be computed by rounding the vector solution of (Eq. 4). The solutions of the SDP formulation suggest to cut nodes i and j if $U_{ij} = \mathbf{u}_i^\top \mathbf{u}_j$ is close to -1 . The Goemans-Williamson randomized rounding technique is to choose a uniformly random hyperplane through the origin and use it to cut vectors into separate parts. See [9] for details. Similar ideas can be applied to solve combinatorial problems of minimizing quadratic functionals in binary decision variables subject to linear constraints, which has many applications in image segmentation, perceptual grouping, and image restoration. See, for example, [10].

Maximum variance unfolding. Another application is embedding high-dimensional data (such as image data) into an underlying low-dimensional space by maximizing the variance while maintaining the data's local neighborhood. Here, the input data are assumed to be sampled from a much lower dimensional manifold that is embedded inside of a higher dimensional vector space. The primary idea of maximum variance unfolding is to create a mapping that preserves local neighborhoods at every point of the underlying manifold.

Let \mathbf{u}_i ($i = 1, \dots, n$) be the original data points in the high-dimensional manifold and \mathbf{v}_i be the *unfolded* low-dimensional data points. For $(i, j) \in E$ are neighbors, the local isometry constraints are

$$\|\mathbf{v}_i - \mathbf{v}_j\|_2^2 = \|\mathbf{u}_i - \mathbf{u}_j\|_2^2 = d_{ij}, \forall (i, j) \in E. \quad (5)$$

If we constrain the embedded data to center at the origin, we have

$$\sum_i \mathbf{v}_i = \mathbf{0}. \quad (6)$$

The variance of the embedded data can be written as $\frac{1}{n} \sum_i \mathbf{v}_i^\top \mathbf{v}_i$. So the optimization problem becomes

$$\begin{aligned} \max_v \sum_i \mathbf{v}_i^\top \mathbf{v}_i, \text{s.t. } & \sum_i \mathbf{v}_i = \mathbf{0}, \|\mathbf{v}_i - \mathbf{v}_j\|_2^2 \\ & = d_{ij}, \forall (i, j) \in E. \end{aligned} \quad (7)$$

This problem is a non-convex quadratic program. To formulate it into a semidefinite problem, we introduce a new variable $V_{ij} = \mathbf{v}_i^\top \mathbf{v}_j$, the same as in the first example. We can then relax (Eq. 7) into

$$\begin{aligned} \max_V \langle V, \mathbf{I} \rangle, \text{s.t. } & \sum_{ij} V_{ij} = 0, V_{ii} + V_{jj} - 2V_{ij} \\ & = d_{ij}, \forall (i, j) \in E; V \succcurlyeq 0. \end{aligned} \quad (8)$$

Here, \mathbf{I} is an identity matrix. Problem (Eq. 8) is a relaxation of (Eq. 8). The optimal value of (Eq. 7) is an upper bound of the one of (Eq. 7) because the feasibility set of (Eq. 8) is a superset of (Eq. 7)'s feasibility set. The advantage of this relaxation is that now (Eq. 8) can be efficiently solved using off-the-shelf semidefinite programming solvers. The embedded points \mathbf{v} can be obtained via Cholesky decomposition of the matrix V . Weinberger and Saul [11] applied maximum variance unfolding to detect low-dimensional structure in high-dimensional data sets of images.

Definition

Sensor fusion refers to systems, techniques, theory, and tools that exploit the synergy in the information acquired from multiple sensors to enhance system performance.

Background

Conventional systems used single sensors for monitoring phenomenon of interest and make inferences regarding them. Due to significant advances in sensing, networking, and computing technologies, multiple sensors are increasingly being used. This provides improved system performance, resulting in a better understanding of the phenomenon being monitored. In addition, distributed sensing improves robustness and extends spatial and temporal coverage while resulting in shorter response time [1–3]. In order to optimally fuse information acquired from different distributed sensing architectures, advances in theory and algorithm design are required.

Theory

Data from multiple sensors can be combined at three possible levels. In data-level fusion, raw sensor data is combined. This requires that data acquired from different sensors be commensurate and the data needs to be transported to a fusion center for centralized processing. This approach has the potential of achieving the best possible performance at the expense of large communication requirements. For noncommensurate data, either feature-level fusion or decision-level fusion is employed. In feature-level fusion, features are extracted from the data which are then fused. In decision-level fusion, higher-level decisions such as detections and estimates are obtained based on data from individual sensors. These decisions are then fused at the fusion center. In feature-level fusion and decision-level fusion, data transmission requirements are lower, but the quality of fused result degrades due to data compression

involved in the feature extraction and decision-making processes. Several topologies for sensor fusion such as parallel, serial, tree, and network topologies can be used. Choice of topology is often application dependent, but parallel topology is used quite commonly.

Sensor fusion is employed to solve a number of generic problems that results in improved situational awareness for the phenomenon under observation. Object and event detection using multisensor data is carried out based on distributed detection theory and decision fusion [4–6]. For conditionally independent observations, a likelihood ratio-based quantizer is employed at the sensors, and the fusion rule is based on a weighted sum of incoming quantized data. For parameter estimation or tracking problems, quantized data are fused at the fusion center [7, 8]. For tracking, a number of distributed filtering and track fusion algorithms are employed [9, 10]. When tracking multiple objects, data association is a major challenge [11, 12]. When sensor data is image and video data, data-level image fusion techniques are employed. One popular approach is to transform image data into another domain, e.g., wavelet domain, perform fusion in the transformed domain, and then transform the fused data back to the image domain [13]. Sensor fusion approaches are often problem and sensing modality dependent. New approaches are constantly being devised, such as distributed inference based on probabilistic graphical models [14] or through consensus and gossip algorithms [15, 16]. More recently, there has been a lot of interest in the fusion of heterogeneous multimodal data and the use of deep learning methods for information fusion [17].

Application

There are many military and nonmilitary applications of sensor fusion. In military applications, sensor fusion is employed for the detection, location, tracking, and identification of military entities such as aircrafts, ships, submarines, ground units, emitters, and weapons. Different sensing modalities such as radar, sonar, electro-

optic imagers, infrared imagers, and electronic intelligence are employed. Nonmilitary applications are numerous and continue to increase. Wireless sensor networks [18, 19] and distributed camera networks [20, 21] are being deployed for many application domains. These include air traffic control, homeland security, medical diagnosis, smart homes and buildings, monitoring of critical infrastructures, robotics, vehicle health management, remote sensing, and environmental monitoring. Other more recent applications include wearable sensors for health monitoring [22], target tracking using swarms of unmanned aerial vehicles [23], and the Internet of Things (IoT) paradigm [24] for a variety of consumer products and services [25–27].

Open Problems

There are many theoretical and practical challenges to fully utilize the potential of distributed sensing and sensor fusion. These include scaling, fundamental limits on achievable performance, fusion of heterogeneous, multimodal sensors, treatment of dependent data, fusion of hard and soft data, sensing resource management, and security of information fusion systems.

Definition

Shape-from-(de)focus is a method that reconstructs 3D shape of the captured scene (object) using multiple differently focused images obtained by changing position of the lens with respect to the image sensor such as CCD and CMOS. This entry provides a summary of shape-from-(de)focus techniques including both classical model-based and recent learning-based approaches.

Background

Exploiting differently blurred versions of images captured with different focus settings allows not only to estimate 3D shape of the captured scene but also to restore the latent all-in-focus image [8,9]. Therefore, shape-from-(de)focus technique has been studied for several decades to retrieve 3D shape (i.e., depth map) from a single camera and to improve the image quality by removing the blur by defocus [1,3].

Shape-from-(de)focus is one of well-known inverse problems. To solve the highly ill-posed inverse problem, traditional approaches simultaneously estimate the shape of the scene and the all-in-focus image by optimizing energy functions based on physical modelling [3,4,6], and recent learning-based approaches predict the dense depth maps through deep neural networks without explicitly taking into account the all-in-focus image during inference [2,5,7].

Theory

Traditionally, shape-from-(de)focus problem has been dealt with by model-based energy-minimization techniques, but due to the recent development of learning-based approaches, methods using deep neural networks (DNNs) are being studied very actively and showing good performance.

Model-based Approach Under an assumption that a camera lens is thin, defocus blur of a 3D scene point is depending on the depth of the scene and the distance from the focus plane to the lens (i.e., focal distance), and a defocused image can be modeled at a pixel location (x, y) as:

$$\mathbf{B}(x, y) = (\mathbf{K}(\mathbf{D}(x, y), F)\mathbf{R})(x, y), \quad (1)$$

where \mathbf{B} denotes a given (partially) defocused image and \mathbf{R} is a radiance and the all-in-focus image without defocus blur. The focal distance is F , depth of the scene is \mathbf{D} , and a linear operator \mathbf{K} which is called the point spread function (PSF) is depending on the scene depth \mathbf{D} and the

camera parameter F . We assume that the camera parameter F is available from camera metadata (e.g., EXIF data). Note that, PSF \mathbf{K} is nonuniform and spatially varying since the depth map \mathbf{D} can vary over pixel locations.

The goal of shape-from-(de)focus is to estimate the scene depth \mathbf{D} based on the model in (1); however, it is very challenging and difficult to achieve since it requires to infer the radiance \mathbf{R} jointly. Therefore, additional regularization terms are necessary to solve the joint problem, and it yields the following energy minimization formula.

$$\arg \min_{\mathbf{D}, \mathbf{R}} \psi(\mathbf{D}, \mathbf{R}) + \lambda \cdot \|\mathbf{K}(\mathbf{D}, F)\mathbf{R} - \mathbf{B}\|_p, \quad (2)$$

where $\psi(\cdot)$ is a regularization function which enforces smoothness of the radiance and depth maps among neighboring pixel values. To be specific, sparse gradient models which can preserve edges while suppressing noise at homogeneous regions are favored to regularize the latent all-in-focus image, and smoothness models such as Potts model and Ising model are used to regularize the depth map. The second term is a data term which measures the data fidelity based on the blur constraint in (1), and p -norm is used in measuring the similarity between the observed image \mathbf{B} and blurred version of the all-in-focus image $\mathbf{K}(\mathbf{D}, F)\mathbf{R}$. User parameter λ controls the weight between the regularization and data terms.

In general, the objective function in (2) is not a convex function and thus difficult to minimize. In practice, to solve the problem, iterative and alternating optimization technique is widely employed. To do so, the original objective function is decomposed into several subproblems, and each subproblem is solved via conventional optimization tools such as iteratively reweighted least squares (IRLS) in turn. To be specific, for being fixed \mathbf{R} , the subproblem becomes depth estimation problem, and the scene depth \mathbf{D} is updated. In addition, for being fixed \mathbf{D} , the subproblem becomes a defocus deblurring problem and the radiance map \mathbf{R} is improved alternately. This alternating optimization is repeated several

times until convergence, and the scene depth and all-in-focus image are produced in the end.

Learning-based Approach Classical shape-form-(de)focus algorithms require complex joint optimization technique based on the physical modeling including prior and likelihood models. However, recent learning-based approaches which adopt deep neural networks can infer the scene depth without estimation of the all-in-focus image \mathbf{R} and show promising results with the aid of a large number of training datasets and very deep neural networks (DNNs). To train the DNNs which predict depth map from a stack of differently focused images, a great number of paired images including focal stacks as network inputs and corresponding depth maps as training targets are required. Note that focal stacks can be easily generated by light-field images which enable to change the depth of focus and ground-truth depth maps can be collected by RGB-D camera which is calibrated to the light-field (or plenoptic) camera.

Let $\{\mathbf{B}\}$ be a stack of multiple differently focused image and an input of the network. Then, the network parameter θ can be trained through minimization of a loss function as follows:

$$\arg \min_{\theta} \frac{1}{N} \sum_{i=1}^N \|\mathbf{D}_i - \mathbf{f}_{\theta}(\{\mathbf{B}\}_i)\|_2^2, \quad (3)$$

where the function f denotes the deep neural network and i represents the index of a training sample, and the loss function is typically defined with L_2 -norm. To solve this regression problem in (3) with large datasets, conventional optimizers such as SGD and ADAM can be used. The learned parameter θ can yield the desired outputs near real-time during the test-period unlike classical approaches which require test-time optimization.

Applications

A typical application of the shape-from-(de)-focus algorithm is refocusing that generates photos focused to different depths and provides

aesthetically better photographs. To obtain a refocused image, partially blurring the all-in-focus image \mathbf{R} according to the depth map \mathbf{D} is carried out. Note that, the inputs \mathbf{R} and \mathbf{D} for refocusing task are achievable by the shape-from-(de)focus technique. Similarly, the outputs produced by shape-from-(de)focus technique can be used to create high-quality effects such as tilt-shift and dolly zoom.

Open Problems

In the classical model-based approaches, conventional alternating and iterative optimization algorithms do not give a guarantee to find a globally optimal solution, and the solutions are sensitive to initialization of the latent depth maps and all-in-focus images. Moreover, in the learning-based approaches, domain misalignment (e.g., nonidentical distributions of training datasets and real input data) can cause severe artifacts, but acquiring a large number of realistic training datasets is a very time-consuming and expensive open problem.

Shape from Interreflections

Yasuyuki Matsushita

Professor, Graduate School of Information Science and Technology, Osaka University, Suita, Osaka, Japan

Related Concepts

► Radiance

Definition

Shape from Interreflections is a method for recovering shape and reflectance in the presence of interreflections from a set of intensity observations of a surface under different illumination conditions.

Background

Shape from intensity methods aim at recovering shape and reflectance from intensity observations, for example, shape from shading and photometric stereo. Many of these methods assume a simple image formation model where interreflections, or mutual illuminations, are nonexistent. In the early 1990s, the effect of interreflections to intensity observations has been studied by Nayar, Ikeuchi, and Kanade [1, 2] and also by Forsyth and Zisserman [3, 4], and it has been pointed out that shape from intensity methods are significantly affected by the effect of unmodeled

interreflections. To overcome the issue, a method of *shape from interreflections* has been developed [1, 2] by explicitly accounting for the effect of interreflections.

Theory

Let us consider a Lambertian surface illuminated by a distant point light source. The radiance $L(\mathbf{x})$ at the scene point \mathbf{x} is related to its irradiance $E(\mathbf{x})$ via reflectance (albedo) ρ as

$$L(\mathbf{x}) = \frac{\rho(\mathbf{x})}{\pi} E(\mathbf{x}). \quad (1)$$

When there are no interreflections, e.g., the case of a concave surface where no other surface points are visible from the scene point \mathbf{x} , the irradiance $E(\mathbf{x})$ is purely due to the light source. It results in $L(\mathbf{x}) = L_s(\mathbf{x})$, where $L_s(\mathbf{x})$ represents the \mathbf{x} 's outgoing radiance to the direct illumination from the light source. On the other hand, when there are interreflections, the radiance $L(\mathbf{x})$ is affected by radiance from other scene points that are visible from the surface point \mathbf{x} . Let \mathcal{X} be the set of all points that are visible from the scene point \mathbf{x} , then the total radiance $L(\mathbf{x})$ leaving \mathbf{x} becomes the sum of $L_s(\mathbf{x})$ and the radiance due to interreflections as

$$L(\mathbf{x}) = L_s(\mathbf{x}) + \frac{\rho(\mathbf{x})}{\pi} \int_{\mathcal{X}} K(\mathbf{x}, \mathbf{x}') L(\mathbf{x}') d\mathbf{x}', \quad (2)$$

in which $\mathbf{x}' \in \mathcal{X}$ is a surface point visible from \mathbf{x} , $K(\mathbf{x}, \mathbf{x}')$ is a function depends on the visibility of \mathbf{x}' from \mathbf{x} , surface orientations at \mathbf{x} and \mathbf{x}' , and their distance.

It has been shown by Nayar et al. [1] in their shape from interreflections paper that, by discretizing the expression of (2), a closed-form solution to the forward interreflection problem can be derived. Based on the result, they develop a method for recovering shape and reflectance in the presence of interreflections.

By assuming the surface consists of discrete facets, Eq. (2) can be written in a discrete form as

$$L_i = L_{si} + \frac{\rho_i}{\pi} \sum_{j \neq i} L_j K_{i,j}, \quad (3)$$

where i and j are facet indices and $K_{i,j} = K(\mathbf{x}_i, \mathbf{x}_j) d\mathbf{x}_j$. In a matrix form for m facets, it becomes

$$\mathbf{L} = \mathbf{L}_s + \mathbf{PKL}, \quad \text{or} \quad \mathbf{L} = (\mathbf{I} - \mathbf{PK})^{-1} \mathbf{L}_s, \quad (4)$$

in which $\mathbf{L} = [L_1, \dots, L_m]^\top \in \mathbb{R}^m$, $\mathbf{L}_s = [L_{s1}, \dots, L_{sm}]^\top \in \mathbb{R}^m$, \mathbf{P} is a diagonal $m \times m$ matrix defined as $\mathbf{P} = \frac{1}{\pi} \text{diag}(\rho_1, \dots, \rho_m)$, and \mathbf{K} is an $m \times m$ kernel matrix defined as

$$\mathbf{K} = \begin{bmatrix} 0 & K_{1,2} & \dots & 0 \\ K_{2,1} & 0 & \dots & 0 \\ \vdots & & \ddots & \vdots \\ 0 & \dots & 0 & K_{m-1,m} \\ 0 & \dots & K_{m,m-1} & 0 \end{bmatrix}.$$

Now let us define a *facet matrix* \mathbf{F} as $\mathbf{F} \stackrel{\text{def}}{=} [\frac{\rho_1}{\pi} \mathbf{n}_1, \dots, \frac{\rho_m}{\pi} \mathbf{n}_m]^\top$, where $\mathbf{n}_i \in S^2$, $S^2 = \{\mathbf{v} \in \mathbb{R}^3 : \|\mathbf{v}\| = 1\}$ is a unit surface normal vector and $\rho_i \in \mathbb{R}_+$ is the reflectance at point i . Using a unit (column) light source direction vector $\mathbf{s} \in S^2$, the following holds with a Lambertian assumption:

$$\mathbf{L}_s = \mathbf{Fs}. \quad (5)$$

Thus, Eq. (4) can be written as

$$\mathbf{L} = (\mathbf{I} - \mathbf{PK})^{-1} \mathbf{Fs}. \quad (6)$$

Let us define a *pseudo facet matrix* \mathbf{F}_p as $\mathbf{F}_p = (\mathbf{I} - \mathbf{PK})^{-1} \mathbf{F}$. The pseudo facet matrix \mathbf{F}_p contains the pseudosurface normal and pseudoreflectance, which are computed by a local shape from intensity method that do not account for interreflections. Given three radiance vectors \mathbf{L}_1 , \mathbf{L}_2 , and \mathbf{L}_3 observed under three different illumination directions \mathbf{s}_1 , \mathbf{s}_2 , and \mathbf{s}_3 , the pseudo facet matrix can be obtained by

$$\mathbf{F}_p = [\mathbf{L}_1 \ \mathbf{L}_2 \ \mathbf{L}_3] [\mathbf{s}_1 \ \mathbf{s}_2 \ \mathbf{s}_3]^{-1} \quad (7)$$

if the inverse $[\mathbf{s}_1 \ \mathbf{s}_2 \ \mathbf{s}_3]^{-1}$ exists.

The shape from interreflections method proposed by Nayar et al. [1] uses an iterative method to obtain the facet matrix \mathbf{F} starting from the pseudofacet matrix \mathbf{F}_p by the following procedure.

1. Initialization: $\mathbf{F}^0 = \mathbf{F}_p$
2. Compute $\mathbf{P}^k \leftarrow \mathbf{P}(\mathbf{F}^k)$ and $\mathbf{K}^k \leftarrow \mathbf{K}(\mathbf{F}^k)$
3. $\mathbf{F}^{k+1} = (\mathbf{I} - \mathbf{P}^k \mathbf{K}^k) \mathbf{F}_p$
4. If not converged, go to Step 2.

As the iteration progresses, more accurate estimates of shape and reflectance in the form of facet matrix \mathbf{F} are obtained. The readers are referred to [1] for the convergence property.

Applications

In contrast to shape from intensity methods that only consider the direct illumination component [5–7], shape from interreflections accounts for the existence of interreflections for accurately determining shape and reflectance. It has been successfully applied to a camera-based photocopier [8], with which 3D shape of an unfolded book surface can be recovered.

More recently, it has been shown that there exists a set of linear operators that cancel interreflections [9], which enables the extraction of the n -th bounce of scene radiance. Since the first bounce of the scene radiance only contains the effect of direct illumination component, by extracting it the effect of interreflections can be naturally neglected. It has also been shown in [10] that, with a high-frequency binary illumination pattern emitted from a projector light source, the direct and global (i.e., interreflections) illumination components of a scene can be separated. These approaches allow extraction of the direct component; thus, a simpler method that does not account for interreflections can be used.

Depth from Scattering

Definition

Light scatters in the presence of volumetric media such as fog, smoke, mist, dust, and murky water.

Volumetric scattering results in several daily life visual effects, such as the glow around the streetlights and car headlights on a foggy day and the murky appearance of underwater scenes. From a computer vision point of view, while on one hand, volumetric scattering degrades images by reducing contrast, it also provides important shape/depth cues, especially for outdoor scenes. This entry provides a summary of various techniques and algorithms for recovering shape/depth using scattering.

Background

Volumetric scattering in the atmosphere (atmospheric scattering) has been studied for over two centuries in the atmospheric optics literature. Some of the prominent sources of literature on the subject are books by Minnaert [1], Middleton [2], and McCartney [3]. In computer vision literature, Cozman and Krotkov [4] and Narasimhan, Schechner, and Nayar [5–12] were among the first to develop techniques for scene analysis under volumetric scattering. Excerpts from these papers are used in several locations in this entry. Most of the algorithms presented in these papers required capturing two or more images of the scene under different weather/imaging conditions. Note that while the models and techniques in this entry are discussed in the context of atmospheric scattering, they are valid in general for other volumetric scattering scenarios, such as underwater imaging [13, 14].

S

Theory

Mechanisms of Atmospheric Scattering: There are two main mechanisms for getting depth from atmospheric scattering: attenuation and airlight.

Attenuation: Light gets deflected and absorbed as it travels through a volumetric medium (e.g., haze, mist, murky water), resulting in exponential *attenuation* of the intensity. Consider a collimated beam of light traveling through a medium from point A to point B. Suppose the irradiance of the beam at point A

is $E_A(\lambda)$, where λ is the wavelength of light. The irradiance of the beam at point B after the attenuation is given as

$$E_B(\lambda) = E_A(\lambda) e^{-\int_A^B \sigma(x, \lambda) dx}, \quad (1)$$

where $\sigma(x, \lambda)$ is the attenuation coefficient of the medium for light of wavelength λ . $\sigma(x, \lambda)$ is directly proportional to the volume density $\rho(x)$ of the medium. For homogeneous media, $\sigma(x, \lambda)$ is constant with respect to the spatial location, that is, $\sigma(x, \lambda) = \sigma(\lambda)$. Thus, in the presence of homogeneous media, the attenuated intensity at point B is given as

$$E_B(\lambda) = E_A(\lambda) e^{-\sigma(\lambda)d}, \quad (2)$$

where d is the distance between points A and B.

So far in this entry, light attenuation only for a collimated light beam has been considered. For diverging beams from point light sources, there is an additional inverse-square falloff. Given a point light source at point A with a radiant intensity of $I_o(\lambda)$, the irradiance at point B is

$$E_B(\lambda) = g \frac{I_o(\lambda) e^{-\sigma(\lambda)d}}{d^2}, \quad (3)$$

where the constant g accounts for the optical parameters of the camera and conversion between radiant intensity and irradiance.

Airlight: A second mechanism causes the atmosphere to behave like a source of light. This phenomenon is called airlight [15], and it is caused by the scattering of environmental illumination by particles in the atmosphere towards the observer. The environmental illumination can have several sources, including, direct sunlight, diffuse skylight, and light reflected by the ground. Consider an observer at a distance d from a physical object. The total radiance due to airlight at the observer is given as (for a derivation, see [5])

$$L(d, \lambda) = L(\infty, \lambda) \left(1 - e^{-\sigma(\lambda)d}\right), \quad (4)$$

where $L(\infty, \lambda)$ is the radiance due to airlight for an object at infinity (e.g., horizon). While attenuation causes the scene radiance to decrease with path length, airlight increases with path length. It therefore causes the apparent brightness of a scene point to increase with depth.

Application

1. *Depth from Attenuation:* Consider the image of a scene at night. Suppose the scene has artificial light sources, for example, street lights, building windows, and car headlights. There is no airlight due to sunlight or skylight. In this setting, the dominant scattering mechanism is attenuation. The observed irradiance due to a light source of radiance intensity $I(\lambda)$ at a distance d is

$$E(d, \lambda) = g \frac{I(\lambda) e^{-\sigma(\lambda)d}}{d^2}, \quad (5)$$

where, as before, $\sigma(\lambda)$ is the attenuation coefficient of the medium and g is the parameter which accounts for the conversion between radiant intensity and irradiance. If the detector of the camera has spectral response $s(\lambda)$, the final image brightness value recorded is determined as

$$\begin{aligned} E'(d) &= \int s(\lambda) E(d, \lambda) d\lambda \\ &= \int g s(\lambda) \frac{I(\lambda) e^{-\sigma(\lambda)d}}{d^2} d\lambda. \end{aligned} \quad (6)$$

Since the spectral bandwidth of the camera is limited (visible light range when camera is black and white and even narrower spectral bands when the camera is color), it is safe to assume the attenuation coefficient $\sigma(\lambda)$ to be constant over this bandwidth. Then

$$E'(d) = g \frac{e^{-\sigma d}}{d^2} \int s(\lambda) I(\lambda) d\lambda = g \frac{e^{-\sigma d}}{d^2} I'. \quad (7)$$

If the light source is observed under two different weather conditions, for example, dense fog and mild fog (or one condition could be

clear weather with $\sigma = 0$), there are two different attenuation coefficients σ_1 and σ_2 . Taking the ratio of the two resulting image brightness values,

$$R = \frac{E'_1}{E'_2} = e^{-(\sigma_1 - \sigma_2)d}. \quad (8)$$

Using the natural log,

$$R' = \ln R = (\sigma_1 - \sigma_2)d. \quad (9)$$

This quantity is independent of the sensor gain and the radiant intensity of the source. By computing the above quantity (log of ratio) for two different light sources in the scene and taking their ratio, the relative depths of the two source locations can be computed:

$$\frac{R'_i}{R'_j} = \frac{d_i}{d_j}. \quad (10)$$

Hence, the relative depths of all sources (with unknown radiant intensities) in the scene can be computed from two images taken under unknown but different haze or fog conditions.

2. Depth from Airlight: Under dense fog and close-by objects or mild fog and distant objects, attenuation of object brightness is severe, and airlight is the main cause of image irradiance. Also, in the case of dense haze around noon, airlight dominates. In these scenarios, scaled scene depths can be computed from a single image [5, 9].

Let a scene point at depth d produce airlight radiance $L(d, \lambda)$. If the camera has a spectral response $s(\lambda)$, the final brightness value recorded for the scene point is

$$E'(d) = g \int s(\lambda) L(d, \lambda) d\lambda, \quad (11)$$

where, as before, g accounts for the constant of proportionality between scene radiance and image irradiance. Substituting the model of airlight from Eq. 4:

$$E'(d) = \int g s(\lambda) L(\infty, \lambda) \left(1 - e^{-\sigma(\lambda)d}\right) d\lambda. \quad (12)$$

By assuming that the scattering coefficient $\sigma(\lambda)$ is more or less constant over the spectral band of the camera,

$$E'(d) = E(\infty) \left(1 - e^{-\sigma d}\right). \quad (13)$$

This equation gives a relationship between the observed airlight intensity E' and the scaled scene depth σd . $E(\infty)$ is the image intensity corresponding to a scene point at infinity and can be measured from the image if the horizon is visible (this part can be identified as the brightest region of the image). Then, the scaled depth can be computed as

$$\sigma d = \ln \left(\frac{E(\infty)}{E(\infty) - E'(d)} \right). \quad (14)$$

3. Depth from Chromatic Decomposition: So far in the entry, attenuation and airlight have been considered separately. At night, there can be no airlight (since there is no environmental illumination) and hence, attenuation dominates. In contrast, under dense fog or haze during daylight, the radiance from a scene point is severely attenuated and hence airlight dominates. However, in most situations, the effects of both attenuation and airlight coexist.

Narasimhan and Nayar presented a technique [6, 9] to recover depths for these situations by considering the chromatic effects of atmospheric scattering. The key idea is that the spectral composition of the irradiance at a scene point is the weighted sum of two distributions, corresponding to the direct transmission after attenuation and airlight. The weights are a function of the weather conditions. Using this model, the authors showed that it is possible to recover depths by capturing and performing simple arithmetic operations on two images of the scene under different bad weather conditions. For details, the reader is referred to Refs. [6, 9].

4. *Depth from Dehazing*: There are several techniques which explicitly remove the effects of scattering from the images, for example, using polarization [8, 10] or image priors [16, 17, 18]. While the primary goal of these *dehazing* techniques is to improve visibility in the images, as a by-product, scene depths are also recovered by using the technique outlined in the section *Depth from Airlight* on the separated haze layer (airlight).

Open Problems

A long-standing open problem has been *single image dehazing*, that is, removing the effects of atmospheric scattering using *a single image*. This would enable image and scene recovery for dynamic scenes. Recently, there have been a few techniques which have addressed this problem [16, 17, 18]. In order to account for the under-constrained nature of the problem, these techniques use a variety of scene priors [16, 17, 18].

Definition

Shape from shading (Shape-from-Shading; SfS) is a method for determining the three-dimensional shape of a smooth and opaque surface in the form of surface normal from a single image taken under a known light direction. Unlike stereoscopy based on matching and triangulation, it exploits the observed shading

Shape from Shading, Fig. 1 Shape from shading recovers a 3D shape from a single shading image

(gradations of reflected light intensity) to determine the shape. While a human can naturally achieve this task, it is computationally nontrivial and remains as one of the central problems in computer vision (Fig. 1).

these advancements, shape from shading has been successfully applied to some real-world applications, such as endoscopy [5], recovery of shape with high-frequency details [6,7], and face recognition [8] to list a few.

Background

The problem of shape from shading was first introduced by Horn in 1970 in his Ph.D. thesis [1]. Since then, because of its mathematically rich problem structure and importance to computer vision, it has stimulated various sophisticated studies. Its major difficulty is due to the fact that the problem is inherently under-constrained, i.e., there are many solutions that exhibit the same appearance. In other words, there exists a set of shapes that yields precisely the same shading appearance under a fixed light direction.

The early approaches to this problem used simplifying assumptions, such as an orthographic projection of scene points to the image coordinates, uniform Lambertian surface, and a point light source at infinity.

More recently, for the purpose of making shape from shading applicable to real-world scenarios, there are threads of works that aim at relaxing the restrictive assumptions. They include the relaxations of known and uniform albedo assumption [2] using a coarse depth information, spatially uniform illumination assumption [3], and known illumination assumption [4] with a discriminative learning approach. With

Theory

Let us assume a uniform Lambertian surface illuminated by a distant point light source with a unit brightness. The measured brightness $E \in \mathbb{R}_+$ of a surface point can be written as

$$E = \rho \mathbf{l}^\top \mathbf{n}, \quad (1)$$

where $\rho \in \mathbb{R}_+$ is a reflectance (albedo) of the surface, $\mathbf{n} \in S^2$, $S^2 = \{\mathbf{v} \in \mathbb{R}^3 : \|\mathbf{v}\| = 1\}$ is a unit three-dimensional vector representing a surface normal, and $\mathbf{l} \in S^2$ is a unit light direction vector. Let us further assume an orthographic image projection and that the viewing direction is parallel to the z -axis; thus the surface can be written as a height map function $z(x, y)$. Let $p \triangleq \partial z / \partial x$ and $q \triangleq \partial z / \partial y$; then the surface normal \mathbf{n} can be written as

$$\mathbf{n} = \frac{1}{\sqrt{1 + p^2 + q^2}} [-p, -q, 1]^\top. \quad (2)$$

Therefore, Eq. (1) can be written using $\mathbf{l} = [l_x, l_y, l_z]^T$ as

$$E = \frac{\rho}{\sqrt{1 + p^2 + q^2}} [l_x, l_y, l_z] [-p, -q, 1]^T \quad (3)$$

To simplify the notation, we assume that the image coordinates are aligned with the world x - y coordinates. Thus the measured brightness $E(x, y)$ is the brightness of the pixel that corresponds to the radiance of the surface point $[x, y, z]$. Equation (3) shows that there are two unknowns (i.e., p and q) per pixel while only one equation is given per pixel, even if we know the light source direction \mathbf{l} and reflectance ρ . This shows the inherent ambiguity in the shape from shading problem.

Image-irradiance equation and reflectance map It has been shown that under a fixed distant light \mathbf{l} and surface reflectance properties ρ , the observed image brightness $E(x, y)$ directly relates to a particular surface gradient $[p, q]$. This association is expressed as the *image-irradiance equation* [9–11] using a *reflectance map* $R(p, q)$ as

$$R(p, q) = E(x, y). \quad (4)$$

The reflectance map is a convenient tool for representing a constraint over p and q given a brightness observation $E(x, y)$. For example, given a light direction \mathbf{l} expressed in p - q -coordinates as $\mathbf{l} = [l_x, l_y, l_z]^T = \frac{1}{\sqrt{1+p_l^2+q_l^2}} [-p_l, -q_l, 1]^T$ and by assuming that reflectance $\rho = 1$, Eq. (3) can be rewritten for the intensity observation $E(x, y)$ as

$$\begin{aligned} R(p, q) &= E(x, y) \\ &= \frac{1 + p_l p + q_l q}{\sqrt{1 + p^2 + q^2} \sqrt{1 + p_l^2 + q_l^2}}. \end{aligned} \quad (5)$$

The surface normal variables (p, q) form a curve in the p - q -space as illustrated in Fig. 2. As seen in the figure, for $E(x, y) < 1$, (p, q) forms an iso-brightness contour in the space, which indicates the ambiguity in determining p and q because any point on the curve can be a solution for

(p, q) . In another view, p and q are constrained by the curve represented by the reflectance map. Only for the case of $E(x, y) = 1$ it can be seen that p and q can be uniquely determined as $(p, q) = (p_l, q_l)$.

Integrability and smoothness constraint To constrain the surface normal variables p and q , by assuming that the surface $z(x, y)$ is of class C^2 , i.e., the second-order derivatives of $z(x, y)$ exist and are continuous, an *integrability constraint* has been introduced to the shape from shading problem by Brooks [12]:

$$\frac{\partial^2 z}{\partial x \partial y} = \frac{\partial^2 z}{\partial y \partial x} \iff \frac{\partial p}{\partial y} = \frac{\partial q}{\partial x}. \quad (6)$$

The integrability shows that the partial derivatives of z with respect to x and y are independent of the order of differentiations.

As another way to constrain the surface normal variables p and q , Ikeuchi and Horn [13] introduced a *smoothness constraint*, which says that surface orientations smoothly vary over the x - y space, i.e., surface normals at neighboring scene points should be similar. Specifically, they have used the following objective function for representing the smoothness constraint:

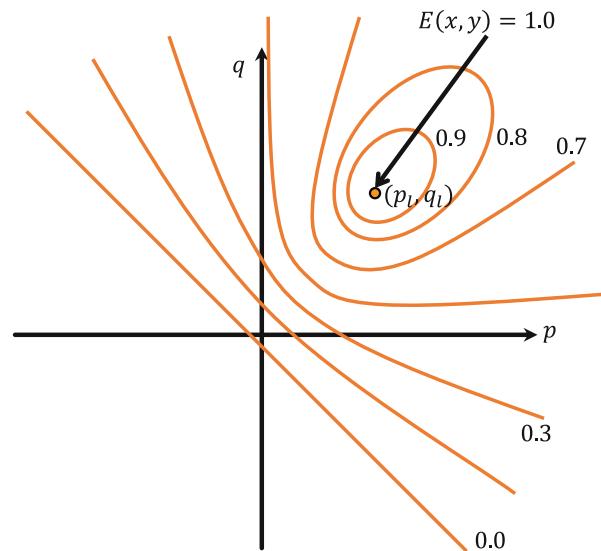

$$\frac{\partial f^2}{\partial x} + \frac{\partial f^2}{\partial y} + \frac{\partial g^2}{\partial x} + \frac{\partial g^2}{\partial y} \rightarrow \min., \quad (7)$$

where $f = 2p(\sqrt{1 + p^2 + q^2} - 1)/(p^2 + q^2)$ and $g = 2q(\sqrt{1 + p^2 + q^2} - 1)/(p^2 + q^2)$ are on the stereographic plane (see [13]). This parameterization has been used for avoiding p and q being infinity when the surface normal is perpendicular to the viewing direction.

Classical solution methods One of the first practical solution methods for shape from shading was based on regularized optimization by Ikeuchi and Horn [13]. Using a weight factor $\lambda \in \mathbb{R}_+$, they put together the image-irradiance equation and smoothness constraint in the energy minimization framework as:

Shape from Shading,

Fig. 2 Iso-brightness contours on a reflectance map $R(p, q)$

$$\int \int \left\{ \frac{\partial f^2}{\partial x} + \frac{\partial f^2}{\partial y} + \frac{\partial g^2}{\partial x} + \frac{\partial g^2}{\partial y} + \lambda (E(x, y) - R_s(f, g))^2 \right\} dx dy \rightarrow \min., \quad (8)$$

where R_s is a reflectance map defined on the stereographic coordinates. The regularization factor λ controls the degree of smoothness with respect to the error of the image-irradiance equation.

Horn and Brooks [14] introduced a variational approach, in which a functional F defined over the image-irradiance equation and the integrability constraint is minimized:

$$F(p, q, z) = \int \int \left\{ (R(p, q) - E(x, y))^2 + \mu(x, y) \left(\frac{\partial p}{\partial y} - \frac{\partial q}{\partial x} \right) \right\} dx dy, \quad (9)$$

where μ is a Lagrange multiplier enforcing the integrability constraint $\frac{\partial p}{\partial y} = \frac{\partial q}{\partial x}$. The minimization of F leads to the associated Euler-Lagrange equations, and it has been shown that the shape can be determined up to convex/concave and offset ambiguities.

An excellent survey of the early methods is found in [15]. A newer survey [16] provides a comprehensive summary of recent shape from shading methods.

Application

To alleviate the difficulty of determining a unique surface from a single shading observation, a photometric stereo approach [17] that uses multiple observations under different light directions has been developed. It has been shown that, for a Lambertian surface, a surface can be uniquely recovered from observations under three distinct (non-coplanar) light directions.

Shape from Shadows

Pascal Mamassian

Laboratoire Psychologie de la Perception,
Université Paris Descartes, Paris, France

Definition

Shape from shadows is the inference of the three-dimensional shape of objects from their shadows.

Background

David Waltz first introduced to computer vision the problem of shape from shadows while attempting to segment objects that had sharp edges in a three-dimensional scene under various lighting conditions [1]. The problem was then refined to arbitrary surfaces [2]. Nowadays, shape from shadows is a cue commonly used when one is interested in inferring the three-dimensional structure of a visual scene. A benefit relative to other cues such as stereopsis or motion parallax is that it is available in a single image. Shape from shadows differs from shape from shading because in the latter the useful information is the gradient of reflected light on a curved surface, whereas shape from shadows considers that the information coming from the area inside cast shadow is uniform (there are no variations inside the shadow that are related to the scene geometry [3]). However, it is important to remember that similar to most cues to three-dimensional shape, shape from shadows is an under-constrained problem in the sense that several critical scene parameters are often unknown, in particular the light source position and the nature of the surface on which the shadow is cast.

Shadow Identification

The first serious problem in shape from shadows is to identify a region of the image as a shadow. Dark regions on a surface can be caused by the absence of illumination or by a darker surface reflectance (albedo). The cues that allow humans to distinguish variations in light intensity from variations in material properties include luminance relations across shadow borders, figural relations, 3D-shape, depth, color, texture, and motion [4]. In computer vision, very promising results have been obtained if a shading model is assumed [5].

Another dichotomy exists between self-shadows (or attached shadows, i.e., shadows cast on the object itself) and cast shadows (shadows cast on a remote surface) [6]. This differentiation can be achieved to some extent by using some invariant color properties [7].

In addition, a variety of geometrical constraints of self-shadows on a smooth surface have been derived [8, 9]. The list of shadow properties that human and artificial visual systems could use is still open [10].

Shadow Correspondence Problem

In order for shadows to be useful, appropriate parts of an object should be matched to corresponding parts of shadows. The choice of the appropriate features to solve the correspondence problem is still a topic of intense research [11]. Potential candidates include points of high curvature along the object and shadow contours, some Fourier components for textured surfaces [12], or only the low spatial frequencies if one is merely interested in inferring where an object is relative to the background [11]. The shadow correspondence problem is more complex when the receiving surface is not flat. In particular, perceptual problems are thought to arise when the receiving surface is saddle shaped [13].

Using multiple images of the scene under various illuminations, especially if the light source positions are controlled in an active way, is highly beneficial [14, 15]. Multiple images can also be useful to detect the presence of concavities in an object [16].

Open Problems

Object segmentation and recognition are believed to be easier when shadows are absent from the image [17]. Is it true, and if so, what is the best method to eliminate shadows in a scene?

The dual problem of shape from shadows is to infer the illumination from shadows [18]. Should we separately estimate the shape and the illumination from shadows or is it better to attempt to infer both simultaneously?

Moving shadows bring new challenges for object segmentation and tracking [19]. So why do human observers appear to excel at extracting the spatial layout of a scene when moving shadows are present [20]?

Definition

Shape from silhouette (SfS) algorithms compute the (approximate) 3D shape of an object from multiple 2D projections considering only the outline of the object in the projections. The most important class of SfS methods are Visual Hull algorithms.

Background

The problem of computing shape from outlines (silhouettes) of projections is generally under-constrained. Depending on the object's geometry and the number of available views, approximations can be computed which are sufficient for some applications. Often, the SfS output serves as initialization for appearance-based shape reconstruction methods such as volumetric reconstruction or multiview stereo.

The most general class of SfS approaches, where no assumptions about the type of objects to reconstruct are made, are the Visual Hull algorithms (e.g., [1–4]). These are treated in a dedicated article.

If the class of objects to handle is restricted, specialized model-based algorithms can solve SfS-like problems even for a single view. In this case, the 3D shape is not actually reconstructed. The algorithms rather compute a shape within the scope of the model that satisfies silhouette constraints and otherwise maximizes domain-specific priors (e.g., a likelihood with respect to a learned distribution). Examples are [5, 6], where human body pose is estimated from a single silhouette, or [7] where the shape of a head is estimated from a face profile.

[Shape from specular reflections](#)

Definition

Specular reflections or *specularities* carry valuable information about the geometry of reflective surfaces and can be used to recover their shape.

Background

Cues such as texture and shading are often inadequate for recovering the shape of shiny reflective objects. For such objects it is not possible to observe their surfaces directly, rather only what they reflect. Yet, specular reflections present an additional cue that potentially may be exploited for shape recovery. A curved mirror produces “distorted” images of the surrounding world. For example, the image of a straight line reflected by a curved mirror is, in general, a curve (Fig. 2). It is clear that such distortions are systematically related to the shape of the surface. Is it possible to invert this map and recover the shape of the mirror from its reflected images? The general “inverse mirror” problem is under-constrained: by opportunely manipulating the surrounding world, we may produce a great variety of images from any curved mirror surface. This inverse problem may become tractable under the assumption that some knowledge about the structure of the scene, the shape of the object, or the observer is available.

Theory

The basic shape from specularities problem is formulated as follows: Let M be a reflective surface whose shape is unknown (Fig. 1). Consider a camera observing M and let \mathbf{c} be the camera projection center. Given a scene point (or light point source) \mathbf{p} , let \mathbf{q} be the image of \mathbf{p} observed in the image plane through a specular reflection on the reflective surface at \mathbf{r} . Let \mathbf{n}_r be the unit normal to the surface at \mathbf{r} (i.e., the normal of the tangent plane of M at \mathbf{r}). The main objective of the shape from specularities problem is to recover the 3D location of \mathbf{r} in the camera reference system given the observation \mathbf{q} . Often, it is desirable to recover higher-order local shape information around \mathbf{r} . In this case the objective is to estimate \mathbf{r} , the unit normal \mathbf{n}_r , and second- or higher-order local parameters of M at \mathbf{r} such as, for instance, directions and magnitudes of the surface principal curvature at \mathbf{r} .

If the camera is calibrated (i.e., if the internal camera parameters are known), the surface position at \mathbf{r} is completely determined by a single distance parameter s . This is easy to show: It follows from the perspective projection constraint that the point \mathbf{r} must belong to the line defined by \mathbf{c} and \mathbf{q} , resulting in the following relationship:

$$\mathbf{r} = \mathbf{c} + s\mathbf{d}, \quad (1)$$

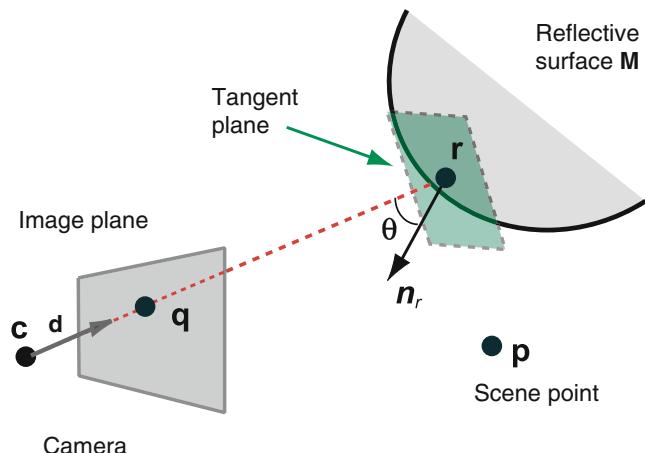

where the unit vector $\mathbf{d} = (\mathbf{q} - \mathbf{c})/\|\mathbf{q} - \mathbf{c}\|$ is parallel to the line of sight and $s = \|\mathbf{r} - \mathbf{c}\|$ is the distance from \mathbf{c} to \mathbf{r} . It follows that \mathbf{r} is known up one degree of freedom (i.e., s). Notice that no information about the surface normal \mathbf{n}_r or other higher-order surface parameters can be obtained in this case.

Assumptions on geometrical configuration of the scene (light source) or the reflectance properties of the surface lead to further constrains for estimating s and higher-order local shape information around \mathbf{r} . Some of the most notable cases are:

- *Single calibrated scene point (light point source).* If one assumes that the location of \mathbf{p} is known in the camera reference system,

Shape from Specularities, Fig. 1

The basic shape from specularity problem. Given a scene point reflected off a specular surface M at \mathbf{r} and given its observation in the camera image plane at \mathbf{q} , the goal is to recover 3D location of \mathbf{r} and higher-order local parameters of M around \mathbf{r}

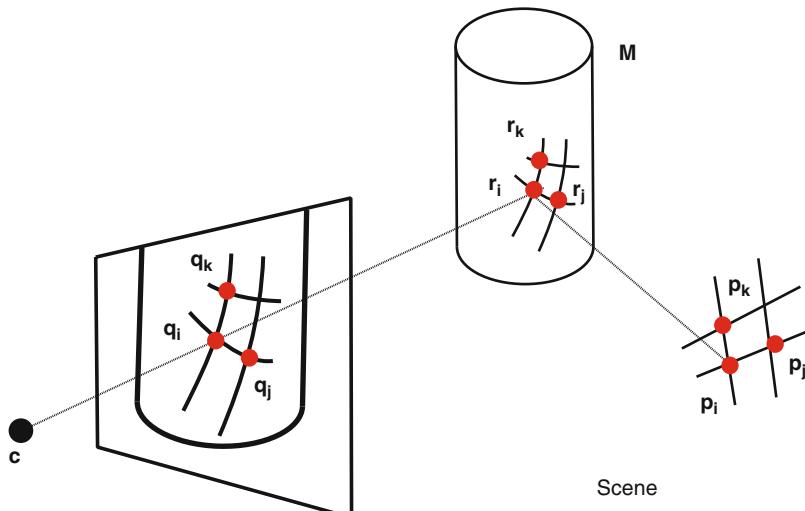

it can be shown that \mathbf{r} and \mathbf{n}_r are known up to one-dimensional family of solutions parameterized by s [1, 2]. This unknown can be determined if one further assumes that \mathbf{p} is at infinity [3].

- *Extended calibrated scene (light source).* The following assumptions are made. Assume that (at least) three points $\{\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k\}$ can be identified within a neighborhood of a scene planar patch and their reflection $\{\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k\}$ off the surface M are observable in the image plane as $\{\mathbf{q}_i, \mathbf{q}_j, \mathbf{q}_k\}$ (Fig. 2). Assume that correspondences between image points and scene points can be established (e.g., one knows that \mathbf{q}_i is the observation of reflection \mathbf{r}_i of scene point \mathbf{p}_i , for any i). Then, it can be shown that location of $\{\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k\}$ and corresponding surface normals at $\{\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k\}$ can be recovered as long as $\{\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k\}$ are close enough and are not colinear. Moreover, second-order information of M at $\{\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k\}$ (i.e., directions and magnitudes of principal curvature) can be estimated up to one-dimensional family of solutions. Details of this analysis are presented in the theoretical work by Savarese et al. [1] where necessary and sufficient conditions for reconstructing the local shape of a specular surface from one or multiple reflected calibrated points and (or) lines are discussed.
- *Known reflectance model for the surface.* If the reflected light is modeled using a physical reflectance model such as the Torrance-Sparrow BRDF model [4], a reflected point

on the surface. can be in general characterized by an extended pattern which is typically indicated as a *highlight*. It can be shown that by measuring the radiance falloff of specular highlights [5], the local curvature can be estimated.

Several practical methods have been proposed for recovering the shape of specular surfaces that use a setup similar to that in Figs. 1 and 2 wherein a calibrated fixed camera observes a scene element (light source) being reflected off the surface. Methods vary depending on whether the scene is calibrated or uncalibrated, static or time varying, and point source or extended. Pioneering work by Ikeuchi [3] and, later, works by Sanderson et al. [6] utilize distant light sources which are sequentially activated so as to generate sequences of point source reflections. Halstead et al. [7] and Tarini et al. [8] use extended scene structures composed of conically shaped patterns and a sequence of striped patterns, respectively. These methods recover the complete surface of a shiny object by iteratively fitting a parametric representation of the shape to local measurements. Zheng and Murata [9] propose a system where the object rotates while being illuminated by extended radial light sources. Savarese et al. [1] use a single calibrated grid pattern similar to that in Fig. 2 to obtain sparse local surface estimates (up to second order). Rozenfeld et al. [10] extend this analysis and demonstrate that dense reconstruction can be obtained from

Shape from Specularities, Fig. 2 Local shape of a reflective surface M can be recovered up second order if (at least) three points $\{p_i, p_j, p_k\}$ (along with their

sparse correspondences between scene points and observations. Kutulakos and Steger [11] exploit directed ray measurements of a calibrated planar target reflected off the surface and positioned at different locations in the world reference system. Adato et al. [12] show that it is possible to relax the hypothesis of calibrated scene by analyzing the reflection of a time varying distant unknown scene observed by an orthographic camera.

Additional constraints for estimating the reflection point r (along with higher-order shape information) can be obtained by having multiple observations of r from different vantage points. These observations can be generated from a moving camera. Unfortunately, standard structure from motion (SFM) constraints based on epipolar geometry [13] cannot be used in this case: As the camera vantage point changes, reflected points move (flow) on the surface following the law of reflection; this violates the assumption of static 3D points which is essential in SFM methods. As shown in the pioneering studies by Koenderink and van Doorn [14], Blake [15], and Zisserman et al. [2], even when multiple observations of the same reflected point r are available, r and n_r can still be estimated up to one-dimensional family of solutions (whereas the local concave/convex shape ambiguity can be determined [15]).

observations $\{q_i, q_j, q_k\}$) can be identified within a small planar patch in the scene [1]

Similarly to the case of static cameras, additional constraints are required to estimate the unknown parameters. The theoretical analysis in Oren and Nayar [16] and more recently the level set formulation by Solem et al. [17] demonstrate that camera movements allow to recover 3D surface profiles if boundary conditions at object occluding contours are used. Bonfort and Sturm [18] develop a discrete multi-view approach where the surfaces reflect a calibrated 3D scene using a volumetric stereo framework [19]. Roth and Black [20] relax the assumption of calibrated scene by introducing a probabilistic formulation-based expectation-maximization that combines cues from specular and diffuse components, the former being defined as *specular flow*.

S

Application

Modeling the shape of reflective surfaces is valuable in numerous research and industrial applications such as digital archival (e.g., acquisition of digital models for preservation of artistic artifacts with reflective components), medicine (e.g., noninvasive inspection of organs such as the cornea of the eye [7]), and metrology of industrial parts.

Definition

In window-based stereo matching, *shiftable windows* refer to the strategy of finding the best matching window for a particular pixel p in order to determine its depth. The window can be the usual central window (in which p is located in the middle) or an offset version, as long as it contains p .

Background

In a multi-view stereo problem, we are given a collection of images $\{I_k(x, y), k = 0 \dots K\}$ and associated camera matrices $\{\mathbf{P}_k, k = 0 \dots K\}$. $I_0(x, y)$ is the *reference image* for which we wish

to compute a *disparity map* $d(x, y)$ such that pixels in $I_0(x, y)$ project to their corresponding locations in the other images when the correct disparity is selected.

In the classic forward-facing multi-baseline stereo configuration [1], the camera matrices are such that disparity (inverse depth) varies linearly with horizontal pixel motion:

$$\hat{I}_k(x, y, d) = I_k(x + b_k d(x, y), y), \quad (1)$$

where $\hat{I}_k(x, y, d)$ is image I_k warped by the disparity map $d(x, y)$. In a more general (plane sweep) multi-view setting [2, 3], each disparity corresponds to some plane equation in 3D. Hence, the warping necessary to bring pixels at some disparity d into registration with the reference image can be represented by a homography $H_k(d)$:

$$\hat{I}_k(x, y, d) = H_k(d) \circ I_k(x, y), \quad (2)$$

where the homography can be computed directly from the camera matrices \mathbf{P}_0 and \mathbf{P}_k and the value of d [3].

Given the collection images warped at all candidate disparities, we can compute an initial *raw* (unaggregated) matching cost

$$E_{\text{raw}}(x, y, d, k) = \rho \left(I_0(x, y) - \hat{I}_k(x, y, d) \right), \quad (3)$$

where $\rho(\cdot)$ is some (potentially) robust measure of the color or intensity difference between the reference and warped image (see, e.g., [4, 5] for some comparative results with different robust metrics).

The task of stereo reconstruction is then to compute a disparity function $d(x, y)$ such that the raw matching costs are low for all images (or at least the subset where a given pixel is visible) while also producing a “reasonable” (e.g., piecewise smooth) surface. Since the raw matching costs are very noisy, some kind of spatial aggregation or optimization is necessary. The two main approaches used are local methods, which only look in a neighborhood of a pixel before making a

decision, and global optimization methods, which minimize some objective function over the entire image.

The simplest aggregation step is the classic sum of sum of squared distances (SSSD) formula, which simply aggregates the raw matching score over all frames:

$$E_{\text{SSSD}}(x, y, d) = \sum_{k \neq 0} \sum_{(u, v) \in \mathcal{W}(x, y)} E_{\text{raw}}(u, v, d, k), \quad (4)$$

where $\mathcal{W}(x, y)$ is an $n \times n$ square window centered at (x, y) . This can readily be seen as equivalent to a convolution with a three-dimensional box filter. This aggregation step can be used in a local method or global method (in the latter case, being part of the objective function).

After the aggregated errors have been computed, local techniques choose the disparity with the minimum SSSD error, which measures the degree of photoconsistency at a hypothesized depth. The best match can also be assigned a local confidence computed using the variance (across disparity) of the SSSD error function within the vicinity of the best match [6].

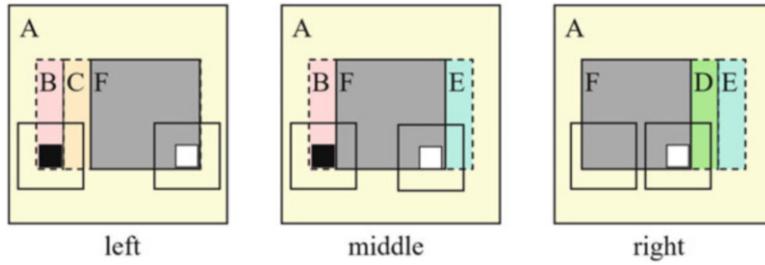

To handle occlusions or depth discontinuities for window-based stereo matching, aggregation for a given pixel may be an offset window version to avoid locally straddling two objects at different depth. This strategy is termed *shiftable window*. In cases where there are more than two input images, an additional strategy of *view selection* (or “best camera selection”) is required for better performance.

S

Theory

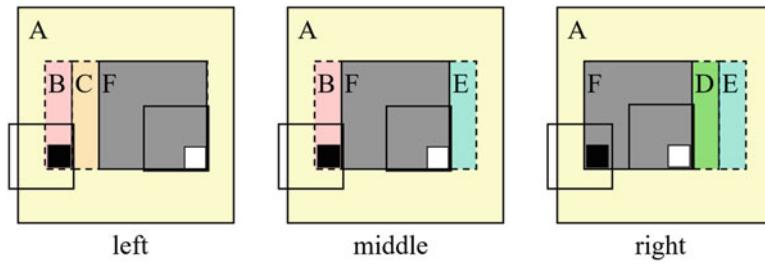

When a conventional-centered window approach is used for stereo matching, the results are degraded by pixels that are either occluded in one view but not the other. This occurs at object boundaries with depth discontinuities. Figure 1 illustrates this problem.

The principle of shiftable windows is illustrated in Fig. 2. The idea is to find support for a

Shiftable Windows for Stereo, Fig. 1 A simple three-image sequence (the middle image is the reference image), with a frontal gray square (marked F), and a stationary background. Regions B, C, D, and E are partially occluded. A regular SSD algorithm will make mistakes

when matching pixels in these regions (e.g., the window centered on the black pixel in region B) and also in windows straddling depth discontinuities (the window centered on the white pixel in region F). From [7] (used with permission of IEEE©)

Shiftable Windows for Stereo, Fig. 2 Shiftable windows help mitigate the problems in partially occluded regions and near depth discontinuities. The shifted window centered on the white pixel in region F now matches correctly in all frames. The shifted window centered on

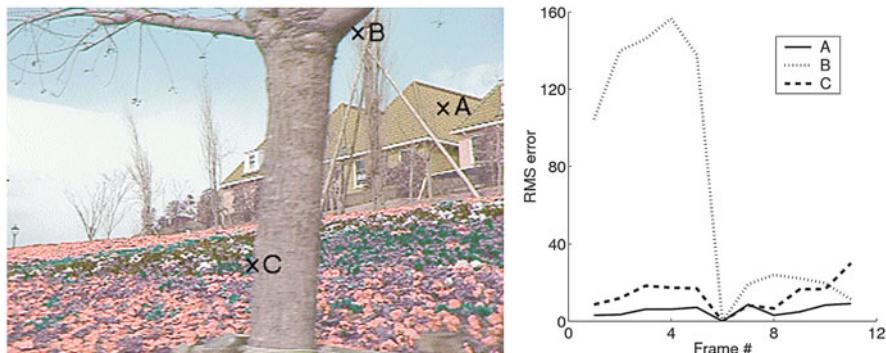

the black pixel in region B now matches correctly in the left image. View selection is required to disable matching this window in the right image. From [7] (used with permission of IEEE©)

pixel that avoids straddling two different depths within the same window. If there are more than two input images, it is advisable to also implement some form of view selection to avoid matching possible occluded regions in non-reference views.

View selection as a means of handling occlusions and disocclusions can be illustrated by considering selected error profiles depicted in Fig. 3. To generate the error graph, the root-mean-square (RMS) error for frame k is computed based on Eq. (3), with $\rho(x) = x^2$ and $\text{RMS}(k) = \sqrt{\sum_{(u,v) \in \mathcal{W}(x,y)} E_{\text{raw}}(u, v, d_X, k)}$ for point X . The corresponding disparities at points A, B, and C (d_A , d_B , and d_C , respectively) are assumed known for illustrative purposes. Points such as A, which can be observed at all viewpoints, work

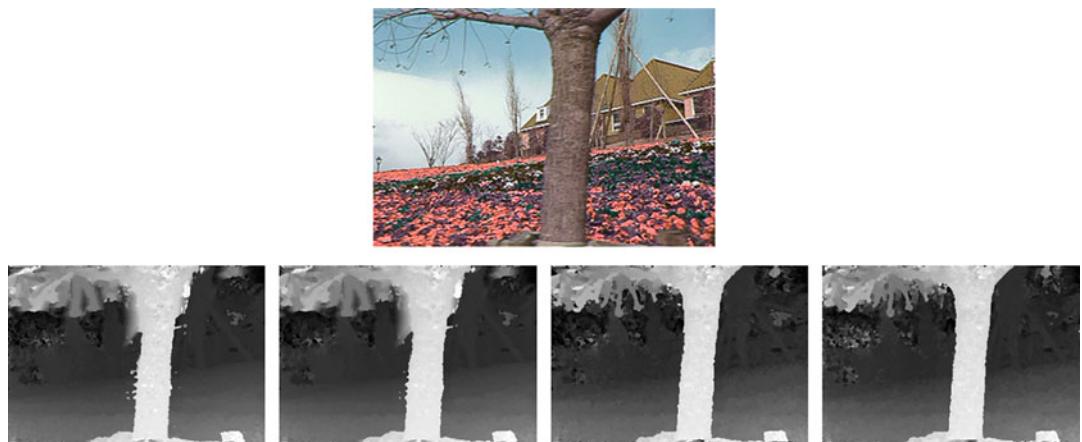

without shiftable windows and view selection. Points such as C, which is an occluding point, work better with shiftable windows but do not require view selection. Points such as B, however, which is occluded in a fraction of the viewpoints, work best with both shiftable windows and view selection.

Rather than just picking the preceding or succeeding frames (one-sided matching), a more general variant would be to pick the best 50% of all images available. In this case, we compute the local SSD error for each frame separately and then sum up the lowest values. This kind of approach can better deal with objects that are intermittently visible along a camera trajectory, which is caused by the presence of thin foreground occluders.

optimal depths with respect to the frame number (frame #6 is the reference). See text for explanation on RMS error computation. From [7] (used with permission of IEEE©)

Shiftable Windows for Stereo, Fig. 4 Comparison with different window-based stereo techniques. Top: middle (reference) image of an 11-image flower garden sequence. Bottom, from left to right: conventional-centered win-

dow, shiftable windows and using all neighboring frames, shiftable windows and using best 5 of 10 neighboring frames, shiftable windows and using better half sequence. From [7] (used with permission of IEEE©)

The discussion above assumes a fixed window size. There are other extensions, such as adaptive window sizes (e.g., [8–10]) and adaptive soft window shapes in the form of spatially variable support weights (e.g., [11–13]).

Smodeling, augmented reality (AR), creation of photo or video special effects such as bokeh and background modification, and obstacle detection for advanced driver-assistance systems (ADAS) and autonomous vehicles.

Application

Stereo is a fundamental problem in computer vision, and it has been used in applications which require depth information. Examples include 3D

Experimental Results

Figure 4 shows results for different variants of window-based stereo, with and without the strategy of shiftable windows. Notice that in

this case, using just shiftable windows improves depth at object boundaries only slightly over the conventional-centered window. Using shiftable windows in conjunction with view selection significantly improves results.

► [Many-to-Many Graph Matching](#)

Definition

The shock graph is obtained from the 2D Blum medial axis by incorporating properties of the radius function along the skeleton. The direction in which the radius function increases, or equivalently, the direction of the grassfire flow, is used to order groups of skeletal points and to derive parent-child relationships. This results in a directed acyclic graph whose nodes represent skeletal points and whose edges represent adjacency relationships. A variant of this construction associates skeletal points with edges, with the nodes representing the adjacencies.

Background

When Blum conceived of the medial axis or skeleton, his goal was to use it as a means to categorize objects from their projected (2D) outlines [4]. Specifically, by associating the direction of increasing radius value along a skeletal branch, or equivalently the direction of propagation of singularities of the grassfire flow, he proposed the concept of an axis-morphology or *a-morph* by which to achieve object categorization. His basic

insight was that this could lead to a decomposition that reflected the qualitative part structure of the object. As an example, ignoring their detailed boundary geometry, outlines of hands would have similar a-morphs and these would be quite distinct from those of outlines of humans, fish or other object classes. In fact, he drew upon these later examples towards the end of his classic paper [4], where he also sketched possible extensions to 3D.

Whereas much has been written about medial or skeletal representations over the years (see [23] and also the medial axis/skeleton entry in this encyclopedia) the idea that an a-morph was essentially a directed graph which could be used for object recognition caught on only in the early 1990s. One likely reason is that it took the image analysis and computer vision communities many years to develop robust algorithms for skeleton computation. Since this time, however, a variety of successful approaches to view-based recognition using shock-graphs have been proposed and have been validated on large databases. Several of these are described in the present entry. There also exist more recent variants of the shock graph, such as Macrini et al.'s bone graph [14], which attempt to mitigate the representational instability of the Blum medial axis. In fact, the mapping of the Blum skeleton to a graph-based representation, of which the shock graph is the most widely researched example, remains an active area of investigation.

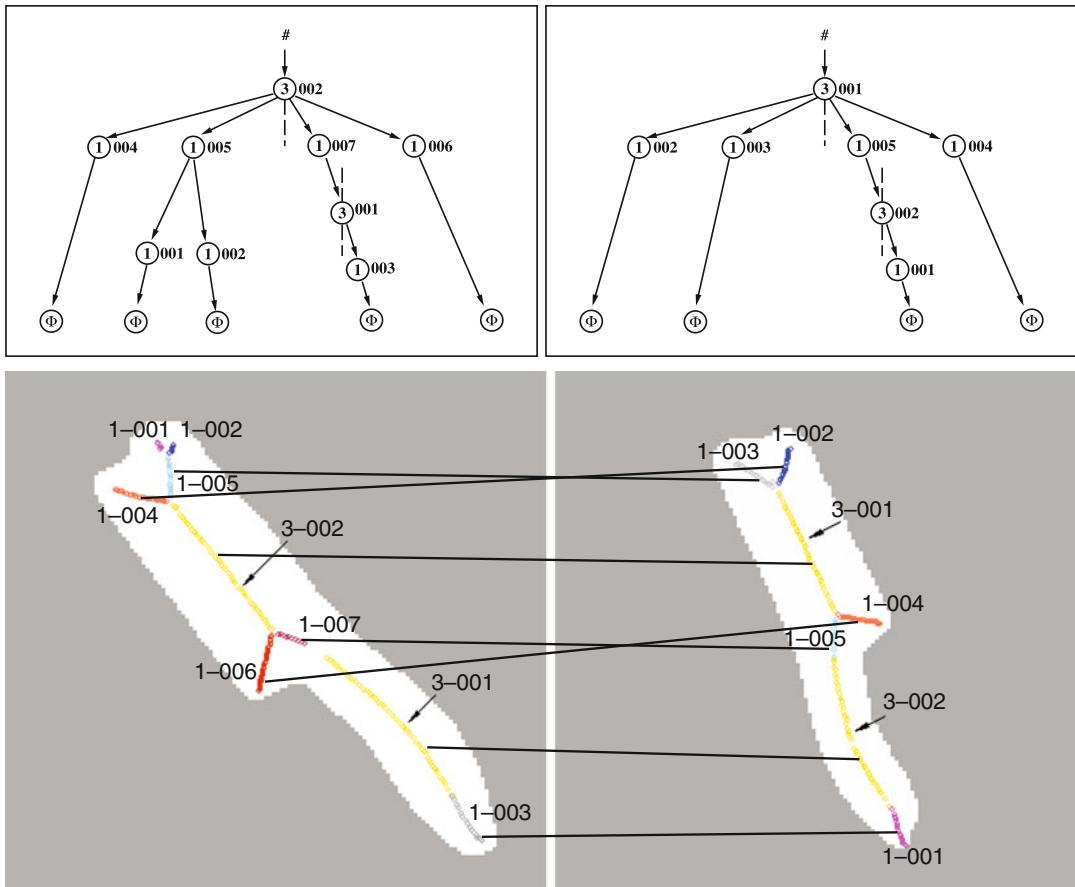

Theory

The Blum medial axis or skeleton of a 2D outline is homotopic to it and is comprised of three types of skeletal points: endpoints of skeletal curves, interior points and branch points. The branch points are generically of degree 3, i.e., three skeletal curves are connected at a branch point. A formal classification is presented in [11]. The shock graph takes the 2D skeleton of a simple closed curve as input (one without holes) and

labels each skeletal point according to whether the radius function at it is increasing monotonically (a 1-shock), is a local minimum (a 2-shock), is constant (a 3-shock) or is a local maximum (a 4-shock). Groups of adjacent 1-shocks are considered together, as are groups of 3-shocks. Given this interpretation, a directed acyclic graph is obtained by considering the skeletal points with the largest radii, which are the last to form in the grassfire flow, as the children of a dummy root node. The children are then placed, recursively, in order of decreasing radius value. This process of reversing the grassfire flow and adding 1-shock groups or 3-shock groups as children, is governed by the rules of a grammar, as shown in [24].

Rather than provide all the details of the grammar in this entry, the reader is referred to the examples in Fig. 1, which show the construction of the shock graphs of two brush shapes. The medial axis of each object is shown in the bottom row, with distinct groups of shocks being given a unique color (3-shocks are shown in yellow). In the labeling, the shock type appears first, followed by a unique identifier. The associated shock graphs are shown in the top row. It is clear that each shape is abstracted by a single root node (the 3-shock group describing the elongated portion of the brush), with its children being additional protrusions (1-shock groups). One of these protrusions has a 3-shock group as a child, which describes the handle of each brush. From this example it is evident that the shock graph is a formalization of Blum's a-morph, with the advantage that it lends itself to the use of graph-based methods for object categorization, as detailed below.

It is also important to point out that there is a variant of the shock graph where the representation places the skeletal points at edges of the graph, with the nodes representing connections. This variant is described in detail in [18, 19]. This representation has led to different but equally successful methods for object recognition, based on a notion of the edit-distance between two

Shock Graph, Fig. 1 The shock graphs derived for two different views of a brush using the algorithm of Siddiqi et al. [24] are represented in the top row. The bottom row

depicts the correspondences between nodes in the shock graphs computed by the matching algorithm

graphs. The results of using this approach are also briefly described below.

Shock Graph-Based Object Categorization

An object categorization system based on shock graphs consists of two components: (1) an indexing component, which takes an input shock graph and returns, from a large database of model shock graphs, a small number of candidate shock graphs that might account for the input; and (2) a matching component, which takes one of the candidates and the input, and computes a similarity (or distance), along with a set of node correspon-

dences. Under ideal conditions, the input shock graph would contain no artifacts due to noise, occlusion, or clutter, and would be isomorphic to one of the model shock graphs (provided that the input object represents one of the model objects). However, such conditions are highly unlikely, for in addition to noise, occlusion, and scene clutter, ligature-induced instabilities [1] often lead to spurious nodes/edges as well as medial branch oversegmentation. Formulating the problem as graph isomorphism, subgraph isomorphism, or even largest isomorphic subgraph will not lead to a meaningful solution, for large, or even significant isomorphisms may simply not exist between two shock graphs that represent instances of the same category. The shock graph indexing and

matching problems are therefore inexact graph indexing/matching problems.

Indexing Shock Graphs

Given an input shock graph, the goal of the indexing module is to quickly (sublinearly) retrieve a small number of candidate model database shock graphs among which the input is likely included. As mentioned above, the input shock graph may be corrupted in a number of ways, precluding a simple global (based on the entire input) indexing framework. For example: (1) occlusion may remove part of the input shock graph and replace the missing part with a shock graph (or subgraph) belonging to a different object; (2) shadows or poor illumination may simply delete some portion of the input shock graph; (3) scene clutter may embed the object shock graph (or portion thereof) in a much larger “scene” shock graph; and (4) ligature-based instability may introduce spurious nodes or may overpartition other nodes in the input shock graph. These factors require a part-based indexing framework that can operate in the presence of noise, occlusion, clutter, and ligature-based instability.

One such indexing framework that is applicable to not only shock graphs but any hierarchical, graph-based representation (specifically, any directed acyclic graph-based representation) was introduced by Shokoufandeh et al. [22], originally for the purpose of shock graph indexing. The key concept behind the approach is to capture the abstract shape of a graph (or subgraph) with a low-dimensional vector, yielding an efficient indexing mechanism. Capturing the abstract shape of a graph is important so that the index is invariant to noise and minor within-class shape deformation. Indexing at the part level is important in the presence of occlusion and scene clutter. Mapping a discrete graph structure to a low-dimensional point facilitates a simple nearest-neighbor search in a geometric space for similar model parts which, in turn, can vote for those model objects that contain those parts. Those model objects receiving the largest votes represent those candidate objects passed to the shock graph matching module for a more detailed analysis.

The graph-based shape abstraction is computed at every non-leaf node, and captures the abstract “shape” of the underlying subgraph rooted at that node. Therefore, each non-leaf node (with only four shock graph node types, leaf nodes are far too uninformative/ambiguous) “votes” for those objects that share its substructure; the root of the graph would therefore vote at the object level, and would be meaningful only if the object were unoccluded and not embedded in a larger scene. Mapping the structure of a rooted subgraph to a vector assigned to the subgraph’s root is based on a spectral analysis of the graph’s structure. The eigenvalues of a graph’s adjacency matrix (whose values are 0,1, -1) capture important properties of the degree distribution of the graph’s nodes. The eigenvalues can be combined to yield a low-dimensional abstraction of the graph’s shape in terms of how and where the edges are distributed throughout the graph. Moreover, such a spectral “signature,” called the *topological signature vector*, is proven to be stable under minor perturbations of graph structure due to noise. Details of the approach are found in [22], while an application of the same indexing framework to a different hierarchical graph, specifically a 3-D medial surface graph, can be found in [25].

Matching Shock Graphs

Given two shock graphs, e.g., one representing the input and one representing a model candidate, the matching component needs to return not only a similarity or distance measure that can be used to rank order the candidates, but also an explicit correspondence that defines which model nodes correspond to which input nodes. Such correspondence is necessary, for in the case of a cluttered scene, those nodes found to match a given model would be removed, and another candidate model matched to the remaining nodes. Moreover, the correspondence need not be one-to-one, for in the case of ligature-induced medial branch oversegmentation, node correspondence many be *many-to-many*.

Siddiqi et al. [24] developed a matching algorithm for shock graphs which, like the indexing framework of Shokoufandeh et al. [22] dis-

cussed above, can be applied to the matching of any directed acyclic graph structure, provided that a domain-dependent node similarity function is given. The algorithm is based on the same spectral graph theoretic abstraction that forms the heart of the indexing component described above. The algorithm formulates the matching of two graphs as finding a maximal matching in a bipartite graph over the two nodes sets (input and model). The edge weights (each spanning one input shock graph node and one model shock graph node) in the graph have two components: (1) the distance between the two nodes' respective topological similarity vectors, defining the similarity of their underlying graph structures (rooted at the two nodes); and (2) a node similarity function (the only domain-dependent component of the algorithm) that defines the similarity of the node attributes (for shock graphs, this encodes the geometric similarity between the two skeletal branches corresponding to the two nodes).

At first glance, the matching algorithm would seem to throw out all the important hierarchical structure in the two graphs (absent in the bipartite graph); nodes in one graph are matched to nodes in the other graph, but the edges in the two original graphs appear to play no role. However, the key contribution of the algorithm is that the hierarchical edge structure is brought back via the topological signature vector similarity term. For the bipartite matching algorithm to match two nodes (i.e., select that edge in the matching), both their geometric similarity and their topological similarity must be high. In other words, the contents of the two nodes must be similar and the subgraphs rooted at the two nodes must be similar. The algorithm iterates by computing a matching, selecting the best edge from the matching (having maximum similarity), adding it to the solution set, and recursively continuing the process on the remaining graphs (after removing the pair of matching nodes defined by the best edge). Details of the approach are found in [24], while its application to other shape matching problems is described in [21] (multiscale blob and ridge graphs), [25] (medial surface graphs), and [8, 26] (curve skeleton graphs).

The above algorithm eventually yields a one-to-one node correspondence between the two graphs. However, because the algorithm generates the node correspondence in a coarse-to-fine manner, stopping the algorithm at the level of a coarse node-to-node correspondence defines an explicit many-to-many correspondence between the nodes in the subgraphs rooted at the coarse nodes. Moreover, since the topological signature vectors are stable under small amounts of additive graph noise, similarity can remain high even though the two subgraphs may have different numbers of nodes. As the cardinalities of the two graphs' node sets begin to differ more dramatically, for example due to heavy under- or over-segmentation, the method breaks down and more powerful many-to-many graph matching must be employed.

One such method for many-to-many graph matching of medial axis-based graphs was proposed by Demirci et al. [9, 10]. Their algorithm transforms the graphs into a finite dimension metric space in which an approximate solution to the many-to-many matching problem becomes tractable. The embedding step will result in a set of points, each representing a vertex of the original graph. Their proposed embedding has the additional property that pairwise distances between points in the target metric space closely resemble the shortest-path distances between the corresponding nodes in the graphs. Matching two graphs can then be formulated as the problem of matching their two embeddings. The many-to-many matching of the two embeddings then can be computed by solving a transportation problem using the Earth Mover's Distance algorithm [7]. The solution of this latter problem computes the mass which flows from one weighted point set to another that minimize the total transportation cost. The computed flows, in turn, define the many-to-many node correspondences between the original graphs.

The problem of matching shock graphs has also been studied in the context of edit-distance methods [18, 29]. These algorithms estimate the cost of matching as a function of edit operations, including node relabelings, additions and deletions, and edge contraction that transform

one graph into another. A fundamental issue in devising algorithms based on edit-distance is the choice of cost of each operation. Torsello and Hancock [29] use the heuristic proposed by Bunke [5] for the cost associated with their edit operations. For example, the cost of relabeling elements is less than the cost of performing a deletion followed by inserting a new node with a new label. In contrast, Sebastian et al. [18] propose a multi-step heuristic to derive their edit costs. Their overall heuristic is centered around the notion of a shape cell, i.e., a collection of shapes which have identical shock graph topology. They define the cost of the deformation operation as a function of the discrepancy between matching shock attributes of shapes within a given cell. The cost associated with other edit operations is derived as the limit of the deforma-

tion cost when a shape moves to the boundary a shape cell.

Caelli and Kosinov [6] show how inexact matching can be utilized for measuring shape similarity between shock graphs. Their method establishes correspondence between sets (clusters) of vertices of two given graphs and as such can be viewed as a many-to-many matching approach. Their algorithm can be viewed as a generalization of the approach of Scott and Longuet-Higgins [17]. The actual matching is established using the renormalization of projections of vertices into the eigenspaces of graphs combined with a form of relational clustering. Similar to other inexact matching algorithms, their eigenspace renormalization projection clustering method is able to match graphs with different numbers of vertices.

Shock Graph, Fig. 2 Similarity between database and class prototypes computed using the algorithm of Siddiqi et al. [24]. In each row, a box is drawn around the most similar shape

Experimental Results

This section presents some examples of shock graphs and their matchings using the approaches described above. Figure 1(top) illustrates two shock graphs, describing different views of a brush, computed by the algorithm of Siddiqi et al. [24]. The underlying shocks, along with the computed matchings between segments (nodes), are shown in Fig. 1(bottom). Figure 2 represents the ability of the algorithm to compare objects based on their prototypical or coarse shape. Here, columns 2 through 10 denote the prototype views for each of nine object classes. The similarity between the prototypes and some of the objects in the database is reflected in the rows of this table. For each row, a box has been placed around the most similar shape. Demirci et al. [9] also evaluated the effectiveness of their matching algorithm for shape retrieval based on shock graphs from the Rutgers Tool Database [24]. Figure 3 shows some examples of the many-to-many feature matching results obtained from the algorithm for some of the objects in the Rutgers Tools Database. Finally, Fig. 4 shows the results obtained from applying the edit-distance algorithm of Sebastian et al. [18] to the matching of shock segments. Note that their edit distance algorithm will also produce a sequence of intermediate shock graphs that identify the steps of the transformation of one input shock graph to another.

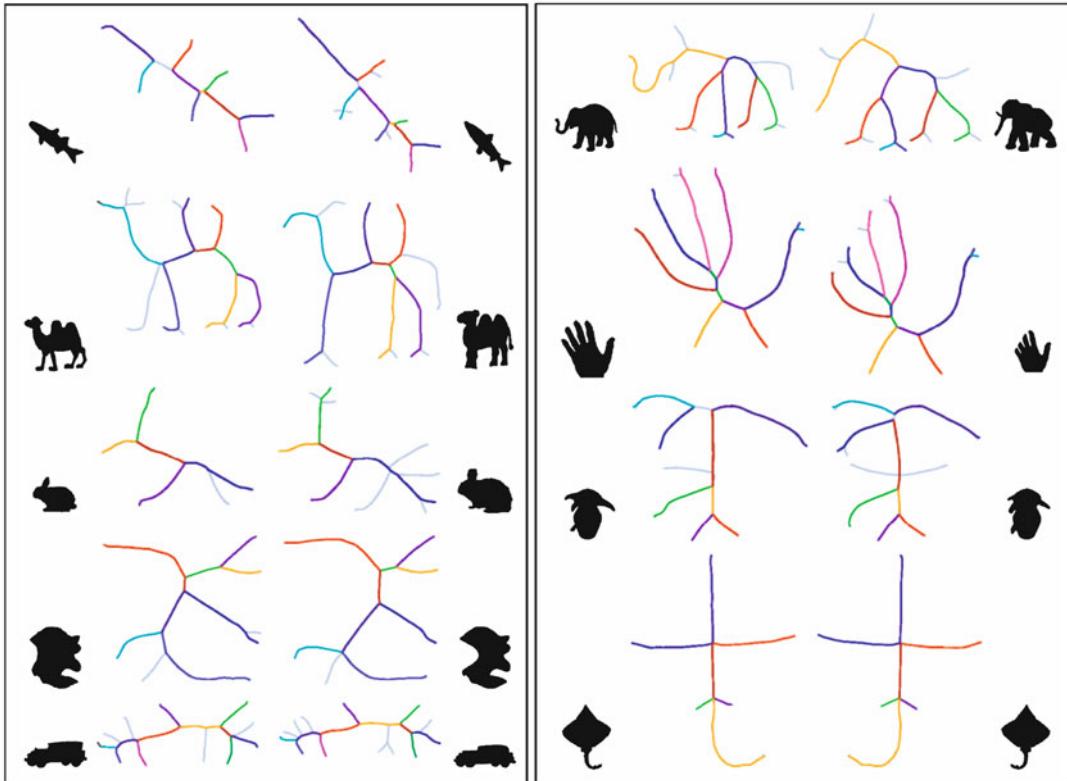

Open Problems

Symmetry is a powerful shape regularity that has formed the basis of many shape representations, including generalized cylinders [3], superquadrics [16], and geons [2]. Just as geons provide a qualitative and discrete shape abstraction of a generalized cylinder, shock graphs provide a discrete and qualitative shape abstraction of a medial axis. The resulting graph is ideally suited to shape categorization, for it is part-based, is stable under within-class deformation, and is stable under part articulation. However, the shock graph also faces some

Shock Graph, Fig. 3 The results of matching skeleton graphs for some pairs of shapes in the Rutgers Tools Database using the algorithm of Demirci et al. [9]. Corresponding segments are shown using the same color. Observe that correspondences are intuitive in all cases

important challenges. First of all, it assumes that a closed contour has been recovered from an image, separating figure from background. While figure-ground segmentation remains an open research problem, it is important to note that in a categorization system, a perfect figure-ground separation may not be necessary. If a significant portion of the figure's boundary is correctly segmented, a significant portion of the resulting shock graph may be correct – enough to yield the correct candidate (among the list of returned

Shock Graph, Fig. 4 The matching results for a few shock graphs produced by the edit-distance algorithm of Sebastian et al. [18]. Matching shock branches are shown

candidates) during indexing. Still, while a shock graph does preserve locality of representation, significant figure-ground segmentation errors can propagate through the representation, disrupting it to a degree that prevents effective indexing. A recent attempt to recover a symmetric part decomposition from a cluttered scene has been reported by Levinstein et al. [13], in which symmetric parts are detected locally (bottom-up) and then grouped to form an approximation to a medial axis.

The second challenge facing the shock graph is the ligature-based instability discussed earlier [1]. A number of approaches exist to try and regularize the medial axis through boundary smoothing, e.g., [12, 20, 27]; however, these methods do not effectively address the ligature structure. Other methods have sought to abstract the medial axis by regularizing out small internal branches, e.g., [28, 30]; however these meth-

ods don't explicitly target ligature structure. A recent promising approach to abstracting out ligature structure is proposed by Macrini et al. [14, 15], yielding a representation, called the *bone graph*, whose parts are the non-ligature medial branches that represent the salient parts and whose edges represent the "glue" (defined by the ligature branches) that binds the parts.

► Camera Calibration

Definition

Simplified Active Calibration (SAC) is defined as a set of closed-form and linear mathematical equations to estimate the internal camera parameters in active platforms where the camera rotations are known or can be estimated.

Background

One of the main steps in many computer vision applications is Camera Calibration to find a mapping between the 3D world and its projection on the 2D image. Estimating this mapping is a twofold process consisting of intrinsic and extrinsic parameters. Intrinsic or internal camera parameters are focal length, center of projection, pixel skew, and aspect ratio. Knowing these internal elements, one can project points that are in the camera coordinates onto the 2D image coordinates. Extrinsic parameters, on the other hand, transfer the points into the camera coordinate system and are comprised of rotation and translation of the camera.

A classic way of calibrating cameras is to relate the 3D world to the 2D image using calibration objects such as grids, wands, or LEDs or even by adding augmented reality markers to a camera [14]. This imposes a major limitation on the calibration task since the camera can be calibrated only in off-line and controlled environments. To address this issue, Maybank and Faugeras [9, 12] proposed the so-called *self-calibration* approach in which they used the information of matched points in several images, taken by the same camera from different views, instead of using known 3D points (calibration objects). In their two-step method, they first estimated the epipolar transformation from three pairs of views and then linked it to the image of an absolute conic using the Kruppa equations [12]. Not long after the seminal work of

Maybank and Faugeras, Basu proposed the idea of Active Calibration [1, 2] in which he included rotations of a camera and eliminated point-to-point correspondences.

The main downside of the Active Calibration strategies (A and B) in [1–3] is that it calculates the camera intrinsics using a component of the projection equation in which a constraint is imposed by the degenerate rotations. For example, after panning the camera, the equation derived from vertical variations observed in the new image plane is unstable. Furthermore, the small angle approximation using $\sin(\theta) = \theta$ and $\cos(\theta) = 1$ decreases the accuracy of strategies when the angle of rotation is not very small. Also, rolling the camera [4] is impractical (without having a precise mechanical device) because it creates translational offsets in the camera center.

Theory

Simplified Active Calibration (SAC) [5, 6] has been inspired by the novel idea of approximating the camera intrinsics using small rotations of the camera which was initially proposed in [1, 2] and extended in [3, 4]. SAC is used for calibrating active cameras that are mostly rotated around the center of the camera. Therefore, the translation vector of the camera has three zero elements. The estimates obtained by the SAC equations can then be used as an initial guess in a nonlinear refinement process. More specifically, closed-form equations for estimating the focal length of the camera using only three images have been proposed in [5]. Later in [6], linear solutions for approximating the coordinates of the principal point using the same three images that have been used to estimate the focal length along with the focal lengths have been proposed and evaluated.

S

Rotation Formulation

The rotation of the camera is defined by the Euler angles and is denoted by a separate 3×3 matrix. The final rotation matrix can be calculated by:

$$\mathbf{R} = \mathbf{R}_z \mathbf{R}_y \mathbf{R}_x \quad (1)$$

where \mathbf{R}_x , \mathbf{R}_y , and \mathbf{R}_z denote the rotations about x , y , and z , respectively. The elements of the final rotation matrix are represented as:

$$\mathbf{R} = [r_{ij}]_{3 \times 3} \quad (2)$$

where i denotes the row-wise element indices and j represents the column-wise element indices.

Camera Model

SAC makes an assumption that the camera is placed at the origin of the Cartesian coordinate system and is looking along z -axis where the principal point is specified. It should be noted that f represents the focal length of the camera. Furthermore, the principal axis coincides with the z -axis, and the image plane is perpendicular to the principal axis. A point on the normalized camera coordinates is denoted by $\mathbf{x} = [x \ y \ 1]^T$. Also, the column (u) and row (v) coordinate axes of the reference image plane are parallel to the x -axis and the y -axis of the camera, respectively.

Every 3D point $\mathbf{X} = [X \ Y \ Z]^T$ in the world that is visible to the camera can be projected onto a specific point $\mathbf{v} = [u \ v \ 1]^T$ of the image plane and can be calculated using the camera intrinsic matrix.

$$\mathbf{K} = \begin{bmatrix} f_u & s & u_0 \\ 0 & -f_v & v_0 \\ 0 & 0 & 1 \end{bmatrix} \quad (3)$$

Note, $f_u = f m_u$ is the focal length of the camera in the u direction (in pixels) and $f_v = f m_v$ represents the focal length of the camera in the v direction. With modern cameras it is reasonable to assume that sensor elements are perpendicular and so the value of the camera skew (s) is zero [10].

Also, any camera transformation is equivalent to a similar transformation of the scene but in the opposite direction [11]. For stationary cameras that freely rotate but stay in a fixed location, the camera transformation is only modeled by its rotation. In other words, the translation of the camera is zero. Therefore, every point \mathbf{v} in an

image seen by a stationary camera is transformed to a point \mathbf{v}' in another image taken after camera rotation. The mathematical relationship between \mathbf{v} and \mathbf{v}' is thus represented by:

$$w\mathbf{v}' = \mathbf{K}\mathbf{R}^T\mathbf{K}^{-1}\mathbf{v} \quad (4)$$

where w is the scale of the projection and represents the depth of the point. It should be noted that $\mathbf{R}^T = \mathbf{R}^{-1}$ because the rotation matrix is orthonormal.

Simplified Active Calibration Algorithm

Having access to the rotation of the camera, SAC proposes a three-step process to calibrate the camera:

1. Estimate the focal length in the u direction:

A closed-form solution to calculate an approximation of the focal length in the u direction (f_u) using an image taken after a pan rotation of the camera, assuming that u and v represent the two major axes of the image plane.

$$f_u \approx \frac{u' - r_{11}u - (1 - r_{11})c_u}{r_{31}} \quad (5)$$

where r_{ij} are known elements of the rotation matrix at row i and column j .

2. Estimate the focal length in the v direction:

A closed-form solution to calculate an approximation of the focal length in the v direction (f_v) using an image taken after a tilt rotation of the camera.

$$f_v \approx \frac{r_{22}v - v' + (1 - r_{22})c_v}{r_{32}} \quad (6)$$

where c_u and c_v are image centers in the u and v directions, respectively.

3. Principal point:

Having an image taken after a pan and tilt rotation of the camera and a reference image, SAC forms a system of linear equations to estimate the location of the principal point (u_0, v_0) in the image.

$$\begin{aligned}
 & \begin{bmatrix} A + I_1 - Gu'_1 & B - Hu'_1 \\ \vdots & \vdots \\ A + I_n - Gu'_n & B - Hu'_n \\ D - \hat{v}'_1 G & E - I_1 - Hv'_1 \\ \vdots & \vdots \\ D - \hat{v}'_n G & E - I_n - Hv'_n \end{bmatrix} \begin{bmatrix} \delta_u \\ \delta_v \end{bmatrix} \\
 &= \begin{bmatrix} \hat{u}'_1 I_1 - C_1 \\ \vdots \\ \hat{u}'_n I_n - C_n \\ \hat{v}'_1 I_1 - F_1 \\ \vdots \\ \hat{v}'_n I_n - F_n \end{bmatrix} \quad (7)
 \end{aligned}$$

where

$$\begin{aligned}
 A &= -r_{11}, \quad B = r_{21} \frac{f_u}{f_v} \\
 C &= r_{11}\hat{u} + r_{21}\hat{v} \frac{f_u}{f_v} + r_{31}f_u \\
 D &= -r_{12} \frac{f_v}{f_u}, \quad E = r_{22} \\
 F &= r_{12}\hat{u} \frac{f_v}{f_u} + r_{22}\hat{v} + r_{32}f_v \\
 G &= -\frac{r_{13}}{f_u}, \quad H = \frac{r_{23}}{f_v} \\
 I &= r_{13} \frac{\hat{u}}{f_u} + r_{23} \frac{\hat{v}}{f_v} + r_{33}
 \end{aligned}$$

and $\hat{u} = u - c_u$, $\hat{v} = v - c_v$ where C_u and C_v are image centers in the u and v directions, respectively.

Therefore, SAC estimates the four main components of the intrinsic matrix, namely, f_u , f_v , u_0 , and v_0 , and hence, it requires three pairs of images, one taken before and after a small pan rotation, one taken before and after a small tilt rotation, and one taken before and after a small pan-tilt rotation.

Application

Generally, SAC can be used in any platform in which information about the camera motion is provided by the hardware, such as in robotic applications where the rotation of the camera can be extracted from the inertial sensors or in surveillance control softwares that are able to rotate the PTZ cameras by specific angles.

SAC has made a basic assumption about the rotation of a fixed camera; i.e., to solve the proposed equations, knowing the rotation angles of the camera is necessary. The proposed formulation can be used in practical applications such as surveillance, because in PTZ cameras accessing the camera motion information is straightforward.

The proposed closed-form formulations for estimating the focal lengths can be solved with only one point correspondence. Finding the correspondence point is straightforward. Following recent developments in feature extractors, one can extract repeatable regions from a pair of images. This is especially useful for applications that favor no point correspondences but instead contour-to-contour correspondences that were done in the original Active Calibration [4], where instead of the reference and transferred points in Eqs. 5 and 6, the average of contour points or the centroid of the region can be used.

Definition

Simulated annealing is a stochastic computational technique derived from statistical mechanics for finding near globally minimum-cost solutions to large optimization problems [1].

Background

Many computer vision problems require the minimization of an application-dependent objective function in a high-dimensional state space subject to conflicting constraints. Finding the global minimum can be an NP-complete problem since the objective function tends to have many local minima. A procedure for solving hard optimization problems should sample values of the objective function in such a way as to have a high probability of finding a near-optimal solution and should also lend itself to efficient implementation. A method which meets these criteria was introduced by Kirkpatrick et al. [2] and independently by Černý [3] in the early 1980s. They introduced the concepts of annealing in combinatorial optimization. These concepts are based on a strong analogy between the physical annealing process of solids and the problem of solving large combinatorial optimization problems.

Theory

Statistical mechanics is the study of the behavior of very large systems of interacting components, such as atoms in a fluid, in thermal equilibrium at a finite temperature. If the system is in thermal equilibrium at a given temperature T , then the probability $\pi_T(s)$ that the system is in a given state s depends upon the energy $E(s)$ of the state and follows the Boltzmann distribution:

$$\pi_T(s) = \frac{\exp\left(-\frac{E(s)}{k_B T}\right)}{\sum_{s' \in \Omega} \exp\left(-\frac{E(s')}{k_B T}\right)}, \quad (1)$$

where k_B denotes a physical constant known as the Boltzmann constant and Ω the set of all possible states.

Using a technique developed by Metropolis et al. [4], one can simulate the behavior of a system of particles in thermal equilibrium at temperature T . Suppose that at time t the system is in state q_t . Then, a subsequent state r_{t+1} is generated by a perturbation mechanism which transforms the current state into a next state. If the

energy difference, $E(r_{t+1}) - E(q_t)$, is less than or equal to 0, the state r_{t+1} is accepted as current state. Otherwise, the state r_{t+1} is accepted with probability

$$p = \frac{\pi_T(r_{t+1})}{\pi_T(q_t)} = \exp\left(-\frac{E(r_{t+1}) - E(q_t)}{k_B T}\right) \quad (2)$$

Since the method accepts states that decrease the energy as well as those that increase the energy, it is the principle that avoids entrapment at a local minimum. It can be shown that as $t \rightarrow \infty$, the probability that the system is in a given state s equals $\pi_T(s)$ and thus that the distribution of states generated converges to the Boltzmann distribution [5].

In order to obtain a low-energy state of the energy function E , one must use an annealing process, where the temperature of the system is elevated, and then gradually lowered, spending enough time at each temperature to reach thermal equilibrium. Applying simulated annealing to an optimization problem in computer vision where the energy function becomes the objective function to minimize requires two ingredients:

- An annealing schedule consisting of a starting temperature, a decreasing set of temperatures, and the amount of time to spend at each temperature;
- A perturbation mechanism that generates new states.

The annealing algorithm proposed by Kirkpatrick et al. [2] consists of running the Metropolis-Hastings algorithm [4, 6] at each temperature in the annealing schedule for the amount of time prescribed by the schedule and selecting the final state as a near-optimal solution.

Geman and Geman [5] applied simulated annealing to image restoration and determined an annealing schedule sufficient for convergence. Specifically, for a given sequence of temperatures $\{T_t\}$ such that $T_t \rightarrow 0$ as $t \rightarrow \infty$ and $T_t \geq \frac{c}{\log(t)}$ for a large constant c , the probability that the system is in configuration s as $t \rightarrow \infty$ is equal to $\pi_0(s)$. For a finite set Ω , the optimal annealing

schedule for the convergence of the generated states to the set of global minima with probability 1 was determined by Hajek [7].

Simulated annealing is not limited to discrete state spaces. It can also be applied to minimize objective functions defined on Euclidean spaces, i.e., $\Omega \subseteq \mathbb{R}^d$, where similar convergence results have been proved [8]. Further convergence results and detailed discussions on simulated annealing are given in the books [9, 10].

In the discrete case, the perturbation mechanism depends usually on the application where some examples are given in [9]. In the simplest case, a new state is randomly sampled from a local neighborhood of the previous state, e.g., by permutations, swapping, or inversions. In the continuous case, the visiting distribution can be modeled as Gaussian distribution that favors local search, and the algorithm is also called the Boltzmann machine, but also other distributions like the Cauchy-Lorentz distribution, known as fast simulated annealing [11], can be applied. This distribution results in frequently local searches but can also generate a state that is very distant to the current state. Having the state q_t , a new state $r_{t+1} = q_t + \Delta s$ is generated by sampling from

$$g_t(\Delta s) = \frac{1}{(\pi T_t)^{\frac{d}{2}}} \exp\left(-\frac{\|\Delta s\|^2}{T_t}\right) \quad (\text{Boltzmann machine}), \quad (3)$$

$$g_t(\Delta s) = \frac{\Gamma(\frac{d+1}{2})}{\pi^{\frac{d+1}{2}}} \frac{T_t}{(\|\Delta s\|^2 + T_t^2)^{\frac{d+1}{2}}} \quad (\text{Cauchy machine}). \quad (4)$$

The new state is then accepted according to the probability p (2). An approach that covers Gaussian and Cauchy-Lorentz distribution as special cases is called generalized simulated annealing [12]. The generalized acceptance probability (2) reads

$$p = \left(1 + \frac{(a-1)(E(r_{t+1}) - E(q_t))}{T_t^a}\right)^{-\frac{1}{a-1}}, \quad (5)$$

the generalized visiting distribution is defined by

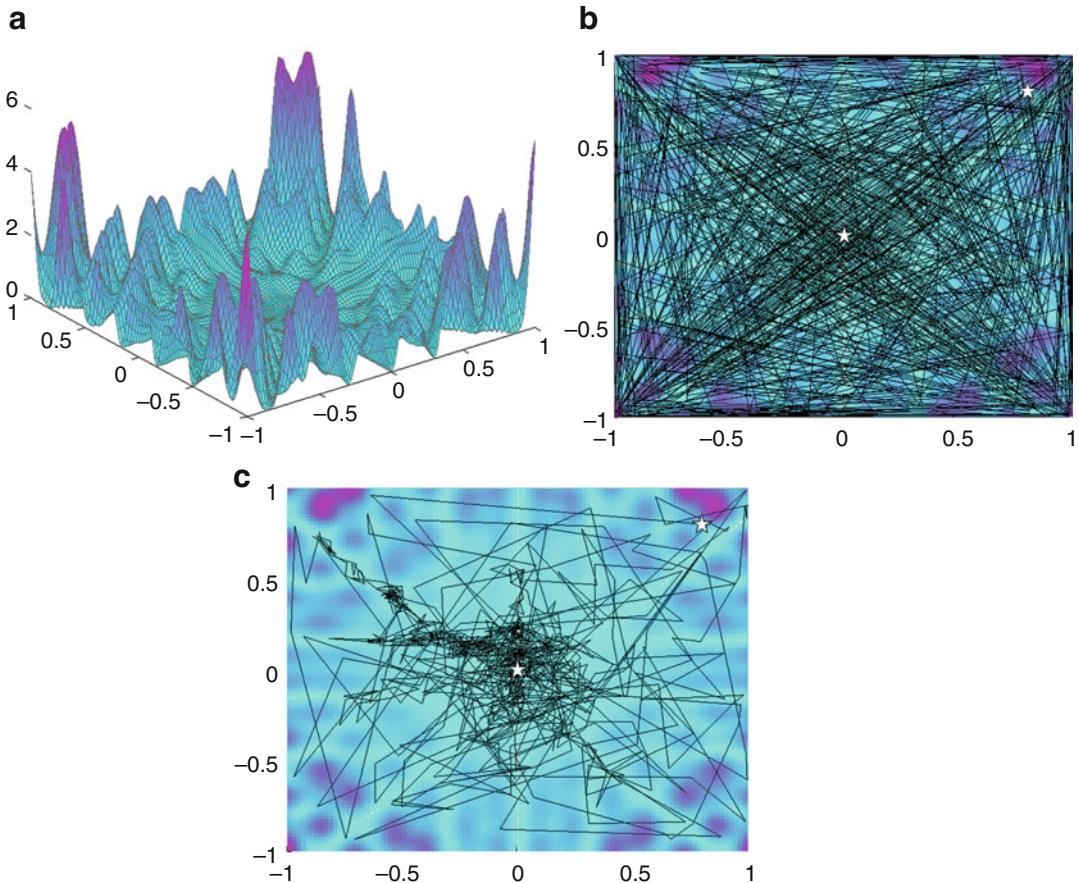

$$g_t^v(\Delta s) = \left(\frac{v-1}{\pi} \right)^{\frac{d}{2}} \frac{\Gamma\left(\frac{1}{v-1} + \frac{d-1}{2}\right)}{\Gamma\left(\frac{1}{v-1} - \frac{1}{2}\right)} \frac{(T_t^v)^{-\frac{d}{3-v}}}{\left(1 + (v-1)\frac{\|\Delta s\|^2}{(T_t^v)^{\frac{2}{3-v}}}\right)^{\frac{1}{v-1} + \frac{d-1}{2}}}, \quad (6)$$

and the generalized annealing schedule is given by

$$T_t^b = T_1^b \frac{2^{b-1} - 1}{(1+t)^{b-1} - 1} \quad b \in \{a, v\}. \quad (7)$$

Additional parameters (a, v) give an additional flexibility where $(1, 1)$ corresponds to the Boltzmann machine and $(1, 2)$ to the Cauchy machine. In practice, the optimal choice of (a, v) depends on the objective function and needs to be empirically determined.

For speeding up simulated annealing, the algorithm can be implemented in parallel [9]. The annealing principle is also used for other optimization methods. For instance, a deterministic annealing method has been proposed for clustering [13], or an interacting particle system with annealing properties has been proposed in [14] and applied to human motion capture [15], where at each iteration, a set of particles estimates the current distribution.

Simulated Annealing, Fig. 1 (a) Function $h(x, y)$. (b) Visited points using Boltzmann machine and initial temperature 100. The starting point, $(0.8, 0.8)$, and the final

estimate are indicated by a white star. (c) Visited points using Cauchy machine. The Cauchy machine cools down faster, focusing the search more on low-energy regions

Application

Since its introduction in 1983, simulated annealing has been applied for solving complex, non-convex optimization problems in image processing and computer vision. An overview of applications in the 1980s including the work of Geman and Geman [5] is given in [9]. Nowadays, simulated annealing is still an easy-to-implement and practically useful tool for solving a wide spectrum of optimization problems, particularly for solving hard problems where no completely successful heuristics exist. For an optimal performance, however, the algorithm needs to be tailored to the problem at hand.

Experimental Results

The following example for global optimization in \mathbb{R}^2 is taken from [16]: Let

$$\begin{aligned} h(x, y) = & (x \sin(20y) + y \sin(20x))^2 \cdot \cosh \\ & (\sin(10x)x + (x \cos(10y) - y \sin(10x))^2 \cdot \\ & \cosh(\cos(20y)y) \end{aligned} \quad (8)$$

be the objective function to minimize (Fig. 1). Its global minimum is 0, attained at $(x, y) = (0, 0)$.

In Table 1, results are shown for the Boltzmann and the Cauchy machine. The starting point was $(0.8, 0.8)$, and each simulation was repeated 100 times. Each simulation was stopped when the average change in value of the objective function in 1,000 iterations was less than 10^{-6} . The table contains the average and standard deviation for the obtained estimate (\hat{x}, \hat{y}) , its function value

$h(\hat{x}, \hat{y})$, and the number of necessary function evaluations.

Definition

Spectral decomposition is an expression of a symmetric matrix in terms of its eigenvalues and eigenvectors, while singular value decomposition is a similar expression of a nonzero rectangular matrix in terms of its singular values and singular vectors.

Background

A linear mapping from \mathcal{R}^n to \mathcal{R}^m is represented by an $m \times n$ matrix \mathbf{A} . It is determined by the images $\mathbf{a}_1, \dots, \mathbf{a}_n \in \mathcal{R}^m$ of an orthonormal basis $\{\mathbf{u}_1, \dots, \mathbf{u}_n\}$ of \mathcal{R}^n in the form

$$\mathbf{A} = \sum_{i=1}^n \mathbf{a}_i \mathbf{u}_i^\top. \quad (1)$$

From the orthogonality $\langle \mathbf{u}_i, \mathbf{u}_j \rangle = \delta_{ij}$ (Kronecker delta), where $\langle \cdot, \cdot \rangle$ denotes the inner product of vectors, we can confirm that $\mathbf{A}\mathbf{u}_i = \mathbf{a}_i$ holds indeed.

For an $n \times n$ symmetric matrix \mathbf{A} , there exist a real value λ , called *eigenvalue*, and a nonzero vector \mathbf{u} ($\neq \mathbf{0}$), called *eigenvector*, such that

$$\mathbf{A}\mathbf{u} = \lambda\mathbf{u}. \quad (2)$$

An $n \times n$ symmetric matrix has n eigenvalues $\lambda_1, \dots, \lambda_n$ (with possible overlaps), and the corresponding eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_n$ can be chosen to be mutually orthogonal unit vectors. Hence, $\{\mathbf{u}_1, \dots, \mathbf{u}_n\}$ serve as an orthonormal basis of \mathcal{R}^n . Eigenvalues and eigenvectors are easily computed using mathematical software [1, 2].

The relationship $\mathbf{A}\mathbf{u}_i = \lambda_i\mathbf{u}_i$, $i = 1, \dots, n$, implies that \mathbf{A} maps an orthonormal basis $\{\mathbf{u}_1, \dots, \mathbf{u}_n\}$ to $\lambda_1\mathbf{u}_1, \dots, \lambda_n\mathbf{u}_n$. Letting $\mathbf{a}_i = \lambda_i\mathbf{u}_i$ in (1), we can write the matrix \mathbf{A} in the form

$$\mathbf{A} = \sum_{i=1}^n \lambda_i \mathbf{u}_i \mathbf{u}_i^\top, \quad (3)$$

which is called the *spectral* (or *eigenvalue*) *decomposition* of \mathbf{A} .

Theory

For a nonzero $m \times n$ matrix \mathbf{A} ($\neq \mathbf{0}$), there exists a positive value $\sigma (> 0)$, called *singular value*, a nonzero m -dimensional vector \mathbf{u} ($\neq \mathbf{0}$), called *left singular vector*, and a nonzero n -dimensional vector \mathbf{v} ($\neq \mathbf{0}$), called *right singular vector*, such that

$$\mathbf{A}\mathbf{v} = \sigma\mathbf{u}, \quad \mathbf{A}^\top\mathbf{u} = \sigma\mathbf{v}. \quad (4)$$

The left and right singular vectors are referred to simply as *singular vectors*.

Multiplying the first and the second equations of (4) by \mathbf{A}^\top and \mathbf{A} , respectively, we can see that

$$\mathbf{A}\mathbf{A}^\top \mathbf{u} = \sigma^2 \mathbf{u}, \quad \mathbf{A}^\top \mathbf{A} \mathbf{v} = \sigma^2 \mathbf{v}. \quad (5)$$

Namely, \mathbf{u} and \mathbf{v} are, respectively, the eigenvectors of the $m \times m$ symmetric matrix $\mathbf{A}\mathbf{A}^\top$ and of the $n \times n$ symmetric matrix $\mathbf{A}^\top \mathbf{A}$ for eigenvalue σ^2 . Hence, the number of singular values of \mathbf{A} equals the number of nonzero eigenvalues of $\mathbf{A}\mathbf{A}^\top$ and $\mathbf{A}^\top \mathbf{A}$, which is equal to the rank r of \mathbf{A} . Singular values and singular vectors are easily computed using mathematical software [1, 2].

Since the singular vectors \mathbf{u}_i and \mathbf{v}_i are eigenvectors of symmetric matrices, the singular vectors $\{\mathbf{u}_i\}$ and $\{\mathbf{v}_i\}$, $i = 1, \dots, r$, can be chosen as orthonormal sets. The set $\{\mathbf{v}_i\}$, $i = 1, \dots, r$, can be extended to an orthonormal basis $\{\mathbf{v}_i\}$, $i = 1, \dots, n$, of \mathcal{R}^m , in such a way that \mathbf{v}_i , $i = r+1, \dots, n$, are the null vectors, i.e., eigenvectors for eigenvalue 0, of $\mathbf{A}^\top \mathbf{A}$. Hence,

$$\mathbf{A}\mathbf{v}_i = \mathbf{0}, \quad i = r+1, \dots, n. \quad (6)$$

This and (4) imply that \mathbf{A} maps an orthonormal basis $\{\mathbf{v}_1, \dots, \mathbf{v}_m\}$ to $\sigma_1 \mathbf{u}_1, \dots, \sigma_r \mathbf{u}_r, \mathbf{0}, \dots, \mathbf{0}$. Hence, from (1), the matrix \mathbf{A} is written as

$$\mathbf{A} = \sum_{i=1}^r \sigma_i \mathbf{u}_i \mathbf{v}_i^\top, \quad (7)$$

which is called the *singular value decomposition (SVD)* of \mathbf{A} .

Pseudoinverse

If an $m \times n$ matrix \mathbf{A} ($\neq \mathbf{O}$) has the singular value decomposition (7), its *pseudoinverse* (or *generalized inverse*) of *Moore-Penrose type* is defined by

$$\mathbf{A}^- = \sum_{i=1}^r \frac{\mathbf{v}_i \mathbf{u}_i^\top}{\sigma_i}. \quad (8)$$

Some authors write \mathbf{A}^- for general (not necessarily of Moore-Penrose type) pseudoinverse and specifically write \mathbf{A}^+ for the Moore-Penrose type to distinguish it from others.

Note that inverse is defined only for nonsingular (hence square) matrices, while pseudoinverse

is defined for all nonzero (generally rectangular) matrices. The inverse of a nonsingular matrix is defined so that its product with the original matrix is the identity. This is not necessarily so for pseudoinverse. From (7) and (8), we can see that

$$\mathbf{A}\mathbf{A}^- = \sum_{i=1}^r \mathbf{u}_i \mathbf{u}_i^\top \quad (\triangleq \mathbf{P}_{\mathcal{U}}), \quad (9)$$

$$\mathbf{A}^- \mathbf{A} = \sum_{i=1}^r \mathbf{v}_i \mathbf{v}_i^\top \quad (\triangleq \mathbf{P}_{\mathcal{V}}). \quad (10)$$

The matrix $\mathbf{P}_{\mathcal{U}}$ represents projection onto the subspace \mathcal{U} spanned by $\mathbf{u}_1, \dots, \mathbf{u}_r$. In fact, the orthogonality $\langle \mathbf{u}_i, \mathbf{u}_j \rangle = \delta_{ij}$ implies that $\mathbf{P}_{\mathcal{U}} \mathbf{u} = \mathbf{u}$ for $\mathbf{u} \in \mathcal{U}$ and $\mathbf{P}_{\mathcal{U}} \mathbf{u} = \mathbf{0}$ for $\mathbf{u} \perp \mathcal{U}$. From (7), we see that \mathcal{U} coincides with the subspace spanned by the columns of \mathbf{A} . Similarly, the matrix $\mathbf{P}_{\mathcal{V}}$ represents projection onto the subspace \mathcal{V} spanned by the rows of \mathbf{A} . Thus, the product of a matrix \mathbf{A} with its pseudoinverse \mathbf{A}^- is the projection onto the subspace spanned by the columns or the rows of \mathbf{A} . Since the columns and rows of a nonsingular matrix span the entire space, for which the identity is the projection onto it, pseudoinverse is a natural extension of the inverse to arbitrary rectangular matrices.

Since the columns of \mathbf{A} span the subspace \mathcal{U} and the rows span \mathcal{V} , the following identities hold:

$$\mathbf{A}\mathbf{A}^- \mathbf{A} = \mathbf{A}, \quad \mathbf{A}^- \mathbf{A}\mathbf{A}^- = \mathbf{A}^-. \quad (11)$$

Historically, the first equation is the definition of the general (not necessarily of Moore-Penrose type) pseudoinverse, and the Moore-Penrose type is obtained by requiring the second equation (called *reflexivity*) and the condition that $\mathbf{A}\mathbf{A}^-$ and $\mathbf{A}^- \mathbf{A}$ be symmetric.

Since pseudoinverse is defined for any nonzero matrices, it can be defined for vectors, regarded as $n \times 1$ and $1 \times n$ matrices. For a vector \mathbf{a} , the definition of pseudoinverse implies

$$\mathbf{a}^- = \frac{\mathbf{a}^\top}{\|\mathbf{a}\|^2}, \quad (\mathbf{a}^\top)^- = \frac{\mathbf{a}}{\|\mathbf{a}\|^2}. \quad (12)$$

Consider a linear equation

$$\mathbf{A}\mathbf{x} = \mathbf{b}, \quad (13)$$

where \mathbf{A} is a nonzero $m \times n$ matrix, \mathbf{x} is an n -dimensional unknown vector, and \mathbf{b} is a given m -dimensional vector. The expression

$$\mathbf{x} = \mathbf{A}^{-1}\mathbf{b} \quad (14)$$

gives a *least-squares solution* such that (i) it minimizes $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2$ over all \mathbf{x} and (ii) if the minimum is not unique, it returns \mathbf{x} for which $\|\mathbf{x}\|^2$ is the smallest among them. This procedure is an essential component of multiview 3D reconstruction, using redundant geometric constraints in the presence of noise [3].

Subspace Fitting

Given N points $\mathbf{x}_1, \dots, \mathbf{x}_N$ in \mathcal{R}^n , we consider the problem of finding an r -dimensional subspace ($r < N$) that is the closest to them, where the closeness is measured by the sum of square distances. We assume that the coordinate system is translated so that the origin O coincides with the centroid of the N points. Let

$$\mathbf{S} = \sum_{\alpha=1}^N \mathbf{x}_{\alpha} \mathbf{x}_{\alpha}^{\top}. \quad (15)$$

This matrix is called by many different names such as the “moment matrix” and the “scatter matrix” (both from physics). Here, let us call it, for convenience, the *covariance matrix*, a term borrowed from statistics.

The form of (15) implies that it is a positive semidefinite symmetric matrix, having nonnegative eigenvalues. Let σ_i^2 be its eigenvalues and \mathbf{u}_i the corresponding unit eigenvectors, $i = 1, \dots, n$. The spectral decomposition of \mathbf{S} has the form

$$\mathbf{S} = \sum_{i=1}^n \sigma_i^2 \mathbf{u}_i \mathbf{u}_i^{\top}. \quad (16)$$

We can show that \mathbf{u}_1 is the direction of the line from which the sum of square distances of the N points is the smallest, \mathbf{u}_2 is the direction of the

line from which the sum of square distances of the N points is the smallest among all directions orthogonal to \mathbf{u}_1 , \mathbf{u}_3 is the direction of the line from which the sum of square distances of the N points is the smallest among all directions orthogonal to \mathbf{u}_1 and \mathbf{u}_2 , and so on. Thus, it is concluded that the r -dimensional subspace that best approximates the N points is spanned by $\mathbf{u}_1, \dots, \mathbf{u}_r$. They are called the *principal directions* of the N points.

Hierarchical construction of such subspaces of dimensions $r = 1, 2, \dots$ is called the *Karhunen–Loéve (KL) expansion* in the domain of signal processing, expanding individual signals with respect to $\{\mathbf{u}_i\}$. The efficiency of transmission and display of the signal improves by omitting those basis vectors with small contributions. In statistics, this scheme is called the *principal component analysis (PCA)*, used for extracting a small number of statistics that characterize the data well.

For most vision applications [4], however, we need not compute the covariance matrix \mathbf{S} . In fact, let

$$\mathbf{X} = (\mathbf{x}_1 \cdots \mathbf{x}_N) \quad (17)$$

be the $n \times N$ matrix consisting of the data vectors \mathbf{x}_{α} , $\alpha = 1, \dots, N$, as its columns. The covariance matrix \mathbf{S} of (16) equals

$$\mathbf{S} = \mathbf{X} \mathbf{X}^{\top}. \quad (18)$$

The singular value decomposition of \mathbf{X} has the form

$$\mathbf{X} = \sum_{i=1}^n \sigma_i \mathbf{u}_i \mathbf{v}_i^{\top}, \quad (19)$$

because, as seen from (5), the eigenvalues of $\mathbf{S} = \mathbf{X} \mathbf{X}^{\top}$ equals the squares of the singular values of \mathbf{X} ; \mathbf{u}_i and \mathbf{v}_i are the eigenvectors of $\mathbf{X} \mathbf{X}^{\top}$ and $\mathbf{X}^{\top} \mathbf{X}$, respectively. Hence, the basis of the fitted r -dimensional subspace is given by the singular vectors $\mathbf{u}_1, \dots, \mathbf{u}_r$ of \mathbf{X} . This approach considerably reduces the computational complexity, since we need not compute the covariance matrix \mathbf{S} , which requires $O(n^2 N)$ operations, and the complexity of eigenanalysis is $O(n^3)$, while for singular value decomposition, it is $O(n^2 N)$.

for $N \geq n$ and $O(nN^2)$ for $n \geq N$ [1], i.e., the complexity is *linear* in the length of the “shorter side” of the matrix.

Exploiting this fact, we can see that 3D reconstruction, for example, from hundreds of thousands of data points, which would require several hours of computation using spectral decomposition, can reduce to several seconds using singular value decomposition [3].

Matrix Product Representation

The spectral decomposition (3) is written as

$$\begin{aligned} A &= (\lambda_1 u_1 \cdots \lambda_n u_n) \begin{pmatrix} u_1^\top \\ \vdots \\ u_n^\top \end{pmatrix} \\ &= (u_1 \cdots u_n) \begin{pmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_n \end{pmatrix} \begin{pmatrix} u_1^\top \\ \vdots \\ u_n^\top \end{pmatrix} \\ &= U \Lambda U^\top, \end{aligned} \quad (20)$$

where U is the $n \times n$ matrix consisting of the eigenvectors u_i as its columns and $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$. Multiplying the above equation by U from right and U^\top from left, we obtain $U^\top A U = \Lambda$, which is known as *diagonalization* of the symmetric matrix A .

Using the same rewriting as (20), we can express the singular value decomposition (7) in the form

$$A = U \Sigma V^\top, \quad (21)$$

where U and V are the $m \times r$ and $n \times r$ matrices consisting of the singular vectors u_i and v_i as their columns, respectively, and $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_r)$. Then, the pseudoinverse (8) is written as

$$A^- = V \Sigma^{-1} U^\top. \quad (22)$$

Application

The singular value decomposition in the form of (21) is utilized in the method of *factoriza-*

tion for 3D reconstruction from images [4, 5]. The singular value decomposition also plays a central role in 3D vision computation problems including optimal fundamental matrix estimation, optimal rotation estimation, and multiview 3D reconstruction computation [3].

Synonyms

Generically describable situation; Situation scheme

Definition

Situation Graph Trees (SGTs) provide a deterministic formalism to represent the knowledge required for human behavior modeling.

Background

In many domains, high-level descriptions to represent the status of an environment are desirable. Describing a situation requires to conceptualize the knowledge about the possible actions of the actors involved in the environment and their possible interactions. Conceptual descriptions of different application domains like traffic analysis [1], parking lot security [2, 3], and human behavior recognition [4] are of primary importance. The conceptualization can proceed from simple descriptions (simple events) to complex descriptions (complex events). Following relations, concepts can be aggregated into more complex concepts. Hence, an event can be described as a sequence of simple events. To allow such an incremental description of the events, two main processes are required: (a) modeling of the behaviors and (b) the reasoning engine. Different approaches like Bayesian networks [5], hidden Markov models [6], SVM [7], and deep learning [8] have been investigated. However, in complex environments, such models are difficult to apply as they would require a large amount of data for training the models. In such cases, a formalism to model behaviors by means of temporal and semantic relationships or specialization of fundamental concepts can be useful. Situational Graph Trees (SGTs) represent such a modeling tool.

Theory

The Situation Graph Trees (SGTs) [9] provide a deterministic formalism to represent the knowledge necessary to describe an actor behavior. Generally, SGTs are based on the description of the situation that consists on an agent state and the possible actions that the agent can actuate in such a state. Thus, a hierarchy of possible situation is defined on temporal and conceptual terms. This means that given a recognized situation only, its possible successor is evaluated at the next time instant.

The fundamental block of the SGT is the situation scheme that represents the knowledge

of an agent for a given time instant. A situation scheme is composed by sections:

- State: describe the state of an agent in terms of predicates
- Action: describe the possible and supposed actions that an agent can do whenever one of the state predicates is satisfied

Situation schemes are connected by means of direct edges (called *prediction edges*) to define a temporal successor relationship between situation schemes. When an agent is instantiated by its predicates, a possible next situation is represented by a scheme pointed by a prediction edge originated by the current situation. If an agent keeps on staying in its current situation for more than a single time instant, *self-prediction edges*, starting from a situation and pointing to itself, are used to model such a behavior. Thus, a situation scheme can be a ring of a chain of situation schemes describing a sequence of situations. Such sequences, composed by situation schemes and prediction edges, are called situation graphs. A situation can be temporally or conceptually refined by particularizing its situation scheme. In such a case, a situational graph is connected to a situational scheme by means of a particularized edge. Following [9], it is possible to derive the following definitions for SGTs:

Definition 1 (SGT-episode) Any sequence E of situations inside a situation graph G that is a path from a start situation to an end situation is defined as SGT-Episode.

Definition 2 (Particularized SGT-episode) Any SGT-Episode of a situation graph G particularizing a situation scheme s is defined as a particularizing SGT-Episode.

Definition 3 (SGT-event) Given a SGT T , an event is defined as:

- Any SGT-Episode E within the root situation graph of T .
- Given an SGT-Event E , replacing any situation S in E with a particularized SGT-Episode of S is a new SGT-Event.

Definition 4 (Particularized SGT-event) Given a SGT T and a SGT-Event E , a SGT-Event \hat{E} is defined as a particularized SGT-Event of E iff \hat{E} is obtained from E by substituting any situation scheme S of E with a particularized SGT-Episode of S .

Definition 5 (Maximal event) Given a SGT T , any SGT-Event E is a maximal event iff there not exists a situation scheme S in E that can be substituted with a particularized SGT-Episode of S .

Definition 6 (Compatible events) Given a SGT T , E and E' are compatible events iff:

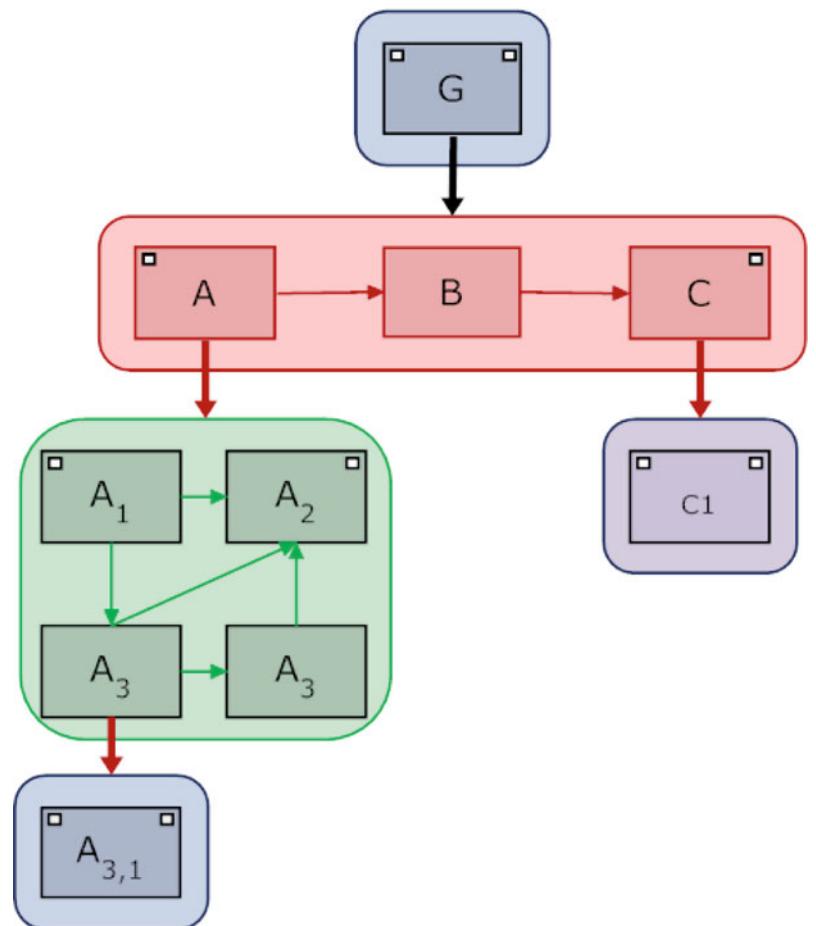

- Each situation scheme in E is a situation scheme in E' .

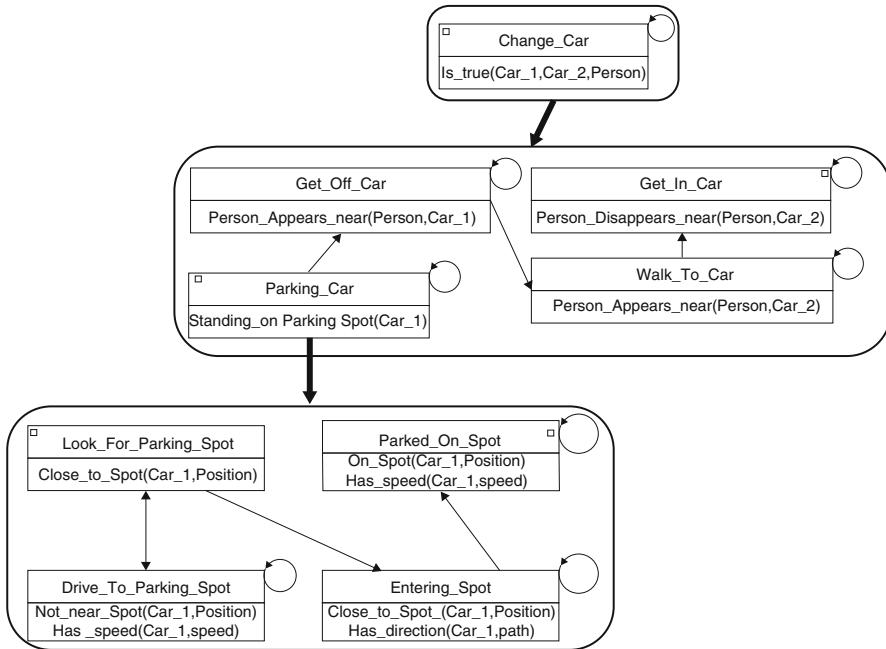

- For each pair (S_i, S_j) in E where S_i proceed S_j , there is the same pair in E' .

Representation

The common representation of SGTs is given in Fig. 1. Situation schemes are represented as rectangles and situation graphs as set of rectangles with rounded corners. Start situations (end situations) are depicted with small rectangles in the upper left (right) corner of the situation schemes. Prediction edges are thin arrows that decide the current situation and the possible next situation. Thick arrows represent particularization edges.

**Situation Graph Trees,
Fig. 1** Example of SGT

Situation Graph Trees, Fig. 2 Example of SGT for an event of interest in a parking lot monitoring context

Application

A common application of SGTs is the representation of behaviors in video-surveillance context. In such a field, contrary to anomaly detection algorithm, expected behaviors or behaviors of interest can be defined for all the actors/agents operating inside the monitored environment. To represent such behaviors, SGT can be powerfully exploited. As example in a parking lot, the monitoring application may be interested in detecting and recognizing a person driving into a parking spot, leaving the parked car, and driving away on board of a second car. Such an event can be described by the SGT depicted in Fig. 2 that can be further particularized in the situation schemes of the first child node.

Sparse representation

Definition

Sparse coding is the act of expressing a given input signal (e.g., image or image patch) as a linear superposition of a small set of basis signals chosen from a prespecified dictionary.

Background

At a high level, the problem of sparse coding is one of representing a given input signal as efficiently as possible:

Given an input signal $y \in \mathbb{R}^m$ (say an image or image patch) and a dictionary of basis signals $a_1 \dots a_n \in \mathbb{R}^m$, find a good approximation

$$y \approx x_1 a_1 + x_2 a_2 + \dots + x_n a_n$$

in which most of the coefficients x_i are zero.

That is, we try to represent y as a linear combination of basis elements in which only a few of the coefficients are nonzero (i.e., the vector $\mathbf{x} = (x_1 \dots x_n)$ is *sparse*). This deceptively simple problem arises repeatedly in signal processing, modern statistics, and machine learning. The most readily apparent application is in data compression, where we can consider the sparse coefficients \mathbf{x} as a compressed representation of the signal \mathbf{y} . However, numerous additional applications arise in signal and image acquisition, denoising, and inpainting. Sparse coding techniques have also received significant attention in the statistics literature, where sparsity is recognized as a means of regularizing high-dimensional inference – in particular, for regularizing linear regression when the number of predictors is larger than the number of observations.

These interactions make sparse coding a very vibrant area of research, with contributions from statistics, signal processing, optimization, applied mathematics, and cognitive neuroscience. Indeed, the term “sparse coding” originally comes from the neuroscience literature, where it has been observed that seeking a sparse codes for natural image patches yields Gabor-like basis functions that resemble the receptive fields in the human visual system [1]. In applied mathematics and statistics, a deep literature has developed around the question of when it is possible to solve sparse coding problems efficiently.

While the tools and problems encountered in sparse coding have precedents dating back almost a century, much of the development has been relatively recent. In computer vision, techniques from sparse coding (and related areas of sparse error correction and compressed sensing) have been employed for recognizing faces and objects, performing image upsampling, denoising, and

superresolution. At the time of writing this article, sparse coding techniques are the subject of intense exploration in the vision community [2].

Theory

The model problem in sparse coding is one of searching for the *sparsest representation* of a given input signal \mathbf{y} as a linear combination of dictionary elements:

$$\text{minimize } \|\mathbf{x}\|_0 \text{ subject to } \mathbf{A}\mathbf{x} = \mathbf{y}. \quad (1)$$

Above, the ℓ^0 -pseudonorm

$$\|\mathbf{x}\|_0 = \#\{i | x_i \neq 0\}$$

simply counts the number of elements in \mathbf{x} that are not zero. Although conceptually desirable, the problem (1) is computationally intractable (hard to approximate in the worst case), and so it is common practice to replace the ℓ^0 norm with a more tractable surrogate. One way to do this is to instead minimize the ℓ^1 -norm

$$\|\mathbf{x}\|_1 = \sum_i |x_i|.$$

This gives a convex optimization problem

$$\text{minimize } \|\mathbf{x}\|_1 \text{ subject to } \mathbf{A}\mathbf{x} = \mathbf{y}. \quad (2)$$

This relaxation is well motivated, in the sense that the ℓ^1 norm can be shown to be the tightest convex underestimator of the ℓ^0 norm over the set of all vectors \mathbf{x} with $\max_i |x_i| \leq 1$. Moreover, whereas the nonconvex cardinality minimization problem (1) does not admit an efficient algorithm, the convex problem (2) can be cast as a linear program and solved efficiently. For more details on available techniques for solving the optimization problem (2), the interested reader can refer to the survey paper [3].

In certain situations, the link between (2) and (1) can be made quite a bit tighter. When the dictionary \mathbf{A} satisfies technical conditions that essentially assert that its columns are not too

collinear, it can be shown that these two problems are formally equivalent: the tractable optimization (2) exactly recovers the sparse solution to (1)! For example, suppose that the columns \mathbf{a}_i of \mathbf{A} have unit ℓ^2 norm, and let

$$\mu(\mathbf{A}) \doteq \max_{i \neq j} |\langle \mathbf{a}_i, \mathbf{a}_j \rangle|. \quad (3)$$

Then, whenever $\mathbf{y} = \mathbf{A}\mathbf{x}_0$ for some \mathbf{x}_0 satisfying

$$\|\mathbf{x}_0\|_0 < \frac{1}{2}(1 + 1/\mu(\mathbf{A})), \quad (4)$$

we have that \mathbf{x}_0 is the unique optimal solution to the ℓ^1 minimization (2). That is to say, whenever there exists a sufficiently sparse solution to the system of equations $\mathbf{y} = \mathbf{A}\mathbf{x}$, this solution will be recovered by ℓ^1 norm minimization. Variants of this result have been obtained by a number of authors; the version described above is due to Donoho and Elad [4]. There is a vast literature on guarantees for ℓ^1 -minimization – in particular, a family of beautiful results on ℓ^1 -minimization with random matrices \mathbf{A} has inspired the recent development of *compressed sensing*, an approach to more efficiently acquire signals that are sparse in some known basis. For readers who are interested in learning more, one starting point is the survey paper [5].

In practice, the observation \mathbf{y} may contain noise, and so it is desirable to relax the constraint $\mathbf{A}\mathbf{x} = \mathbf{y}$. This leads to a new convex program

$$\text{minimize } \|\mathbf{x}\|_1 \text{ subject to } \|\mathbf{A}\mathbf{x} - \mathbf{y}\|_2 \leq \varepsilon, \quad (5)$$

which is known in the signal processing literature as *basis pursuit denoising* [6]. Its Lagrangian reformulation,

$$\text{minimize } \|\mathbf{x}\|_1 + \lambda \|\mathbf{A}\mathbf{x} - \mathbf{y}\|_2^2 / 2, \quad (6)$$

is known as the *Lasso* in statistics [7]. The optimization problems (5) and (6) are equivalent under an appropriate calibration $\varepsilon \leftrightarrow \lambda$, although no explicit expressions for the corresponding parameters are known.

The theoretical results alluded to above make ℓ^1 -minimization a very attractive approach to sparse coding. However, it is by no means the only available algorithm. Researchers have explored a number of nonconvex objective functions which may more closely approximate the ℓ^0 norm in (1), at the expense of being hard to solve in general. Examples include the ℓ^p norms $\|\mathbf{x}\|_p = (\sum_i x_i^p)^{1/p}$ ($0 < p < 1$) ($0 < p < 1$) and entropy-like functions such as $\sum_i \log(1 + |x_i|^2)$.

Greedy algorithms comprise another popular alternative to ℓ^1 -minimization. These algorithms construct a solution \mathbf{x} via an iterative procedure that repeatedly selects a “best” dictionary element \mathbf{a}_i to add to the representation. One prototypical example is the Orthogonal Matching Pursuit (OMP) algorithm [8] (which has been rediscovered in a number of different settings). OMP maintains an active set of indices J and a residual \mathbf{r} . Initially, J is empty, and $\mathbf{r} = \mathbf{y}$. At each step, the index $j \in \{1 \dots n\}$ that maximizes $|\langle \mathbf{a}_j, \mathbf{r} \rangle|$ is added to the active set J . The sparse coefficients \mathbf{x} are estimated via

$$\text{minimize } \|\mathbf{y} - \mathbf{A}\mathbf{x}\|_2^2 \text{ subject to } \mathbf{x}(J^c) = \mathbf{0}. \quad (7)$$

The residual \mathbf{r} is updated as $\mathbf{r} = \mathbf{y} - \mathbf{A}\mathbf{x}$. This procedure is repeated until a sufficiently accurate approximation to \mathbf{y} is obtained. OMP is attractive for its simplicity and also comes with performance guarantees in some situations; the interested reader can refer to [5] and the references therein for a start.

All of the algorithms described above assume that the given observation \mathbf{y} indeed has a sparse approximation in terms of a known dictionary \mathbf{A} . In some situations, this can be guaranteed from prior understanding of the physical structure of the problem. For example, in face recognition, the dictionary \mathbf{A} can be constructed from images of training faces chosen in order to guarantee a good approximation of the test image \mathbf{y} [9]. In other situations, it may be possible to design optimal representations for classes of signals – as witnessed by the development of signal representations in signal processing and harmonic analysis over the past few decades.

However, if the signal model is not known ahead of time, or if the specific class of signals is believed to have some additional structure, an attractive alternative is to attempt to learn the dictionary \mathbf{A} itself from sample data. This leads to a problem known as *dictionary learning*, in which we observe multiple examples $\mathbf{Y} = \mathbf{y}_1 \dots \mathbf{y}_p \in \mathbb{R}^m$. The goal is to find a dictionary $\mathbf{A} \in \mathbb{R}^{m \times n}$ of basis functions and sparse coefficient vectors $\mathbf{X} = \mathbf{x}_1 \dots \mathbf{x}_p \in \mathbb{R}^n$ such that $\mathbf{Y} \approx \mathbf{AX}$:

$$\text{minimize}_{\mathbf{A}, \mathbf{X}} \|\mathbf{X}\|_0 \text{ subject to } \|\mathbf{Y} - \mathbf{AX}\|_F \leq \varepsilon. \quad (8)$$

Notice that here the minimization is with respect to both \mathbf{A} and \mathbf{X} , and so even if we relax the ℓ^0 norm, the resulting optimization problem,

$$\text{minimize}_{\mathbf{A}, \mathbf{X}} \|\mathbf{X}\|_1 + \lambda \|\mathbf{Y} - \mathbf{AX}\|_F^2 / 2, \quad (9)$$

is not convex, and guaranteeing a global optimum is difficult. The key observation is that if either \mathbf{A} or \mathbf{X} is fixed, the optimization (9) becomes convex in the remaining variable. This naturally suggests an alternating directions approach:

$$\mathbf{X}_{k+1} = \arg \min_{\mathbf{X}} \|\mathbf{X}\|_1 + \lambda \|\mathbf{Y} - \mathbf{A}_k \mathbf{X}\|_F^2 / 2 \quad (10)$$

$$\mathbf{A}_{k+1} = \arg \min_{\mathbf{A}} \|\mathbf{X}_{k+1}\|_1 + \lambda \|\mathbf{Y} - \mathbf{AX}_{k+1}\|_F^2 / 2. \quad (11)$$

Each of these subproblems can be solved efficiently. It is not difficult to show that this procedure converges to some pair $(\mathbf{A}_*, \mathbf{X}_*)$. However, unlike the problem of sparse coding in a known dictionary \mathbf{A} (as discussed above), for dictionary learning there is currently no theory to explain when the algorithm will succeed. This is partially a consequence of the fact that the unknowns \mathbf{A} and \mathbf{X} enter into the equation $\mathbf{Y} = \mathbf{AX}$ in a bilinear fashion – the dictionary learning problem is difficult to analyze for the same reason that it is difficult to solve.

Nevertheless, empirical evidence suggests that there are situations in which this approach learns

very effective data representations, and many researchers have used dictionary learning techniques to solve problems in image processing and vision. In fact, much of the initial excitement about sparsity in vision came from the classical paper of Olshausen and Field [1], which observed that the dictionary elements \mathbf{a}_i learned from natural images patches are similar to the receptive fields in the human visual system.

Many variants of the basic alternating directions approach have been investigated in the literature. For a more thorough history and additional references, we refer the interested reader to the survey paper [10].

Application

As alluded to above, at the time of this writing, numerous applications of sparse coding are being explored in the computer vision community. Due to their sheer number, most of these works lie beyond the scope of this article. In this section we briefly outline two examples of how the algorithms for sparse coding can be useful for solving problems in imaging and vision. The interested reader is invited to see [2] for a more thorough review.

Our first example comes from automatic face recognition [9]. In this application, the “dictionary elements” \mathbf{a}_i are training images of subjects in the database. Several images of each subject are taken under varying illumination, stacked as vectors in \mathbb{R}^m (here $m = W \times H$ is the number of image pixels), concatenated together to form a large matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$. Given a new test image \mathbf{y} taken under new illumination, and possibly subject to some additional corruption or occlusion, one can solve a sparse coding problem:

$$\text{minimize } \|\mathbf{x}\|_1 + \|\mathbf{e}\|_1 \text{ subject to } \mathbf{y} = \mathbf{Ax} + \mathbf{e}. \quad (12)$$

Here, the sparse “error” term \mathbf{e} allows some robustness to occlusion, while the sparse coefficients \mathbf{x} naturally select images of the same subject to participate in the representation of \mathbf{y} . This sparse code can be used for identifying the

subject pictured in \mathbf{y} or rejecting impostors not present in the database; see [9] for details.

Another representative example comes in image inpainting and superresolution [11, 12]. Suppose that patches \mathbf{y} of a given input image are known to have good sparse approximations in some dictionary \mathbf{A} , learned from a large collection of natural image patches. Suppose that some of the image pixels missing, so that rather than observing $\mathbf{y} \in \mathbb{R}^m$, we observe only a subset $\mathbf{y}(\Omega)$, where $\Omega \subset \{1 \dots m\}$. Then, one very natural approach to recovering the missing pixels is to solve a sparse coding problem (In [11], greedy algorithms are used, rather than ℓ^1 -minimization.)

$$\begin{aligned} & \text{minimize } \|\mathbf{x}\|_1 \text{ subject to} \\ & \|\mathbf{y}(\Omega) - \mathbf{P}_{\Omega} \mathbf{Ax}\|_2^2 \leq \varepsilon^2, \end{aligned} \quad (13)$$

where $\mathbf{P}_{\Omega} \in \mathbb{R}^{|\Omega| \times m}$ is a projection matrix onto the coordinates indexed by Ω . Once the solution $\hat{\mathbf{x}}$ is recovered, one can estimate the missing elements via $\hat{\mathbf{y}} = \mathbf{A}\hat{\mathbf{x}}$. For more examples of how sparse coding algorithms can be used in inpainting and related problems, see [11].

Open Problems

At the time of writing this article, there are numerous open problems in sparse coding, many of which are currently under vigorous attack. One question that has received significant recent attention is how to incorporate additional structure or prior knowledge into the algorithm to allow more accurate recovery of the sparse coefficients \mathbf{x} . This leads to notions such as “group sparse coding,” in which certain subsets of coefficients are known to all be either active or inactive, simultaneously [13].

For some vision applications, explaining the good performance of sparse coding techniques and understanding their limitations remain open problems. At the same time, with so much recent development, we arguably have yet to fully realize the full power of sparsity for vision problems.

Definition

Specular reflection occurs when light is incident on a boundary interface between two different media and immediately reflects back to the medium where it comes from. Specular reflectance is the ratio of the reflected light by a boundary interface to the incident light. The visual appearance of specular reflections is known as specularity or specular highlight. To find the regions of surfaces that exhibit specular reflections is generally known as specularity detection.

Background

Reflection of light from an object is principally caused by the surface and body of the object. The former is known as specular or interface reflection and the latter is body or diffuse reflection. The specular reflection is the shiny mirrorlike reflection, which is commonly present in both man-made and natural objects. Mirrors, glass, ceramics, gold, silver, many fruits' skins, some leaves, etc. emit specular reflections. Theoretically, by considering the definition, almost all objects emit specular reflections, although the amount of the reflections varies depending on the object's optical properties, such as the surface roughness and the Fresnel reflection coefficient.

There are two main reasons why specular reflection is important in computer vision: (1) Many algorithms in computer vision assume perfect diffuse reflections and deem specular reflections to be outliers. However, in the real world, the presence of specular reflections is inevitable. Hence, incorporating the knowledge of specular reflections is essential to make the algorithms more robust. (2) Many computer vision algorithms may benefit from the information conveyed by specular reflection. This information includes the photometric and the geometric information, where the photometric information may be important for material recognition and the geometric information may be useful for shape recognition.

Theory

Fresnel equations describe the reflection and transmission of light or electromagnetic waves at an interface between two media of differing refractive indices. According to the equations, when unpolarizing light impinges on a point of a flat and smooth surface, the reflection coefficient is $R = 0.5(R_{\perp} + R_{\parallel})$, where R_{\perp} and R_{\parallel} are the reflections of the electric field when it is perpendicular and parallel to the surface, respectively. The reflection coefficient is dependent on the angle of incoming light with

respect to the surface normal and the refractive indices of the two media.

When a surface is perfectly flat and smooth (i.e., a perfect mirror), the direction of specular reflection will follow the law of reflection, which states the angle of incoming light θ_i and the angle of outgoing reflected light θ_r are the same ($\theta_i = \theta_r$). This implies that the specularly reflected light cannot be seen by an observer if the observer's position is not at the same direction as θ_r , which is true for the case of perfect mirrors. However, in many objects which are not perfect mirrors, a certain degree of specularity is still observable, even though the observer's position is slightly apart from the direction of θ_r . In other words, specular reflections do not only form a sharp line (spike) distribution of reflection but also form a lobe distribution. Therefore, there are two components of specular reflections: (1) specular spike and (2) specular lobe.

The Torrance-Sparrow reflection model [1] provides a good approximation of the specular lobe component, which is expressed as:

$$\rho = \frac{FG}{\cos \theta_r} \exp \left(-\frac{\alpha^2}{2\sigma^2} \right) \quad (1)$$

where F is the Fresnel reflection coefficient, G is the geometrical attenuation factor, θ_r is the angle between the viewing direction and the surface normal, α is the angle between the surface normal and the bisector of the viewing direction and the light source direction, and σ represents the surface roughness.

The Torrance-Sparrow reflection model uses geometric optics to describe the mechanism of specular reflection, which is only valid when the wavelength of light is much smaller than the roughness of the surface. According to [2], the model uses a slope distribution model to represent the profile of a surface. The surface is assumed to be a collection of planar microfacets, where their dimension is much larger than the wavelength of incident light. Each microfacet is perfectly smooth, and the orientation of each facet deviates from the mean orientation of the surface by an angle α . The model considers the masking and shadowing of microfacets by

adjacent facets, where they can block light going into a facet or light reflected by it. The geometrical attenuation factor, G , is introduced to compensate the masking and shadowing effect. The surface roughness, σ , represents the spatial distribution of the lobe. The larger the value of σ , the larger the lobe distribution (implying less shiny surfaces), and vice versa. In this reflection model, the distribution of the specular reflections follows the Gaussian distribution, with mean α and standard deviation σ . Later, Cook and Torrance [3] replaced the Gaussian distribution with the Beckmann distribution function.

While the Torrance-Sparrow reflection model is able to approximately generate a mirrorlike distribution, namely, when σ is considerably small, its main drawback is that it cannot generate both the specular spike and specular lobe at the same time. To overcome this drawback, Nayar et al. [2] introduced a model unifying Torrance-Sparrow's specular lobe and a spike specular model, and the latter is modeled as:

$$K_{ss}\delta(\theta_i - \theta_r)\delta(\phi_r) \quad (2)$$

where K_{ss} is the strength of the specular spike and (θ_r, ϕ_r) is the direction of the reflected. Nayar et al. base their analysis on the Beckmann-Spizzichino reflection model [4], which predicts the presence of both the specular lobe and spike. Unlike the Torrance-Sparrow reflection, the Beckmann-Spizzichino reflection model is based on physical optics analysis derived from Maxwell's equations.

In comparison with diffuse reflections, in principle, specular reflections have three different properties [5]:

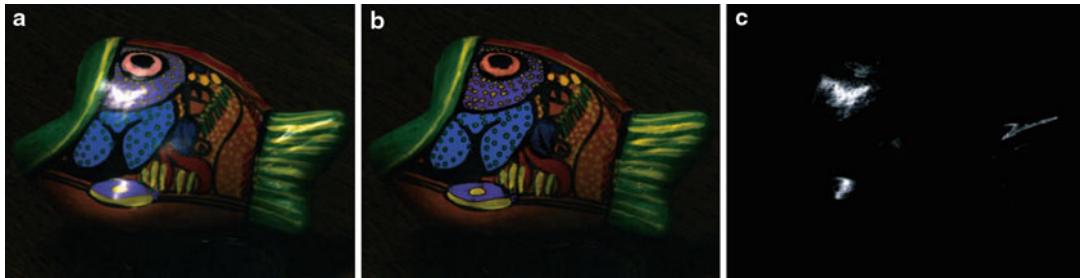

1. The diffuse and specular reflections have different degrees of polarization (DOP). The DOP represents the ratio of the light being polarized. For unpolarized incident light, the DOP of specular reflection is larger than that of diffuse reflection for most angles of incidence light, meaning that specular reflection is generally more polarized than diffuse reflection [6–8].

2. While recently a number of researchers (e.g., [9]) have introduced more complex models, the intensity distribution of diffuse reflections approximately follows Lambert's law [10]. In contrast, the intensity distribution of specular reflections generally follows the Torrance-Sparrow reflection model [1].
3. For optically inhomogeneous objects, the spectral power distribution (SPD) of specular reflection is determined by the object's interface spectral reflectance, which is mostly constant throughout the wavelength of visible spectrum, causing the SPD of specular reflections to be the same as the illumination's SPD [11]. In contrast, the SPD of diffuse reflection is determined by the object's body spectral reflectance. This spectral power distribution (color) independence of diffuse and specular reflections was described in the dichromatic reflection model proposed by Shafer [12].

Note that the condition that the SPD of specular reflections is the same as the illumination's SPD is called neutral interface reflection or NIR [11]. This mostly occurs for the surfaces of optically inhomogeneous objects (such as ceramics, plastics, paints); however, it does not always occur for the surfaces of optically homogeneous objects (such as gold, bronze, copper) [13].

Application

Many existing algorithms in computer vision assume perfect diffuse surfaces and deem specular reflections to be outliers. However, in the real world, the presence of specular reflections is inevitable since there are many objects that exhibit both diffuse and specular reflections. To properly acquire the diffuse-only reflections, a method to separate the two components robustly and accurately is required (e.g., [5]; see Fig. 1 for an example of the separation). Once this separation has been accomplished, the specular reflection component can be advantageous since it conveys useful information of the object photometric properties (e.g., [6, 14]). Moreover,

Specularity, Specular Reflectance, Fig. 1 (a) A dichromatic object exhibiting both diffuse and specular reflection. (b) The separated diffuse reflection component.

(c) The separated specular reflection component. The results were computed using [5]

specular highlights are useful for estimating illumination colors or color constancy (e.g., [15]). Aside from the photometric properties, specular reflections can be employed to estimate the geometric properties (e.g., [16–18]).

Open Problems

Without knowing the polarizing states and only analyzing image intensities, specularity detection from a single image is still an open problem.

- ▶ Parametric Curve

Definition

In mathematics, splines are piecewise continuous functions, such as polynomials, defined in successive subintervals. They are often used to represent one- or multidimensional data set (e.g., a curve or a surface) in the applications requiring interpolation, smoothing or nonrigid transformation [1]. For example, a spline curve is a piecewise collection of curve segments defined in polynomials that are connected end to end to form a single continuous curve. A curve in L -dimensional space can be simply defined by the following form:

$$S : [a, b] \rightarrow \mathbb{R}^L, \quad (1)$$

where function S takes variables from an interval $[a, b]$ and maps them to an L -dimensional real number. If the interval $[a, b]$ is divided into k ordered disjoint subintervals t_i, t_{i+1} with

$$a = t_0 \leq t_1 \leq \cdots \leq t_k = b, i = 0, \dots, k - 1, \quad (2)$$

then in each subinterval $[t_i, t_{i+1}]$ there is a polynomial defined as

$$P_i : [t_i, t_{i+1}] \rightarrow \mathbb{R}^L. \quad (3)$$

Therefore,

$$S(t) = P_i(t), t_i \leq t < t_{i+1}, \quad (4)$$

where t_i is called a *knot* and vector $\mathbf{t} = (t_0, \dots, t_k)^T$ is called a *knot vector*.

Many types of splines have been developed through that $P(t)$ is defined in different types of functions. Some examples of representative splines are Bézier spline, B-spline, Nonuniform rational B-spline and Thin-plate spline which are briefly introduced in the following sections.

Bézier Spline

The polynomial for Bézier spline of degree n is

$$P(t) = \sum_{i=0}^n B_i^n(t) \mathbf{p}_i, \quad (5)$$

where $\mathbf{p}_i (\in \mathbb{R}^L)$ are called the control points of a Bézier spline, and $B_i^n(t)$ are the basis functions determined by *Bernstein polynomials* of degree n as

$$B_i^n(t) = \frac{n!}{i!(n-i)!} t^i (1-t)^{n-i}. \quad (6)$$

Several Bézier spline curves can be concatenated by sharing the first and last control points. While a Bézier spline has C^1 continuity to its defined interval, at the shared control points it gets C^0 continuity. C^1 continuity can be achieved by sharing two control points at the end of two curves. An improvement that adds an adjustable weight to each basis can make it easier to control and more closely approximated to arbitrary shapes.

B-Spline

Similar to Bézier spline, the polynomial for B-spline is defined as

$$P(t) = \sum_{i=0}^n N_{i,k}(t) \mathbf{p}_i, \quad (7)$$

where \mathbf{p}_i ($\in \mathbb{R}^L$) are called the control points of a B-spline curve and the basis functions $N_{i,k}(t)$ of degree k can be derived by the recurrence equations as

$$N_{i,1}(t) = \begin{cases} 1 & (t_i \leq t < t_{i+1}) \\ 0 & (\text{otherwise}) \end{cases} \quad (8)$$

$$\begin{aligned} N_{i,k}(t) &= \frac{t-t_i}{t_{i+k-1}-t_i} N_{i,k-1}(t) \\ &+ \frac{t_{i+k}-t}{t_{i+k}-t_{i+1}} N_{i+1,k-1}(t) \end{aligned} \quad (9)$$

The knots t_i for B-spline are generally with uniform, open uniform or nonuniform intervals.

Compared to Bézier splines, B-splines can have C^2 continuity at the joint control points. B-splines are more flexible and pleasing to work with, and thus it is popular in various graphics development environment.

Nonuniform Rational B-Splines (NURBS)

Since B-spline can be viewed as weighted sum of its control points and the weights $N_{i,k}$ usually have the property: $\sum_{i=0}^n N_{i,k}(t) = 1$. As weights $N_{i,k}(t)$ of B-spline depend only on the knot vector, it is useful to add to every control point one more weight w_i which can be set independently as

$$P(t) = \frac{\sum_{i=0}^n w_i N_{i,k}(t) \mathbf{p}_i}{\sum_{i=0}^n w_i N_{i,k}(t)}. \quad (10)$$

Then increasing a weight w_i makes the point more influential and attracts the curve to it. NURBS is often employed in computer-aided design systems.

Spline Surface

Not only for curve representation, spline is easy to be extended for representing a surface segment. Appropriately parameterized 2D variables are required for defining the 2D region subinterval to control a surface. For example, through a parameterized $u-v$ plane, Bézier spline can be used to represent a surface with the following form:

$$P(u, v) = \sum_{i=0}^m \sum_{j=0}^n B_i^m(u) B_j^n(v) \mathbf{p}_{ij}, \quad (11)$$

where \mathbf{p}_{ij} ($\in \mathbb{R}^3$) are the control points of Bézier spline surface.

Thin-Plate Spline (TPS)

Different to Bézier spline or B-spline in parametric form, Thin-plate spline (TPS) explicitly takes the point \mathbf{x} on a curve or a surface as the variable and maps it to a new value $f(\mathbf{x})$. A TPS function is often composed of a summation of radial basis functions and a low-order polynomial, e.g., defined in the following form:

$$f(\mathbf{x}) = \sum_{i=0}^N w_i \phi(\|\mathbf{x} - \mathbf{c}_i\|) + \mathbf{v}^T \begin{bmatrix} 1 \\ \mathbf{x} \end{bmatrix}, \quad (12)$$

where \mathbf{c}_i are the control points of TPS; w_i are the mapping coefficients through weighting the basis functions $\phi(\cdot)$; \mathbf{v} is the coefficient vector of the polynomial of degree 1; basis function $\phi(\cdot)$ is defined as

$$\phi(r) = \begin{cases} r^k & \text{with } k = 1, 3, 5, \dots, \\ r^k \ln(r) & \text{with } k = 2, 4, 6, \dots, \end{cases} \quad (13)$$

where k is equal to the dimension of dataset.

TPS has been widely applied for building a smooth nonrigid transformation model, by minimizing the integral bending energy [4]. It is also useful for data interpolation, since it can explicitly represent the arbitrarily spaced tabulated data set, e.g., $(x_i, y_i, f(x_i, y_i))$ in 2D case. The interpolation is smooth with derivatives of any order.

Background

The idea of presenting a curve using the connection with splines comes from the ship building industry, where they construct templates for ships by passing thin strips of wood (called “splines”). In some subfields of computer science, wide class of spline functions are applied to the applications where the discrete data requires interpolation

and/or smoothing. Because splines are superior in terms of the following qualities: the simplicity of their construction, the ease and accuracy of control, their capacity to approximate complex shapes and the ability to design curves interactively.

Application and Theory

In addition to the usages of interpreting or smoothing for image representation, such as the work in [9], splines also play an important role in some specific computer vision applications. For example, in the Snake-based image segmentation designed by Kass et al. [5] and modified by Brigger et al. [3], splines are used to model the image contours by minimizing the energy under the guidance of external and internal forces; For image motion estimation, Szeliski and Coughlan [8] proposed to represent the local motion flow field using multi-resolution splines; A classical linear method for estimating the TPS coefficients for image warps is proposed by Bookstein [2]; And Free Form Deformation (FFD) proposed by Sederberg [7] represents the nonrigid deformation of object using grid B-splines, which has a successful application in medical image registration [6].

Synonyms

CIE standard illuminant

Related Concepts

► Chromaticity

Definition

A standard illuminant, as defined by the International Commission on Illumination (Commission International de L'Eclairage, abbreviated as the CIE), denotes a specific relative distribution of energy (“spectral power distribution”) for an illuminant, over the range 300–830 nm [3].

S

Background

The motivation for a definition of standard illuminants arises from the need for accurate measurement of the colors of objects. It is well understood that for a Lambertian surface with a spectral reflectance function given by $r(\lambda)$, and under an illuminant given by $i(\lambda)$, the three-vector of CIE

XYZ tristimulus values is given by [8]:

$$\begin{aligned} X &= k \int_{\lambda} \bar{x}(\lambda) i(\lambda) r(\lambda) d\lambda \\ Y &= k \int_{\lambda} \bar{y}(\lambda) i(\lambda) r(\lambda) d\lambda \\ Z &= k \int_{\lambda} \bar{z}(\lambda) i(\lambda) r(\lambda) d\lambda, \end{aligned} \quad (1)$$

where \bar{x} , \bar{y} , \bar{z} denote the three CIE XYZ color-matching functions (based on a standard observer) and k is a constant. Working in the XYZ color space – natively three-dimensional in nature – when a color changes it is difficult to attribute the change to a specific function of wavelength, because of the above 3-D projection: the observer color-matching functions $\{\bar{x}, \bar{y}, \bar{z}\}$, the illuminant $i(\lambda)$, or the object's reflectance $r(\lambda)$. When the primary objective of a measurement is to quantify the object's reflectance properties, it is therefore helpful to use a standard observer and a standard illuminant. The standardization of the observer is well documented in various CIE standards since the early 1900s, most recently in CIE 15-2004 [1].

Theory

In CIE-1998c (and in CIE 15-2004), the CIE defines the following standard illuminants, along with their relative spectral power distribution, in the spectral range 300–830 nm [1, 3]:

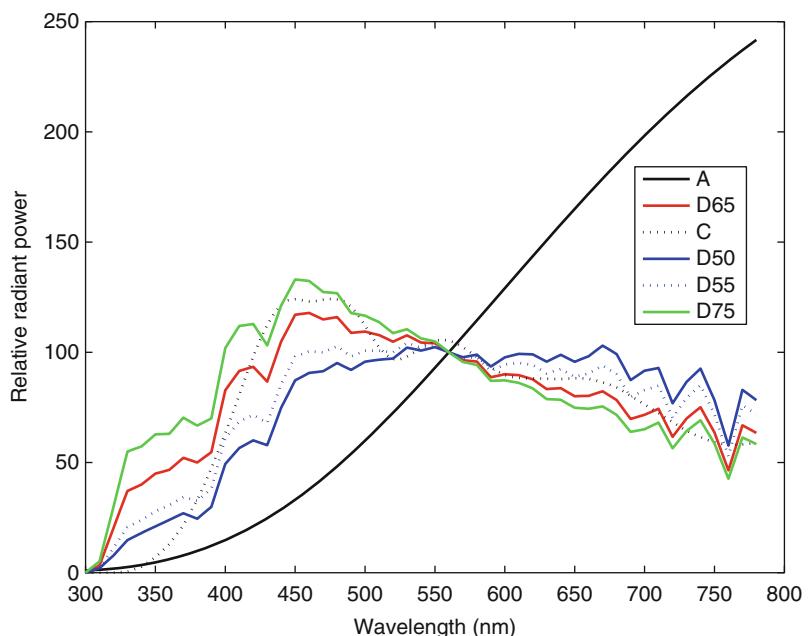

- Standard Illuminant A
- Standard Illuminant C
- Standard Illuminant D50
- Standard Illuminant D55
- Standard Illuminant D65
- Standard Illuminant D75

The spectral range 300–830 nm, wider than the range of visual perception, which is approximately 360–830 nm [8, p.122], is used specifically to enable the evaluation of luminescent samples where the ultraviolet range becomes important. For colorimetric measurements, however, typically 380–780 nm is used.

Standard Illuminant A represents a black-body radiator with a temperature of approximately 2,856 K. Standard Illuminant C, although not used often, represents average daylight with

Standard Illuminants,

Fig. 1 Standard illuminants as specified by the CIE, normalized to a peak of 100 at 560 nm

Standard Illuminants,

**Standard Illuminants,**

Fig. 3 Component vectors (S_0, S_1, S_2 defined by the CIE), also considered as the mean and two additional eigenvectors of the space of daylight illuminants

correlated color temperature of about 6,800 K. Standard Illuminant D65 is used to represent a phase of daylight with a correlated color temperature of approximately 6,500 K and is by far the most commonly used standard illuminant in colorimetry. Other D-illuminants are standard

daylight illuminants annotated with the first two digits of their correlated color temperature; e.g., D55 denotes a standard daylight illuminant with a correlated color temperature of 5,500 K. Figure 1 shows the relative spectral power distributions of the above standard illuminants.

Standard Illuminants,

Fig. 4 Daylight illuminants of different correlated color temperatures as computed from the component vectors (S_0, S_1, S_2 defined by the CIE)

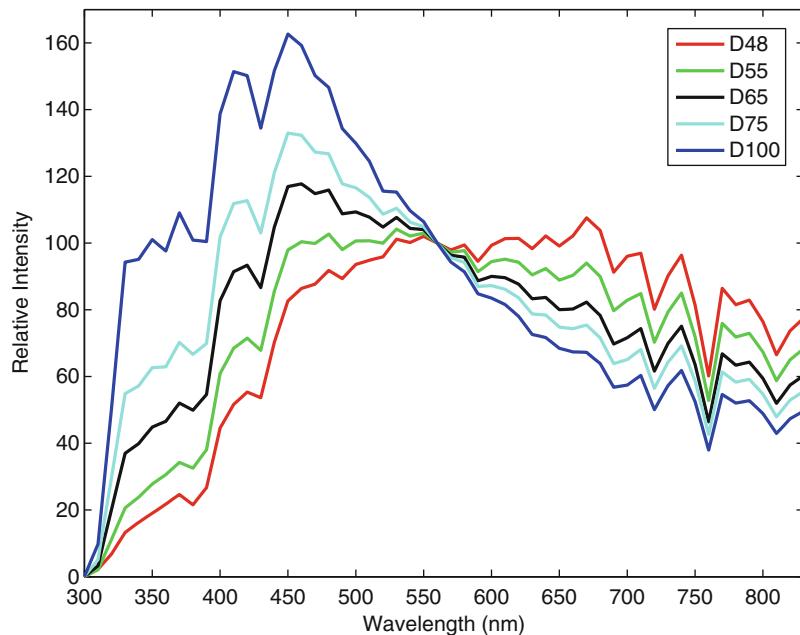

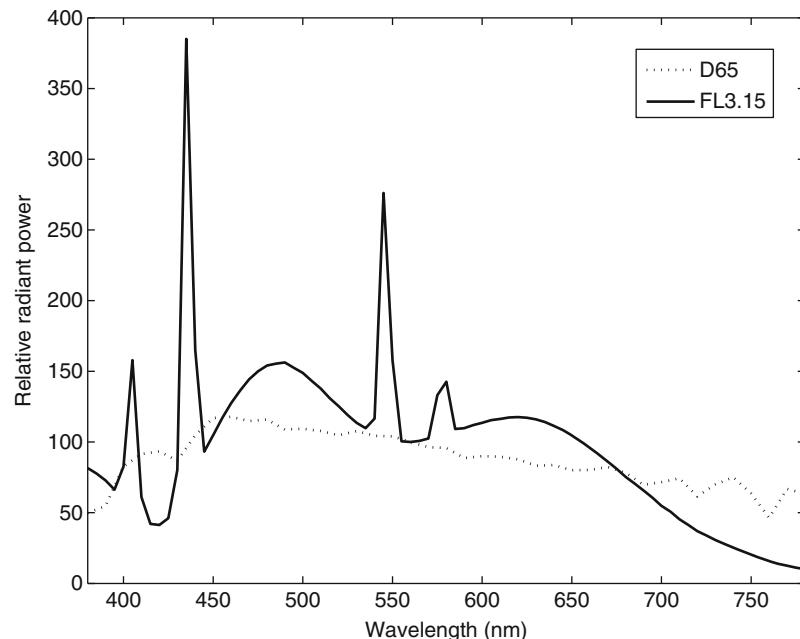

**Standard Illuminants,**

Fig. 5 Comparison of a standard illuminant (D65) and a standard source (FL 3.15) normalized to 100 at 560 nm

It is to be noted that although the plots in Fig. 1 show the spectra in the extended range from 300 to 780 nm (as is given in the CIE standard), data from 300–330 nm to 780–830 nm is extrapolated, but considered sufficiently accurate for colorimetric purposes. Further, the standard provides data to 5 nm increments, and should finer

increments be needed the standard recommends performing linear interpolation on the spectra.

The correlated color temperature (T) of a daylight illuminant, for the purposes of interpolating standard daylights, is related to its chromaticity coordinates in the x, y chromaticity diagram by the following equations [6, p. 111]:

$$y_D = -3.0000x_D^2 + 2.870x_D - 0.275 \quad (2)$$

$$x_D = \begin{cases} \frac{-4.6070 \times 10^9}{T^3} + \frac{2.9678 \times 10^6}{T^2} + \frac{0.09911 \times 10^3}{T} + 0.244063, & 4,000 \text{ K} \leq T \leq 7,000 \text{ K} \\ \frac{-2.0064 \times 10^9}{T^3} + \frac{1.9018 \times 10^6}{T^2} + \frac{0.24748 \times 10^3}{T} + 0.237040, & 7,000 \text{ K} \leq T \leq 25,000 \text{ K}. \end{cases} \quad (3)$$

Note that several other suggestions for a best CCT have been posited [4, 7].

Figure 2 shows the locus of chromaticities of standardized daylight illuminants, specifically denoting the locations D55, D65, and also, for reference, the location of illuminant A and the equi-energy point, E ($x = y = 0.33$) (all for the CIE 1931 2° observer).

The CIE also specifies equations to compute the relative spectral power distribution of other D-illuminants as a function of their x,y chromaticity coordinates.

$$S(\lambda) = S_0(\lambda) + M_1 S_1(\lambda) + M_2 S_2(\lambda), \quad (4)$$

where $S_0(\lambda)$, $S_1(\lambda)$, and $S_2(\lambda)$ are specified in the CIE standard [1] and plotted in Fig. 3. These may be considered as the mean and the following two eigenvectors of the space of daylight illuminants [5].

M_1 and M_2 are scale factors defined as a function of the chromaticity coordinate of illuminant, given by:

$$M_1 = \frac{-1.3515 - 1.7703x_D + 5.9114y_D}{0.0241 + 0.2562x_D - 0.7341y_D} \quad (5)$$

$$M_1 = \frac{0.03 - 31.4424x_D + 30.0717y_D}{0.0241 + 0.2562x_D - 0.7341y_D}. \quad (6)$$

These equations provides the relative spectral power distribution of the various D-illuminants, which are shown in Fig. 4. Customarily, $S(\lambda)$ is scaled such that its value at wavelength $\lambda = 560 \text{ nm}$ is 100.

It is perhaps most important to note that standard illuminants are not the same as standard sources – which are the real-world equivalents of standard illuminants. In other words, a standard illuminant – defined by its relative spectral

power – may not necessarily be realizable by a physical emitter of radiation (see Fig. 5 for an example of a D65 source made by a fluorescent lamp and the D65 illuminant). The details of the challenges between the “theoretical” illuminant that is useful for computations and the “real” source may be found in a different CIE standard [2], and also in the book by Wyszecki and Stiles [8].

Department of Statistics, UCLA, Los Angeles,
CA, USA

Related Concepts

► [Principal Component Analysis \(PCA\)](#)

Definition

Statistical independence is a concept in probability theory. Two events A and B are statistical independent if and only if their joint probability can be factorized into their marginal probabilities, i.e., $P(A \cap B) = P(A)P(B)$. If two events A and B are statistical independent, then the conditional probability equals the marginal probability: $P(A|B) = P(A)$ and $P(B|A) = P(B)$. The concept can be generalized to more than two events. The events A_1, \dots, A_n are independent if and only if $P(\cap_{i=1}^n A_i) = \prod_{i=1}^n P(A_i)$.

Theory

Two random variables X and Y are independent if and only if the events $\{X \leq x\}$ and $\{Y \leq y\}$ are independent for all x and y , that is, $F(x, y) = F_X(x)F_Y(y)$, where $F(x, y)$ is the joint cumulative distribution function and F_X and F_Y are the marginal cumulative distribution functions of X and Y , respectively. If X and Y are continuous random variables, then X and Y are independent if $f(x, y) = f_X(x)f_Y(y)$, where $f(x, y)$ is the joint probability density function and f_X and f_Y are the marginal probability density functions of X and Y , respectively. Similar results hold when both X and Y are discrete, or one is discrete and the other is continuous.

If two random variables X and Y are independent, then their covariance $\text{Cov}(X, Y) = E(XY) - E(X)E(Y) = 0$, that is, they are uncorrelated. However, the reverse may not be true. Two

uncorrelated random variables are not necessarily independent of each other. For example, if $X \sim \text{Uniform}[-1, 1]$ and $Y = X^2$, then $\text{Cov}(X, Y) = 0$, but clearly they are not independent.

The concept of independence can be generalized to more than two random variables. In probability theory, the law of large number, the central limit theorem, and concentration inequalities are usually obtained for independent random variables, although these results can be generalized to dependent random variables. In statistical learning theory, it is usually assumed that the training and testing examples are independent and identically distributed.

Application

Statistical independence is a key assumption in independent component analysis (ICA) [1], where the observed multivariate signal is assumed to be linear mixing of independent sources. A useful extension is independence is conditional independence. Two events A and B are independent given event C if $P(A \cap B|C) = P(A|C)P(B|C)$. If X , Y , and Z are discrete random variables, then X and Y are independent given Z if $P(X = x, Y = y|Z = z) = P(X = x|Z = z)P(Y = y|Z = z)$ for all x , y , z . If X , Y , and Z are continuous, then X and Y are independent given Z if $f_{X, Y|Z}(x, y|z) = f_{X|Z}(x|z)f_{Y|Z}(y|z)$, where $f_{X, Y|Z}$ is the conditional probability density function of (X, Y) given Z and $f_{X|Z}$ and $f_{Y|Z}$ are the conditional probability density functions of X given Z and Y given Z , respectively.

Conditional independence is a key assumption in Markov chains, Markov random fields, and more generally graphical models [2].

Definition

What is shape? Although the use of words *shape* or *shape analysis* is very common in computer vision, its definition is seldom made precise in a mathematical sense. According to the Oxford English Dictionary, it means “the external form or appearance of someone or something as produced by their outline.” Kendall [1] described shape as a mathematical characteristic of an object that remains unchanged under certain transformations such as rotation, translation, and global scaling. Shape analysis seeks to represent shapes as mathematical quantities, such as vectors or functions, that can be manipulated using appropriate rules and metrics. *Statistical* shape analysis is concerned with quantifying shape as a random quantity and developing tools for generating shape comparisons, averages, probability models, hypothesis tests, Bayesian estimates, and other statistical procedures on shape spaces.

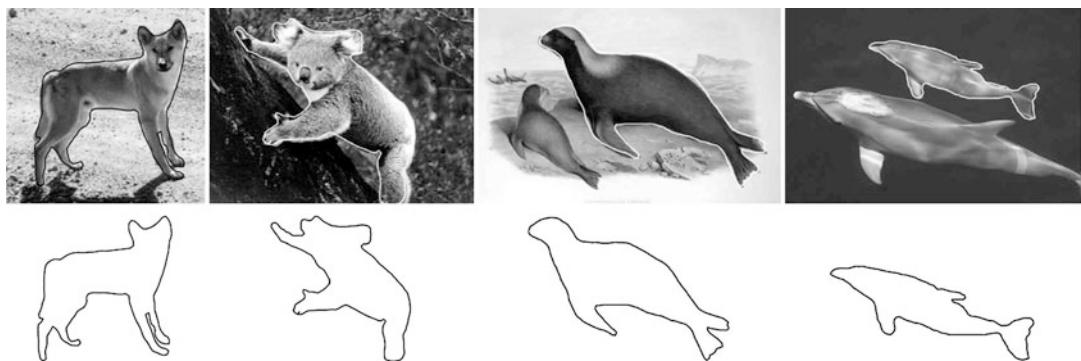

Background

Shape is an important physical property of objects that characterizes their appearances and can play an important role in their detection,

tracking, and recognition in images and videos. One usually restricts to the boundaries of objects, rather than the whole objects, for shape analysis and that leads to a shape analysis of curves (for 2D images) and surfaces (for 3D images). Figure 1 suggests that shapes of boundaries can help characterize objects present in images. A boundary contains only some partial information about the object since the color (texture) information inside and outside the boundary is lost. With the help of this limited information, it is often possible to broadly classify an object using shape analysis.

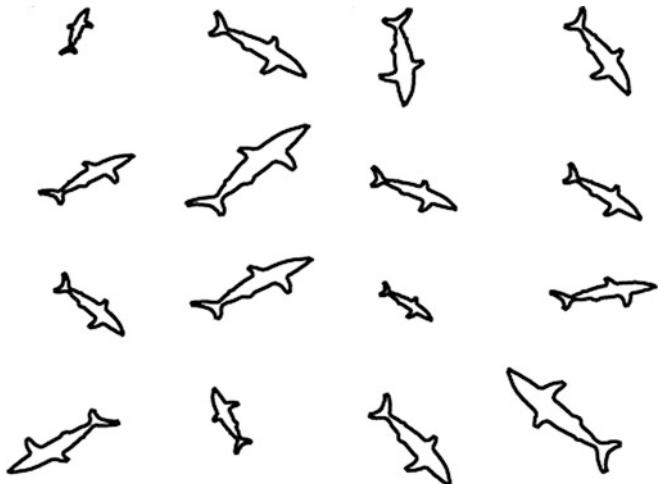

To understand the issues and challenges in shape analysis, one has to look at the imaging process since that is a major source of shape data. A picture can be taken from an arbitrary pose (arbitrary distance and orientation of the camera relative to the imaged object), and this introduces a random rotation, translation, and scaling of boundaries in the image plane. Therefore, any proper metric for shape analysis should be independent of the pose and scale of the boundaries. A visual inspection also confirms that any rotation, translation, or scaling of a boundary, while changing its coordinates, does not change its shape. Figure 2 shows an example of 16 curves that differ in orientations, scales, and locations but still represent the same shape.

In case of parameterized curves and surfaces, an additional challenge arises when it comes to invariance. Let $\beta : [0, 1] \rightarrow \mathbb{R}^2$ represent a parameterized curve and let $\gamma : [0, 1] \rightarrow [0, 1]$ be a smooth, invertible function such that $\gamma(0) = 0$ and $\gamma(1) = 1$. Then, the composition $\tilde{\beta}(t) \equiv (\beta \circ \gamma)(t)$ represents a curve with coordinate functions that are different from those of $\beta(t)$ but have the same shape. $\tilde{\beta}$ is called a *reparameterization* of β . Figure 3 illustrates this issue with a simple example. It shows that the coordinate functions of the reparameterized curve, $\tilde{\beta}_x(t)$ and $\tilde{\beta}_y(t)$, as functions of t , are different from the original coordinate functions $\beta_x(t)$ and $\beta_y(t)$. But when $\tilde{\beta}_x(t)$ is plotted versus $\tilde{\beta}_y(t)$, it traces out the same curve as that traced by $\beta_x(t)$ versus $\beta_y(t)$. This results in an additional invariance requirement in shape analysis of parameterized curves (and similarly for surfaces). That is, the

Statistical Shape Analysis, Fig. 1 Shapes of boundary curves are useful in object characterizations

Statistical Shape Analysis, Fig. 2 Sixteen curves with different orientations, scale, and locations, but with identical shapes

shape metrics should be invariant to how the curves are parameterized.

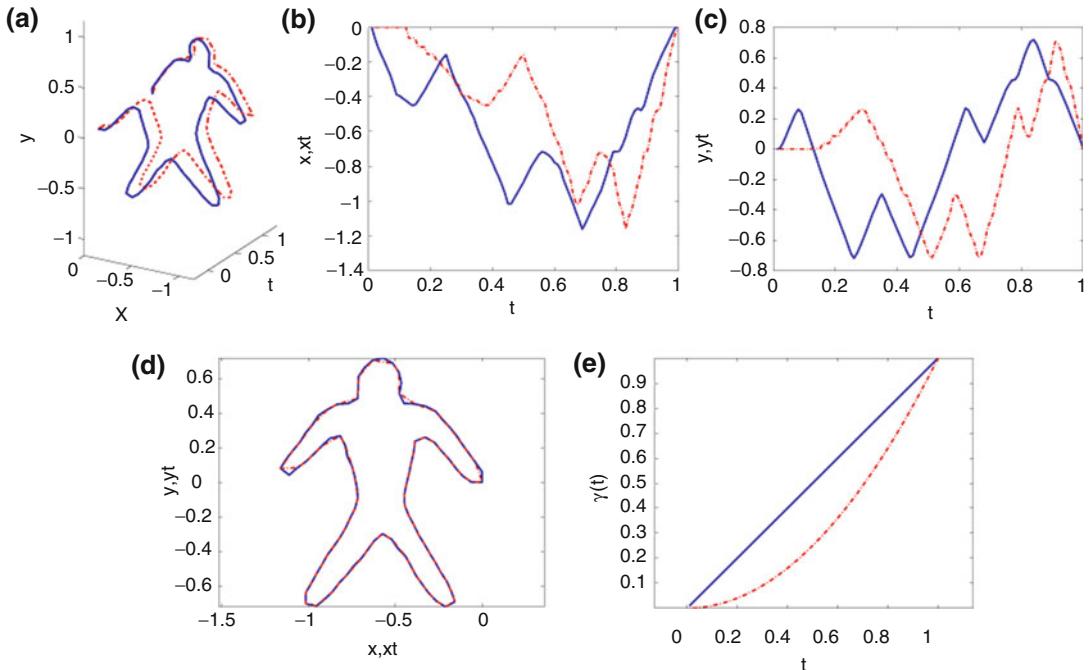

In *statistical* shape analysis, one treats shapes as random quantities and tries to answer questions of the type:

- What is the difference between shapes of any two given objects? How can such shape differences be quantified while maintaining the desired invariances?
- What shape best represents the shapes of a given collection of objects? Another way to ask the same questions is: What is the statistical average of a given collection of shapes?
- What are the principal modes of variations in a given set of shapes?
- How can one capture the main shape variability in a population using probability models?

Can random shapes be generated from such models?

- How can one use such probability models for shape classification and object recognition?

To answer such questions, one needs precise mathematical representations of shapes and tools from algebra and geometry for analyzing them. In the literature there are numerous mathematical representations of objects that have been used for this purpose. These representations include (unordered) point sets, (ordered) landmarks, level sets, deformable templates, medial representations, and parameterized curves and surfaces. An important aspect, common to most representations, is the nonlinear geometry of a shape space. It is easy to recognize that shape is not a quantity that can be added, averaged, or grouped easily

Statistical Shape Analysis, Fig. 3 Reparameterized curve has different coordinate functions but same shape as the original curve. (a) Curves $(t, \beta_x(t), \beta_y(t))$ and

$(t, \tilde{\beta}_x(t), \tilde{\beta}_y(t))$; (b) $\beta_x(t)$ and $\tilde{\beta}_x(t)$; (c) $\beta_y(t)$ and $\tilde{\beta}_y(t)$; (d) curves $(\beta_x(t), \beta_y(t))$ and $(\tilde{\beta}_x(t), \tilde{\beta}_y(t))$; and, (e) $\gamma(t)$

using Euclidean calculus. The desired invariance of shape to certain transformations (rigid motion, global scaling, and reparameterization) implies that certain nontraditional tools are needed.

Among the different methods used in shape analysis, the earlier methods typically represented objects by finite sets of points, such as point sets or landmarks, but more recent methods are beginning to handle parameterized curves and surfaces directly as functions. Two of the earlier ideas based on point set representations are summarized next.

Active Shape Models (ASM) The active shape models approach to shape analysis was introduced by Cootes and Taylor in [2]. The simplest idea in shape analysis is to sample the boundaries at a number of points and form polygonal shapes by connecting those points with straight lines. Of course, the number and locations of these points on the objects can drastically change the resulting polygonal shapes, but this issue will be disregarded for the moment. One can organize

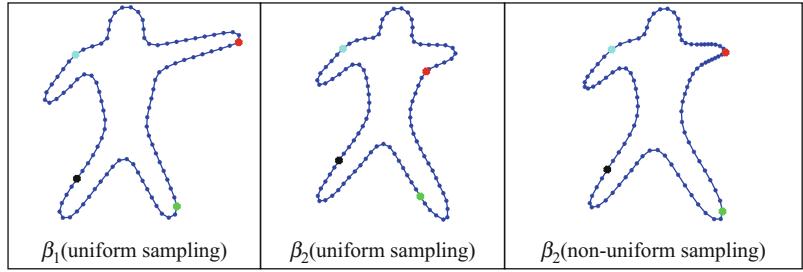

the coordinates of these points in a form of a vector of coordinates and perform standard vector calculus. Let $x \in \mathbb{R}^{n \times 2}$ represent n ordered points selected from the boundary of an object. It is often convenient to identify points in \mathbb{R}^2 with elements of \mathbb{C} , i.e., $x^i \equiv z^i = (x^{i,1} + jx^{i,2})$, where $j = \sqrt{-1}$. Thus, in this complex representation, a configuration of n points x is now $z \in \mathbb{C}^n$. Before analyzing the shape of z , it is “standardized” by moving its center to the origin (of the coordinate system):

$$z^i \mapsto (z^i - \frac{1}{n} \sum_{i=1}^n z^i).$$

To remove the scale variability, z is rescaled to have norm one, i.e., $z \mapsto z/\|z\|$. Then, one uses tools from standard multivariate statistics to analyze and model them. So far, the translation and the scale variability of a configuration are removed, but the rotation still remains a part of the representation. That is, two configurations,

Statistical Shape Analysis, Fig. 4

Registration of points across two curves using the uniform and a convenient nonuniform sampling. Non-uniform sampling allows a better matching of features between β_1 and β_2

z and a rotation of z , will have a nonzero distance between them even when they have the same shape. This problem is solved by using an additional step of rotational alignment when comparing shapes, as follows:

$$\begin{aligned} \phi^* &= \operatorname{argmin}_{\phi \in \mathbb{S}^1} \|z_1 - e^{j\phi} z_2\|^2 \\ &= \operatorname{argmin}_{\phi \in \mathbb{S}^1} (\|z_1\|^2 + \|e^{j\phi} z_2\|^2 \\ &\quad - 2\Re(\langle z_1, e^{j\phi} z_2 \rangle)) \\ &= \operatorname{argmax}_{\phi \in \mathbb{S}^1} (\Re(e^{-j\phi} \langle z_1, z_2 \rangle)) = \theta, \\ &\text{where } \langle z_1, z_2 \rangle = r e^{j\theta}, \end{aligned} \quad (1)$$

and $\langle \cdot, \cdot \rangle$ is the standard Hermitian inner product. The distance between the two rotationally aligned configurations is then $\|z_1 - e^{j\phi^*} z_2\| = \sqrt{2(1-r)}$. The corresponding optimal deformation from one shape to another is simply a straight line between z_1 and $e^{j\phi^*} z_2$, i.e., $\alpha_{asm}(\tau) = (1-\tau)z_1 + \tau e^{j\phi^*} z_2$ for $\tau \in [0, 1]$.

One remaining issue in this analysis is that on a closed curve which point should be selected as z^1 , the first point or the *seed*. If there are n points sampled on a curve, then there are n candidates for the seed. The solution is to select the best seed during a pairwise comparison of configurations. That is, select any point on the first configuration as the seed for the first shape, and try all n points in the second configuration as candidate seeds for the second shape. Of those, select the one that results in the smallest distance from the first configuration. Figure 5 shows several examples of these deformations: one between a pair of human silhouettes, one between a pair of hands,

and so on. These geodesics have been computed using $n = 200$ points on each configuration so that the resulting polygons look like smooth curves.

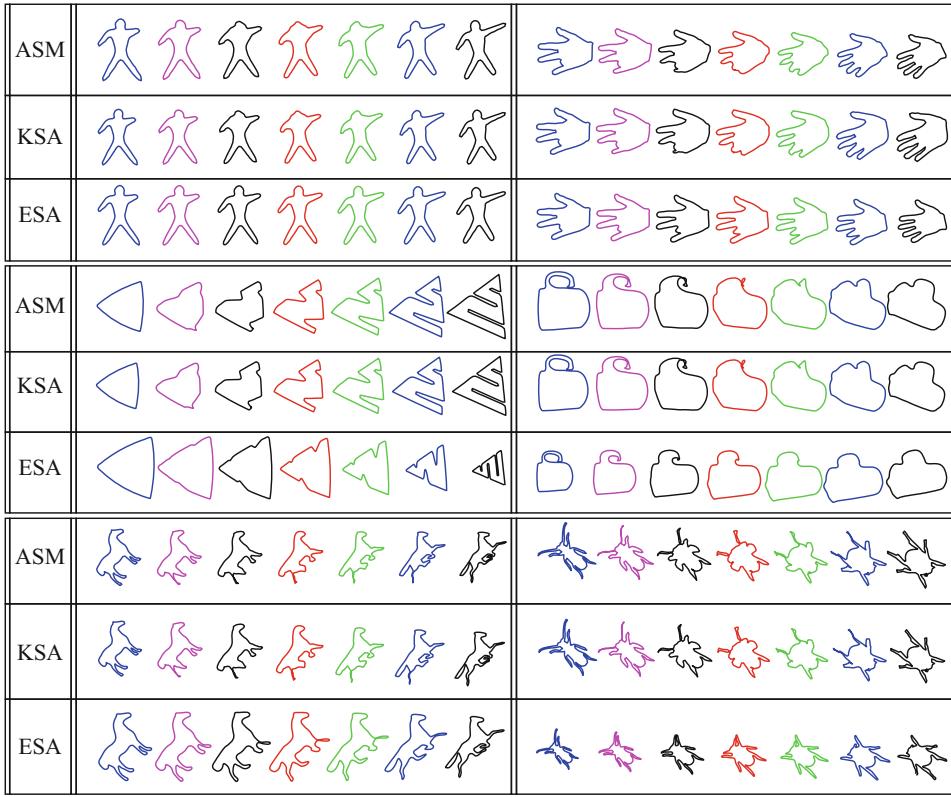

One can define the mean shape of several configurations z_1, z_2, \dots, z_k as the configuration that minimizes the sum of squares of distances:

$$\begin{aligned} \mu_{asm} &= \operatorname{argmin}_{z \in \mathbb{C}^n} \sum_{i=1}^k \|z - e^{j\phi_i^*} z_i\|, \\ \phi_i^* &= \cos^{-1}(\Re(\langle z, z_i \rangle)). \end{aligned}$$

Figure 6 shows several illustrations of the mean computations

Although this technique is relatively simple and fast, it has some important limitations. One limitation is that it does not preserve the scale constraints imposed on the shape representations. For instance, the intermediate shapes along the optimal deformations between any two unit-length configurations do not have unit length. Similarly, the mean shape of $\{z_i\}$ is generally not of unit length. This is because no effort is made to restrict to the set of unit-length configurations, a limitation that is addressed in the next approach.

Kendall's Shape Analysis (KSA) This approach, first laid out by Kendall [1] and advanced by several others [3], preserves desired constraints by restricting to appropriate manifolds. Once again a configuration of n points, taken from the boundary of an object, is treated as a complex vector. As earlier, the translations are removed by restricting to those elements of \mathbb{C}^n whose average is zero and the scale variability by rescaling the complex vector to have norm one. This results in a set:

Statistical Shape Analysis, Fig. 5 Examples of geodesic paths between same shapes using ASM, KSA, and ESA.

$$\mathcal{D} = \{z \in \mathbb{C}^n \mid \frac{1}{n} \sum_{i=1}^n z^i = 0, \|z\| = 1\}.$$

\mathcal{D} is not a vector space because $a_1 z_1 + a_2 z_2$ for $a_1, a_2 \in \mathbb{R}$ and $z_1, z_2 \in \mathcal{D}$ is typically not in \mathcal{D} , due to the unit norm constraint. However, \mathcal{D} is a unit sphere and one can utilize the geometry of a sphere to analyze points on it. Under the Euclidean (Riemannian) metric, the shortest path between any two elements $z_1, z_2 \in \mathcal{D}$, also called a *geodesic*, is given by the great circle: $\alpha_{ksa} : [0, 1] \rightarrow \mathcal{D}$, where

$$\alpha_{ksa}(\tau) = \frac{1}{\sin(\theta)} [\sin(\theta(1 - \tau))z_1 + \sin(\tau\theta)z_2],$$

and

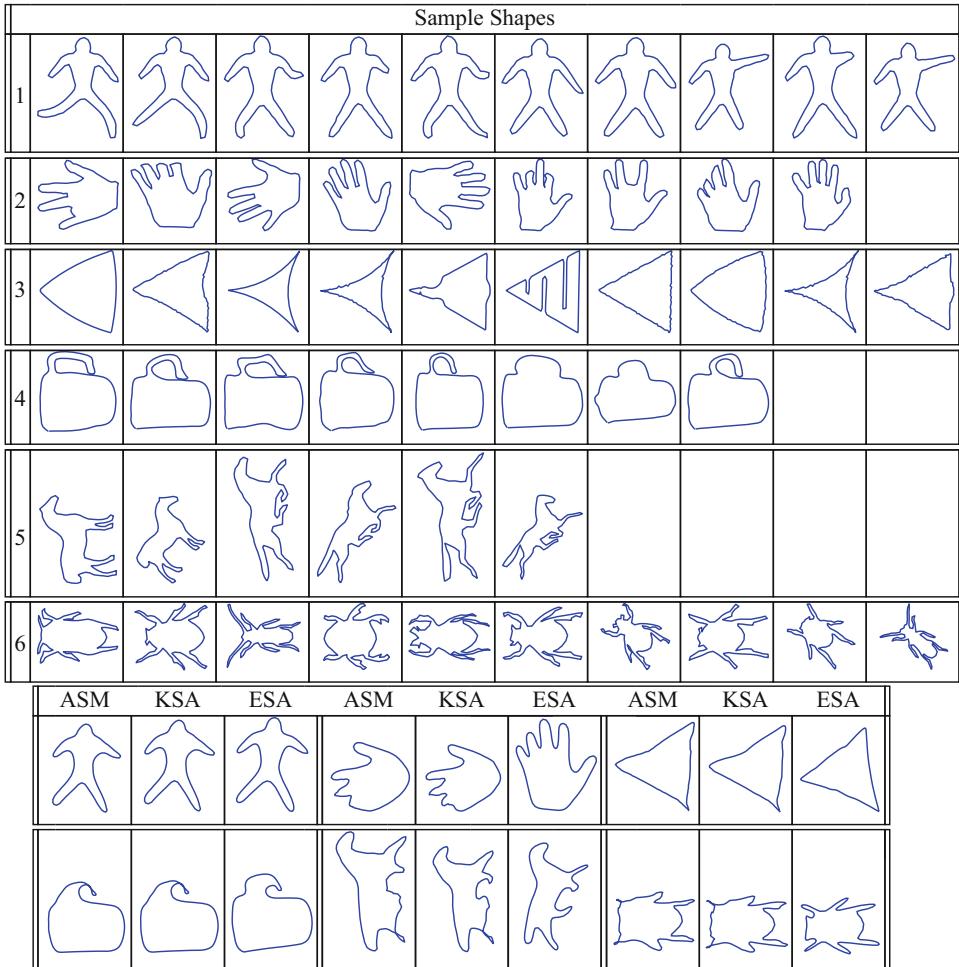

$$\theta = \cos^{-1}(\Re(\langle z_1, z_2 \rangle)). \quad (2)$$

In order to compare the shapes represented by z_1 and z_2 , they need to be aligned rotationally, as

was done earlier, but the shape space is defined more formally this time. Let $[z]$ be the set of all rotations of a configuration z according to:

$$[z] = \{e^{j\phi}z \mid \phi \in \mathbb{S}^1\}.$$

One defines an equivalence relation on \mathcal{D} by setting all elements of this set as equivalent, i.e., $z_1 \sim z_2$ if there exists an angle ϕ such that $z_1 = e^{j\phi}z_2$. The set of all such equivalence classes is the quotient space $\mathcal{D}/U(1)$, where $U(1) = SO(2) = \mathbb{S}^1$ is the set of all rotations in \mathbb{R}^2 . This space is called the *complex projective space* and is denoted by \mathbb{CP}^{n-1} . A geodesic between two elements $z_1, z_2 \in \mathbb{CP}^{n-1}$ is given by computing α_{ksa} between z_1 and $e^{j\phi^*}z_2$, where ϕ^* is the optimal rotational alignment of z_2 to z_1 . The length of the geodesic is given by θ , and that quantifies the difference in shapes of the boundaries represented by z_1 and z_2 . Figure 5 shows

Statistical Shape Analysis, Fig. 6 Examples of mean shapes under three different methods

several examples of geodesic paths between the same shapes as for the ASM examples.

Issue of Landmark Selection Although Kendall's approach succeeds in preserving the unit-length constraints on the landmark configurations, it does not address a very important practical issue: How to systematically select points on objects, say curves, to form representative point sets? This process is difficult to standardize, and different selections can lead to drastically differing solutions. This issue is present in any point-based approach, including the ASM method discussed above. Some may suggest to sample a curve uniformly along its length, i.e., parameterize a curve β using

arclength and sample $\{\beta(t_i)|i = 0, 1, 2, \dots, n\}$ where $t_i = i/n$. Although this provides a standardized way of sampling curves, the results are not always good since this forces a particular registration of points, i.e., the point $\beta_1(t_i)$ on the first curve is matched to the point $\beta_2(t_i)$ on the second curve, irrespective of the shapes involved. Figure 4 illustrates this point using an example. Shown in the left two panels are two curves: β_1 and β_2 , sampled uniformly along their lengths. For $t_i = i/4$, $i = 1, 2, 3, 4$, the corresponding four points on each curve $\{\beta_1(t_i)\}$ and $\{\beta_2(t_i)\}$ are shown in the same color. While two of the four pairs seem to match well, the pairs shown in red and green fall on different parts of the body, resulting in a mismatch of features.

This example shows the pitfall of using uniform sampling of curves. In fact, any predetermined sampling and preregistration of points will, in general, be problematic. A more natural solution is to treat the boundaries of objects as *continuous* curves, rather than discretizing them into point sets at the outset, and find an optimal (perhaps non-uniform) sampling, such as the one shown in the rightmost panel, that better matches features across curves. This way one can develop a more comprehensive solution, including theory and algorithms, assuming continuous objects and will discretize them only at the implementation stage.

Theory

The *elastic shape analysis* (ESA) framework, for analyzing shapes represented by simple, closed, planar curves is described here. (These ideas are also applicable, with some modifications, to curves in higher dimensions but that is not discussed here.) The most natural way to study shapes of curves seems to be by treating them as parameterized curves. As mentioned earlier, an important aspect of this framework is that shape distances, geodesics, and statistics should be invariant to how the curves are parameterized.

Basic Challenge To understand the basic challenge in analyzing shapes of parameterized curves, let $\|\cdot\|$ denote the \mathbb{L}^2 norm of a vector-valued function, i.e., $\|\beta\| = \int_{\mathbb{S}^1} \|\beta(t)\|^2 dt$, where the norm inside the integral is the vector 2-norm. Let $\beta_1, \beta_2 : \mathbb{S}^1 \rightarrow \mathbb{R}^2$ be two parameterized closed curves and γ be a reparameterization function of the type used in Fig. 3. (It is more natural for the domain of parameterization to be \mathbb{S}^1 instead of $[0, 1]$ for closed curves.) The basic challenge in using the \mathbb{L}^2 norm $\|\beta_1 - \beta_2\|$ for comparing shapes of these two curves, even after a proper translation and scaling for standardization, is that $\|\beta_1 - \beta_2\| \neq \|\beta_1 \circ \gamma - \beta_2 \circ \gamma\|$ in general. That is, the distance between any two curves changes even if they are reparameterized in the same way. This implies that the shape distance will depend on parameterizations, and this violates the requirement of invariance to parameterization.

This problem necessitates a new representation and/or a new metric for analyzing shapes of curves.

Mathematical Representation Let a parameterized closed curve be denoted as $\beta : \mathbb{S}^1 \rightarrow \mathbb{R}^2$. In order to analyze its shape, one represents β by its square-root velocity function (SRVF): $q(t) = \frac{\beta(t)}{\sqrt{\|\dot{\beta}(t)\|}} \in \mathbb{R}^2$. The SRVF q includes both the instantaneous speed ($\|q(t)\|^2 = \|\dot{\beta}(t)\|$) and the direction ($\frac{q(t)}{\|q(t)\|} = \frac{\dot{\beta}(t)}{\|\dot{\beta}(t)\|}$) of the curve β at time t . The use of the time derivative makes the SRVF invariant to any translation of curve β . Conversely, one can reconstruct the curve β from q up to a translation. In order for the shape analysis to be invariant to scale, one rescales each curve to length one. With a slight abuse of notation, let us denote the rescaled curves by β . Since $\int_{\mathbb{S}^1} \|\dot{\beta}(t)\| dt = 1$: $\int_{\mathbb{S}^1} \|q(t)\|^2 dt = \int_{\mathbb{S}^1} \|\dot{\beta}(t)\| dt = 1$. In other words, the \mathbb{L}^2 norm of the SRVF q is one. Additionally, if the curve β is closed, then its SRVF satisfies $\int_{\mathbb{S}^1} q(t) \|q(t)\| dt = 0$. Restricting to the curves of interest, represented by their SRVFs, the following set is obtained:

$$\mathcal{C} = \{q : \mathbb{S}^1 \rightarrow \mathbb{R}^2 \mid \int_{\mathbb{S}^1} q(t) \|q(t)\| dt = 0, \int_{\mathbb{S}^1} \|q(t)\|^2 dt = 1\}.$$

\mathcal{C} is called the *preshape space* and is the set of SRVFs of all unit length, closed curves in \mathbb{R}^2 . Four shape-preserving transformations were mentioned earlier: translation, scale, rotation, and reparameterization. Of these, the first two have already been eliminated from the representations, but the other two remain. Curves that are within a rotation and/or a reparameterization of each other result in different elements of \mathcal{C} despite having the same shape. The unification of such curves is performed algebraically as follows. Let $SO(2)$ be the group of 2×2 rotation matrices and Γ be the group of all reparameterizations (they are actually positive diffeomorphisms of the unit circle \mathbb{S}^1). For a curve β , a rotation $O \in SO(2)$ and a reparameterization $\gamma \in \Gamma$, the transformed

curve is given by $O(\beta \circ \gamma)$. The SRVF of the transformed curve is given by $O(q \circ \gamma)\sqrt{\dot{\gamma}}$. In order to unify all elements in \mathcal{C} that denote the same shape, one can define equivalence classes of the type:

$$[q] = \{O(q \circ \gamma)\sqrt{\dot{\gamma}} \mid O \in SO(2), \gamma \in \Gamma\}.$$

Each such equivalence class $[q]$ is associated with a shape uniquely and vice versa. The set of all these equivalence classes is called the shape space \mathcal{S} ; mathematically, it is a quotient space of the preshape space: $\mathcal{S} = \mathcal{C}/(SO(2) \times \Gamma)$. The preshape space \mathcal{C} is a nonlinear manifold because it is a subset of a unit sphere. One cannot perform calculus on this space as if it is a vector space. Operations such as addition, subtraction, and multiplication are not available on nonlinear spaces. This means that standard techniques in functional analysis for inferences on \mathcal{C} and \mathcal{S} cannot be used.

It should be noted that the mathematical representation used here, i.e., the SRVF, is not the only such representation. Younes et al. [4, 5] use a slightly different expression for an SRVF, based on an identification of \mathbb{R}^2 with \mathbb{C} and taking complex square roots of the coordinates. The advantage of the SRVF form used in the current article is that it applies to curves in \mathbb{R}^m for any m , while the complex analysis in [4, 5] is applicable only to curves in \mathbb{R}^2 .

Elastic Riemannian Metric Now that a mathematical representation of the shape of a curve, namely, $[q]$, has been defined how should one compare the shapes of two curves? In other words, for any two curves β_1 and β_2 , represented by their shape classes $[q_1]$ and $[q_2]$, respectively, what should be the shape metric $d_s([q_1], [q_2])$ that quantifies their shape differences? First, consider the role of a metric more closely. When one curve is deformed into another a continuous sequence of curves, or a path in the curve space, is generated, and a natural question is how long that path is. The length of this path also quantifies the amount of deformation in going from one curve to the other. The question changes to: What should be the metric to measure this path length?

A metric called the *elastic metric* will be used for this purpose. An elastic metric is a metric that measures the amount of bending and stretching between successive curves along the path and adds them up for the full path. Mio et al. [6] defined a family of elastic metrics depending upon how much relative weights are attached to bending and stretching. Later on it was shown that (Joshi et al. [7], Srivastava et al. [8]) under the SRVF representation, the complicated elastic metric turns into (using a change of variables) the standard \mathbb{L}^2 metric. That is, one can alternatively compute the path lengths, or the sizes of deformations between curves, using the cumulative norms of the differences between successive curves along the paths in the SRVF space. This turns out to be much simpler and a very effective strategy for comparing shapes of curves, by finding the paths with least amounts of deformations between them, where the amount of deformation is measured by an elastic metric. Another distinct advantage of using SRVFs is that for any $q_1, q_2 \in \mathcal{C}$, $O \in SO(2)$ and $\gamma \in \Gamma$:

$$\|q_1 - q_2\| = \|O(q_1 \circ \gamma)\sqrt{\dot{\gamma}} - O(q_2 \circ \gamma)\sqrt{\dot{\gamma}}\|.$$

This means that the distance between any two curves remains same if they are rotated and reparameterized in the same way! This property, when combined with an optimization step (Eq. 3 later), allows one to make shape metrics invariant to parameterizations.

Shape Comparison and Geodesics Once a Riemannian metric on a manifold has been defined, one can compute distances between points in that manifold. For any two points, the distance between them is given by the length of the shortest path, called a *geodesic*, connecting them in that manifold. An interesting feature of this framework is that it not only provides a distance between shapes of two curves but also a geodesic path between them in \mathcal{S} . This path has the interpretation that it provides the optimal deformation of one shape into another. The geodesics are actually computed using the differential geometry of the underlying space \mathcal{S} .

Consider two curves β_1 and β_2 , represented by their SRVFs q_1 and q_2 . Let $\alpha : [0, 1] \rightarrow \mathcal{C}$ be a differentiable path connecting them in \mathcal{C} . The length of this path is given by:

$$L[\alpha] = \int_0^1 \langle \dot{\alpha}(\tau), \dot{\alpha}(\tau) \rangle^{1/2} d\tau,$$

where the inner product inside the integral is given by the elastic Riemannian metric. A geodesic is a path whose length cannot be minimized by locally perturbing it. It is often obtained by minimizing the cost function of the type:

$$\hat{\alpha} = \operatorname{argmin}_{\{\alpha : [0, 1] \rightarrow \mathcal{C} | \alpha(0) = q_1, \alpha(1) = q_2\}} \left(\int_0^1 \langle \dot{\alpha}(\tau), \dot{\alpha}(\tau) \rangle dt \right).$$

This cost function differs from the expression for $L[\alpha]$ in that the square root inside the integral is missing. It can be shown that a local minimizer of this cost function is also a local minimizer of $L[\alpha]$ and, hence, is a geodesic.

One technique for finding geodesics is called *path straightening*. It is an iterative technique that initializes an arbitrary path and then iteratively “straightens” it by updating it along the negative gradient of the cost function. Klassen and Srivastava [9] provide a nice analytical expression for the gradient of this cost function that results in a convenient gradient iteration. One applies these iterative updates, or straightening, until the gradient becomes negligible and the resulting path is the desired geodesic $\hat{\alpha}$. The length of this curve is denoted by $d_c(q_1, q_2) = L[\hat{\alpha}]$. This gives a geodesic and a geodesic distance between SRVFs in \mathcal{C} , but the goal is to compute geodesic paths in \mathcal{S} . In other words, geodesic paths between the equivalence classes $[q_1]$ and $[q_2]$ are needed and not just q_1 and q_2 . It turns out that the desired geodesic is obtained by finding the shortest geodesic among all pairs $(\tilde{q}_1, \tilde{q}_2) \in ([q_1] \times [q_2])$. This search is further simplified by fixing an arbitrary element of $[q_1]$, say q_1 and searching over all rotations and reparameterizations of q_2 to minimize the geodesic length:

$$(O^*, \gamma^*) = \operatorname{argmin}_{O \in SO(2), \gamma \in \Gamma} d_c(q_1, O(q_2 \circ \gamma) \sqrt{\dot{\gamma}}). \quad (3)$$

The minimization over $SO(2)$ is similar to the ASM and KSA alignments earlier, but the optimization over Γ is new. This is accomplished using the dynamic programming algorithm or a gradient-type approach [8]. The resulting geodesic between q_1 and $O^*(q_2 \circ \gamma^*) \sqrt{\dot{\gamma}^*}$ in \mathcal{C} is actually representation of the geodesic between $[q_1]$ and $[q_2]$ in the shape space \mathcal{S} ; its length $d_s([q_1], [q_2]) = d_c(q_1, O^*(q_2 \circ \gamma^*) \sqrt{\dot{\gamma}^*})$ provides the geodesic distance in \mathcal{S} . Several examples of geodesic paths in the shape space \mathcal{S} are shown in Fig. 5; these geodesics are compared with the deformations/geodesics obtained by two previously described methods: ASM and KSA, for the same shapes. It is easy to see that the geodesics resulting from ESA provide more natural deformations as they are better in matching features across shapes.

The role of geodesics is preeminent in this framework because (1) its length d_s is a quantitative measure of difference between shapes of curves represented by q_1 and q_2 ; (2) this measure is invariant to rigid motion, scaling, and reparameterization of any of the curves; (3) it also provides a full deformation (along the geodesic path) for taking one shape into another in an optimal way; and (4) the availability of geodesics leads to a further development of tools for building statistical summaries of shape classes, as described next.

Mean Shape The first important task in statistical shape analysis is to define and compute the mean shape for a set of curves. Compared to the sample means of real-valued random variables, this task is not straightforward since the shape space \mathcal{S} is not a vector space. One cannot simply take the SRVFs of the given curves and average them point-by-point to get a mean shape. The notion of a mean on a nonlinear manifold is typically established using the Karcher mean [10] or Fréchet mean. For a given set of curves $\beta_1, \beta_2, \dots, \beta_n$, represented by their SRVFs q_1, q_2, \dots, q_n , their Karcher mean is defined as the quantity that satisfies:

$$[\mu] = \operatorname{argmin}_{[q] \in \mathcal{S}} \sum_{i=1}^n d_s([q], [q_i])^2.$$

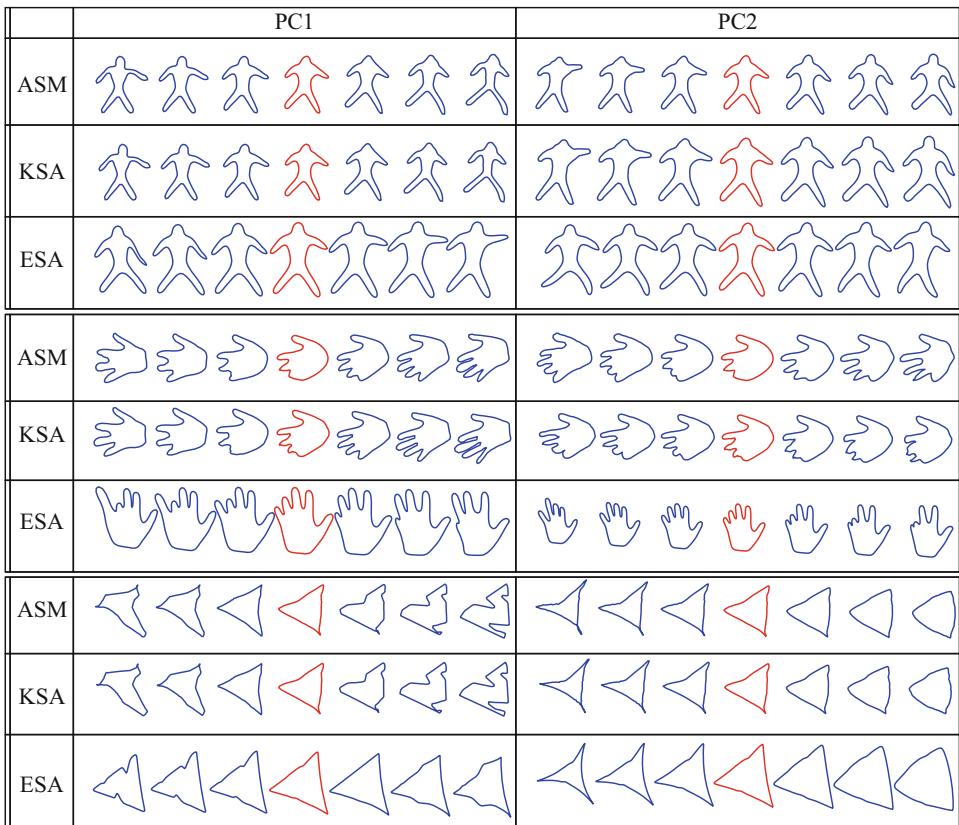

There is a gradient-based iterative algorithm for finding the minimizer of this cost function that can be found in [10–12]. Since this algorithm is based on a local search, the solution obtained is usually local and depends on the initial condition. Shown in Fig. 6 are some examples of mean shapes. The top six rows show a set of given curves, and bottom rows display their means computed using the three methods discussed here: ASM, KSA, and ESA.

Shape Covariance and Principal Modes of Variation Now that the first moment, i.e., the mean, of a set of curves has been defined, one can look for the higher moments. The role of the second centralized moment, the covariance, is especially important as (1) one can define a Gaussian distribution using just the mean and the covariance, and (2) the singular value decomposition (SVD) of the covariance matrix can be used for a principal component analysis (PCA) of shape data. These two ideas are briefly summarized next, starting with the PCA.

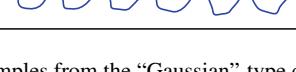

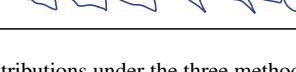

For computing and analyzing the second and higher moments of a shape sample, the tangent space to the shape manifold \mathcal{S} at the point μ is used. This space, denoted by $T_\mu(\mathcal{S})$, is convenient because it is a vector space and one can apply more traditional methods here. First, for each given curve q_i , the vector $v_i \in T_\mu(\mathcal{S})$ is computed such that a geodesic that goes from μ to q_i in unit time has the initial velocity v_i . The function $v_i : \mathbb{S}^1 \rightarrow \mathbb{R}^2$ is also called the *shooting vector* from μ to q_i . Let \hat{K} be the sample covariance matrix of all the shooting vectors from μ to the SRVFs q_i s. For capturing the essential variability in a shape set, one can use principal component analysis (PCA) of the shooting vectors. The basic idea is to compute the SVD $\hat{K} = U\Sigma U^T$, where U is an orthogonal matrix and Σ is the diagonal matrix of singular values. Assuming that the entries along the diagonal in Σ are organized in a nonincreasing order, U_1, U_2 , etc. represent the dominant direc-

tions of variability in the data. If a singular vector U_j is used to form vectors $t\sqrt{\Sigma_{jj}}U_j$, then they represent shooting variability in the direction U_j . One can map these directions back on the shape space \mathcal{S} using an exponential map at μ . The details of this exponential map are omitted here, but it is basically the point reached on \mathcal{S} by constructing a geodesic in the shooting direction so that the length of the geodesic is the same as the length of the shooting vector. The resulting geodesics are also called the *principal geodesic paths*. Figure 7 shows the principal geodesic paths along U_1 and U_2 , respectively, for $t = -1.5$ to $t = 1.5$. Of course, the middle points in each row are the mean shape μ .

Probabilistic Shape Models One important use of means and covariances of shape families is in devising “Gaussian”-type probability densities on the shape space \mathcal{S} . In the case of ASM, this idea is straightforward since the shape representations are simple vectors and one can define multivariate normal densities on these vector spaces. However, for KSA and ESA, the shape spaces are nonlinear manifolds, and such probability densities are not easy to define. One common idea to tackle the nonlinearity of the shape space is to impose a Gaussian distribution on the tangent space $T_\mu(\mathcal{S})$ since that is a vector space. In case of ESA, this space is infinite-dimensional, so the Gaussian model is actually imposed on a finite-dimensional subspace, e.g., a principal subspace, of $T_\mu(\mathcal{S})$. Let $\{U_j\}$, $j = 1, 2, \dots, k$ denote the singular vectors of the sample covariance matrix as earlier. Then, one can define a random vector $v \equiv \sum_{j=1}^k f_j U_j$ where $f_j \sim N(0, \Sigma_{jj})$ and define $q = \exp_\mu(v)$, the exponential map of v from $T_\mu(\mathcal{S})$ to the shape space \mathcal{S} . The procedure defines a generative random model on the shape space and is easy to sample from. Shown in Fig. 8 are examples of random samples from \mathcal{S} using means and covariances estimated from the given data in Examples 1–3 from Fig. 6. For comparison, this figure also shows random samples from similar Gaussian models but using ASM and KSA. It is easy to observe the superiority of the results obtained using ESA; the modelling

Statistical Shape Analysis, Fig. 7 Two principal directions of variability in shapes given in Examples 1–3 in Fig. 6

| Method | “Gaussian” Random Samples | | |
|--------|---|---|--|
| | ASM | KSA | ESA |
| ASM |  |  |  |
| KSA |  |  |  |
| ESA |  |  |  |

Statistical Shape Analysis, Fig. 8 Random samples from the “Gaussian”-type distributions under the three methods: ASM, KSA, and ESA, for parameters estimated from the given shapes shown in Examples 1–3 of Fig. 6

results from ASM are typically the worst of the three methods.

Elastic Shape Analysis of Surfaces

The task of comparing shapes of 3D objects is of great interest in many important applications. For

instance, the shapes of anatomical parts can contribute in medical diagnoses, including monitoring the progression of diseases [13–15]. Shapes of 3D objects can also be used in other computer vision tasks, such as object recognition, classification, and retrieval [16–20]. Although learning techniques have proved successful in these applications, a main challenge in shape analysis comes

from the fact that image data are often collected from different coordinate systems and data registration becomes a critical part of the analysis. In the following discussion, we will focus on surfaces that are embeddings of a unit sphere \mathbb{S}^2 in \mathbb{R}^3 . In other words, the surfaces of interest can be parameterized using the sphere according to a mapping $f : \mathbb{S}^2 \rightarrow \mathbb{R}^3$. For any $s \in \mathbb{S}^2$, the vector $f(s) \in \mathbb{R}^3$ denotes the Euclidean coordinates of that point on the surface. The \mathbb{L}^2 metric is given by $\langle f_1, f_2 \rangle = \int_{\mathbb{S}^2} \langle f_1(s), f_2(s) \rangle m(ds)$, with $m(ds)$ denoting the Lebesgue measure on \mathbb{S}^2 , and the resulting norm is $\|f_1 - f_2\| = \int_{\mathbb{S}^2} |f_1(s) - f_2(s)|^2 m(ds)$. Let (u, v) denote the local coordinates of a point $s \in \mathbb{S}^2$. Then, the vectors $\frac{\partial f}{\partial u}(s)$ and $\frac{\partial f}{\partial v}(s)$ span the two-dimensional space tangent to the surface at point $f(s)$ and

$$n(s) = \frac{\partial f}{\partial u}(s) \times \frac{\partial f}{\partial v}(s)$$

is a vector normal to the surface at $f(s)$. Its magnitude $|n(s)| = \sqrt{\langle n(s), n(s) \rangle}$ denotes infinitesimal area of the current parameterization at that point, and the ratio $n(s)/|n(s)|$ gives the unit normal vector. The mathematical representation of surfaces, suitable for elastic shape analysis, given by the *square-root normal field* (SRNF) defined as [21, 22]:

$$q : \mathbb{S}^2 \rightarrow \mathbb{R}^3, q(s) = \frac{n(s)}{\sqrt{|n(s)|}}.$$

The reparameterization group here is the set of all positive diffeomorphisms of \mathbb{S}^2 . If q is the SRNF of a surface f , then the SRNF of the reparameterized surface $f \circ \gamma$ is given by $(q \circ \gamma)\sqrt{J_\gamma}$, where J_γ is the determinant of the Jacobian matrix of the mapping $\gamma : \mathbb{S}^2 \rightarrow \mathbb{S}^2$. We will denote this by $(q * \gamma)$. Similar to the identities presented for previous two cases, this representation also follows the isometry conditions: for all surfaces f , f_1 , and f_2 , and the corresponding SRNFs q , q_1 , and q_2 , and all $\gamma \in \Gamma$, we have: $\|q\| = \|(q * \gamma)\|$ and $\|q_1 - q_2\| = \|(q_1 * \gamma) - (q_2 * \gamma)\|$.

Once again, from the perspective of shape analysis, a reparameterization and a rotation of

a surface do not alter its shape. The shape of f is exactly same as the shape of $O(f \circ \gamma)$, for any $\gamma \in \Gamma$ and $O \in SO(3)$. This motivates the formulation of equivalence classes, or orbits, of representations that all correspond to the same shape. Let $[f]$ denote all possible rotations and reparameterizations of a surface f . The corresponding set in SRNF representation is given by $[q] = \{O(q * \gamma) | O \in SO(3), \gamma \in \Gamma\}$. Each such class represents a shape uniquely, and shapes are compared by computing a distance between the corresponding orbits. Similar to curves, the joint registration and shape comparison of surfaces is performed according to:

$$\begin{aligned} & \inf_{\gamma \in \Gamma, O \in SO(3)} \|q_1 - O(q_2 * \gamma)\| \\ &= \inf_{\gamma \in \Gamma, O \in SO(3)} \|O(q_1 * \gamma) - q_2\|. \end{aligned} \quad (4)$$

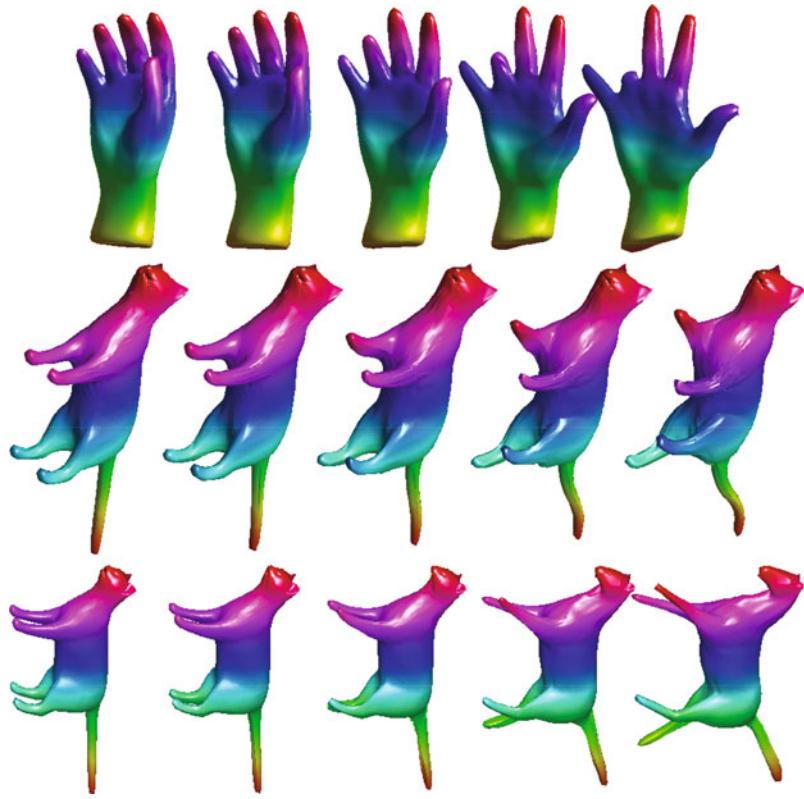

While the optimization over $SO(3)$ is relatively straightforward, the optimization over Γ is much more difficult here than the curve case. We have developed a gradient-based approach that uses the geometry of the tangent space $T_{\gamma_{id}}(\Gamma)$. It uses a set of vector fields that incrementally deform the current grid on f_2 , so as to minimize the cost function given in Eq. (4).

Similar to the case of constrained curves, the task of computing geodesics between any two registered surfaces is not trivial and requires a path straightening-algorithm (see [23]). More recently, [24] have developed an approximation that first computes a straight-line geodesic between any two registered surfaces in the SRNF representation space and then inverts each point along this geodesic to obtain a geodesic in the surface space. For more details, we refer the reader to these papers.

In Fig. 9, we show some examples of geodesics between objects including human hands and animals. In Fig. 10, we compare the geodesics between surfaces to the linear interpolation of surfaces. From the results, we can see that the tail part of the cat is distorted and inflated on the linearly interpolated path, but the tail part is better persevered along the geodesic path.

Statistical Shape

Analysis, Fig. 9 Each row shows an example of geodesic between a pair of objects (the starting and ending shapes)

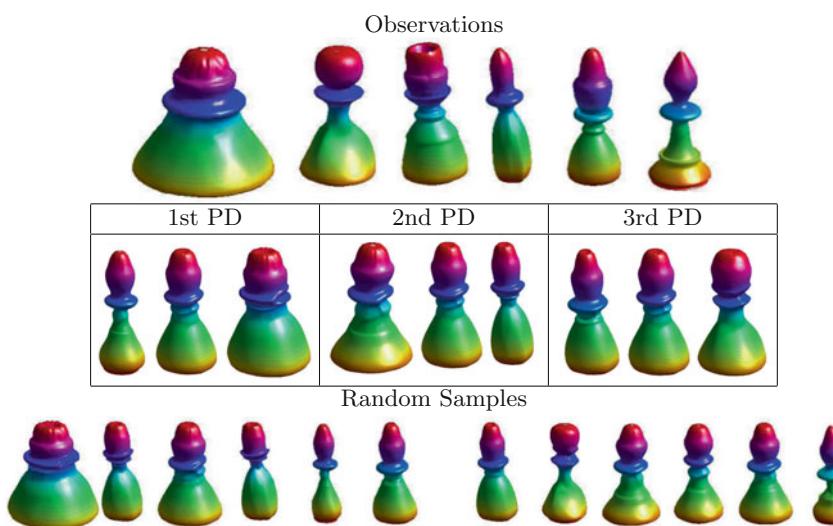

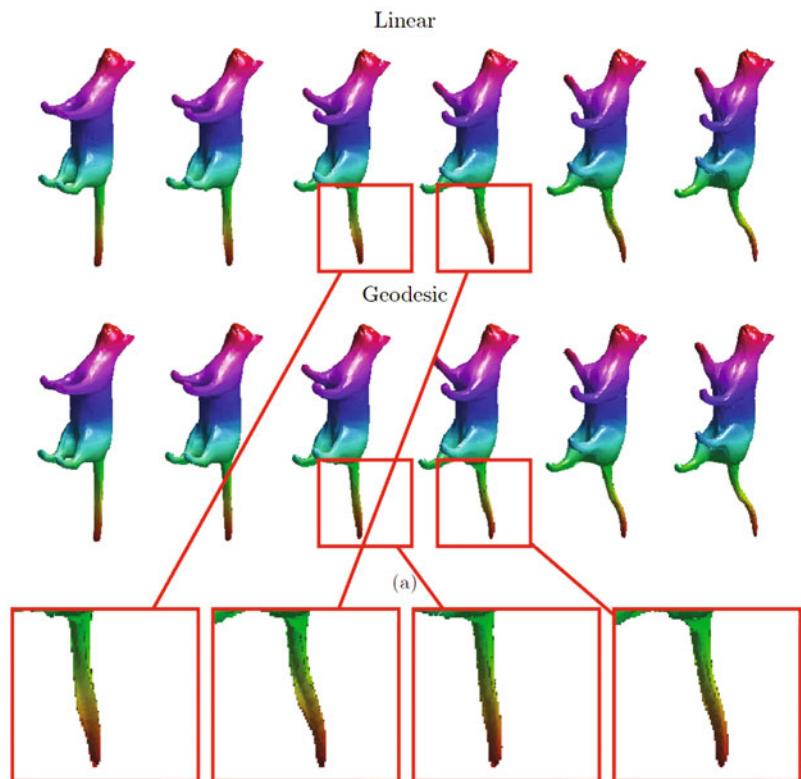

Using geodesics we can define and compute the mean shape using a standard algorithm for computing Karcher mean. Furthermore, we can define and compute Karcher covariance and perform PCA on the tangent space at the mean shape. Figure 11 displays the observations and the k -th principal directions (PD) by constructing principal geodesics $\exp_{\mu}(ts_k \cdot \text{PC}_k)$, where $\text{PC}_k \in T_{\mu}(\mathcal{F})$ is the k^{th} principal component and s_k denotes the corresponding standard deviation. The PDs are displayed using the triples $\{\exp_{\mu}(-s_k \cdot \text{PC}_k), \mu, \exp_{\mu}(s_k \cdot \text{PC}_k)\}$. This analysis can be used to define a multivariate normal distribution on the principal coefficients and thus a random tangent vector from this Gaussian model. Assume that v is a random deformation of the mean surface, i.e., $v \in T_{\mu}(\mathcal{F})$ according to the normal model. Then, we can use the shooting method to get a random sample of surfaces such that $f = \exp_{\mu}(v)$. Several randomly sampled chess pieces are shown in Figure 11 bottom row.

Open Problems

Although there has been a significant progress in shape analysis of curves, especially the planar curves, several important problems remain open. Firstly, the choice of Gaussian-type models for capturing shape variability of curves and surfaces is more for convenience than data driven. It is important to explore and develop statistical models on shape manifolds that are both efficient, e.g., parametric models are more efficient, and provide a better representation of the observed variability. The second set of open problems relates to combining the strengths of deep learning and geometric shape analysis. In current data-driven era, one can learn complex distributions from large data sets using GANs and related architectures. It will be interesting to exploit these strengths and combine them with the invariances of geometric shape analysis to result in more realistic shape models.

Definition

A stochastic partial differential equation (SPDE) is a partial differential equation (PDE) with an extra stochastic term, e.g., an Itô integral. Sometimes partial differential equations where the differential operator is disturbed are also called SPDEs, but the more common term is random PDEs.

Background

First results on SPDEs and infinite-dimensional stochastic differential equations (SDEs) appeared in the mid-1960s. Ample publications and results are due to the end of the 1970s and the early 1980s. Here the work by Walsh [23] and Pardoux [19] should be mentioned. In the early 1990s, Da Prato and Zabczyk published their book with an infinite-dimensional approach to SPDEs driven by Wiener processes [4]. In the last years, a number of books on SPDEs were published, in particular an extension of [4] by Peszat and Zabczyk [20]. Other publications to be mentioned are Chow [3], Prévôt and Röckner [21], Holden et al. [9], and Gawarecki

and Mandreka [8] and more recently Liu and Röckner [15] and Lototsky and Rozovsky [15].

The motivation to study SPDEs was driven on the one hand from the internal development of analysis and theory of stochastic processes and on the other side from applications. Random phenomena studied in natural sciences needed to be described. Especially applications in physics, chemistry, biology, control theory, nonlinear filtering, engineering, and finance pushed the development of the theory of SPDEs and are still pushing it. The field has attained even more attention since Martin Hairer was awarded the Fields Medal in 2014 for his work on SPDEs and regularity structures. In recent years the applications also inspire the design of numerical methods to “create numbers,” i.e., to simulate the equations.

Theory

Let $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \geq 0}, \mathbb{P})$ be a filtered probability space. The filtration is supposed to be right continuous, and \mathcal{F}_0 contains all \mathbb{P} -zero sets. A *stochastic differential equation* is given by

$$dX(t) = a(t, X(t)) dt + b(t, X(t)) dM(t) \quad (1)$$

with initial condition $X(0) = X_0$ and $X : \mathbb{R}_+ \times \Omega \rightarrow \mathbb{R}^d$. The initial condition might be a random variable. This notation is the abbreviation for the integral equation

$$\begin{aligned} X(t) &= X_0 + \int_0^t a(s, X(s)) ds \\ &\quad + \int_0^t b(s, X(s)) dM(s). \end{aligned}$$

In this notation M is a stochastic process adapted to (\mathcal{F}_t) which is, e.g., a local martingale. In many applications the stochastic process is a Brownian motion also called Wiener process and abbreviated by B or W . Especially in recent years, other typical stochastic processes are Lévy processes. The expression

$$\int_0^t b(s, X(s)) dM(s)$$

is a stochastic integral of Itô type (cf. [6, 10, 17, 18, 22]). In order to ensure the existence of a solution to Equation (1), the functions $a : \mathbb{R}_+ \times \mathbb{R}^d \rightarrow \mathbb{R}^d$, $b : \mathbb{R}_+ \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ and the stochastic process M have to satisfy certain conditions. One possibility is that a and b are of linear growth and Lipschitz type.

One approach to derive an SPDE is to extend Equation (1) to maps $X : \mathbb{R}_+ \times \Omega \rightarrow \mathbb{R}^d$ where d tends to infinity. Another approach to derive SPDEs is to start with a PDE. Therefore let A be a differential operator on a bounded domain of $D \subset \mathbb{R}^d$. Then

$$\begin{aligned} \frac{\partial}{\partial t} u(t, x) &= Au(t, x) \\ &\quad + f(u(t, x)) + g(u(t, x))\dot{\eta}(t, x) \end{aligned}$$

with initial condition $u(0, x) = u_0(x)$ for $x \in D$ denotes an SPDE where $\dot{\eta}$ is white noise. As, in general, stochastic processes are almost surely not differentiable with respect to the time t , this notation is used seldom. Instead of that SPDEs are integral equations, i.e.,

$$\begin{aligned} u(t, x) &= u_0(x) + \int_0^t (Au(s, x) + f(u(s))) \, ds \\ &\quad + \int_0^t g(u(s, x)) \, dM(s, x). \end{aligned}$$

One approach to solve equations of that type was introduced by Da Prato and Zabczyk in 1992 [4]. There a more general framework is used. Let H and U be separable Hilbert spaces, e.g., $L^2(D)$, \mathbb{R}^d , or Sobolev spaces $H^\alpha(D)$; then the previous equation can be rewritten as

$$\begin{aligned} u(t) &= u_0 + \int_0^t (Au(s) + F(u(s))) \, ds \\ &\quad + \int_0^t G(u(s)) \, dM(s) \end{aligned}$$

where $F : D(F) \subset H \times \Omega \rightarrow H$, $G : D(G) \subset H \rightarrow L(U, H)$ and M is a U -valued stochastic process, e.g., a square integrable martingale like a Wiener or Lévy process. Here $D(F)$ denotes the domain of F and $L(U, H)$ is the space of linear

operators from U into H . The stochastic process u is a mapping from $\mathbb{R}_+ \times \Omega$ into the Hilbert space H . The abbreviated form of the previous equation is

$$du(t) = (Au(t) + F(u(t))) \, dt + G(u(t)) \, dM(t) \quad (2)$$

with $u(0) = u_0$. So instead of solving an SPDE, here Hilbert space-valued SDEs are solved. Existence and uniqueness of solutions might be shown using, e.g., semigroup theory and classical SDE theory. In the theory of SPDEs, there exist three main concepts of solutions which are similar to those known from PDE theory:

1. *Strong solutions* [4]: A predictable H -valued stochastic process $u = (u(t), t \in [0, +\infty))$ is a *strong solution* to Equation (2), if
 - for all $t \geq 0$ $u(t)$ takes values in $D(A) \cap D(F) \cap D(G)$ \mathbb{P} -a.s.,
 - for all $t \geq 0$ it holds \mathbb{P} -a.s.

$$\begin{aligned} u(t) &= u_0 + \int_0^t (Au(s) + F(u(s))) \, ds \\ &\quad + \int_0^t G(u(s)) \, dM(s). \end{aligned}$$

2. *Weak solutions* [20]: A predictable H -valued process u is a *weak solution* to Equation (2), if
 - $\sup_{t \in [0, T]} \mathbb{E}(\|u(t)\|_H^2) < +\infty$ for all $T \in [0, +\infty)$,
 - for all $a \in D(A^*)$, $t \geq 0$, it holds \mathbb{P} -a.s.

$$\begin{aligned} \langle a, u(t) \rangle_H &= \langle a, u_0 \rangle_H \\ &\quad + \int_0^t (\langle A^*a, u(s) \rangle_H \\ &\quad \quad \quad + \langle a, F(u(s)) \rangle_H) \, ds \\ &\quad + \int_0^t \langle G^*(u(s))a, dM(s) \rangle_{\mathcal{H}}. \end{aligned}$$

Here A^* denotes the adjoint operator and \mathcal{H} is the reproducing kernel Hilbert space generated by M .

3. *Mild solutions* [20]: Let A be the generator of a strongly continuous semigroup $(S(t), t \geq 0)$; then the stochastic process u is a *mild solution* to Equation (2), if

- $\sup_{t \in [0, T]} \mathbb{E}(\|u(t)\|_H^2) < +\infty$ for all $T \in [0, +\infty)$,
- for all $t \geq 0$ it holds \mathbb{P} -a.s.

$$\begin{aligned} u(t) = S(t)u_0 + \int_0^t S(t-s)F(u(s)) \, ds \\ + \int_0^t S(t-s)G(u(s)) \, dM(s). \end{aligned}$$

Furthermore there are viscosity solutions [14]. One could also consider solutions that are weak in the sense of probability theory, i.e., in probability, in distribution, or in expectation and many other concepts.

If A is the generator of a strongly continuous semigroup, similar to SDE theory, solutions exist under linear growth and Lipschitz conditions, but many extensions are possible. The reader is referred to the literature for explicit conditions for existence and uniqueness results. In this context an overview can be found in [20], but the subject is still evolving such that recent research papers will give more general results.

For applications, a suitable type of solution has to be chosen. This leads to the next section where some possible applications are discussed as well as the problem that solutions for most SPDEs are not known. Therefore numerical methods for SPDEs have become more and more important within the last year.

Application

SPDEs are relevant in many different applications. In engineering such as image analysis, surface analysis, and filtering, they result from addition of noise to PDEs. In finance, systems of SDEs are common that extend to infinite-dimensional problems and therefore to SPDEs. Furthermore first applications to life and bio sciences are done.

All these applications are interested in solutions of SPDEs, but these are not known explicitly in most cases. Therefore numerics of SPDEs have become important within the last years. Methods combine SDE methods with PDE methods. Simulation methods for SDEs are especially Euler–Maruyama, Milstein, and higher-order schemes, where a good survey is given in [12], as well as Monte Carlo methods [7]. From PDE theory Galerkin methods, especially finite elements, are relevant, where the reader is referred, e.g., to [5] and [2]. For an introduction to numerical methods for SPDEs, the reader is referred to the textbook by Lord, Powell, and Shardlow [16].

Open Problems

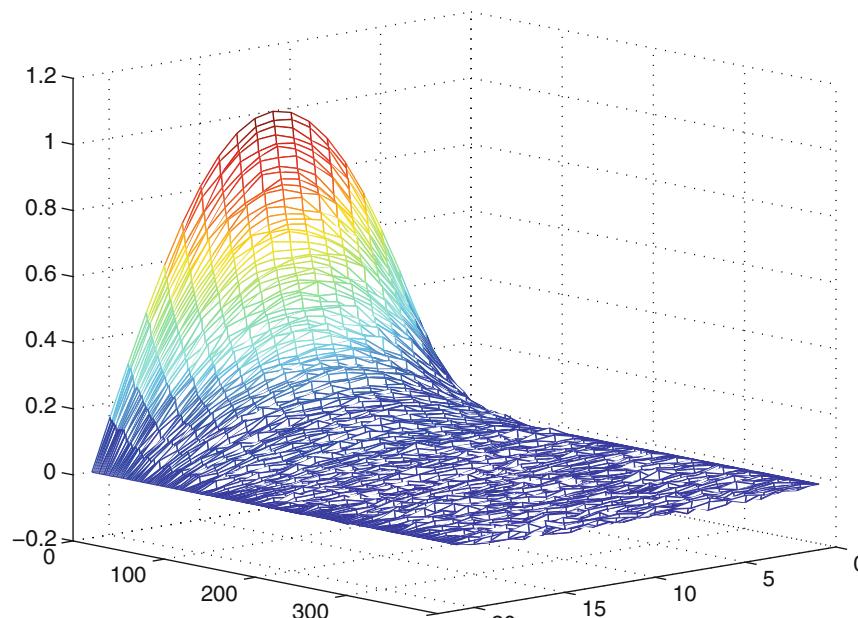

As the topic is still fairly young, there are still many open questions. People are working on existence and uniqueness theory and extending known results especially under non-Lipschitz conditions. Especially the simulation of SPDEs, i.e., the numerical analysis, evolves a lot in recent years. Of special interest are efficient methods, weak convergence analysis, superlinear growth, and connections to geometry. Furthermore research questions on how to solve SPDEs with deep learning methods and how to explain the performance of deep neural networks with SPDEs become more popular.

Experimental Results

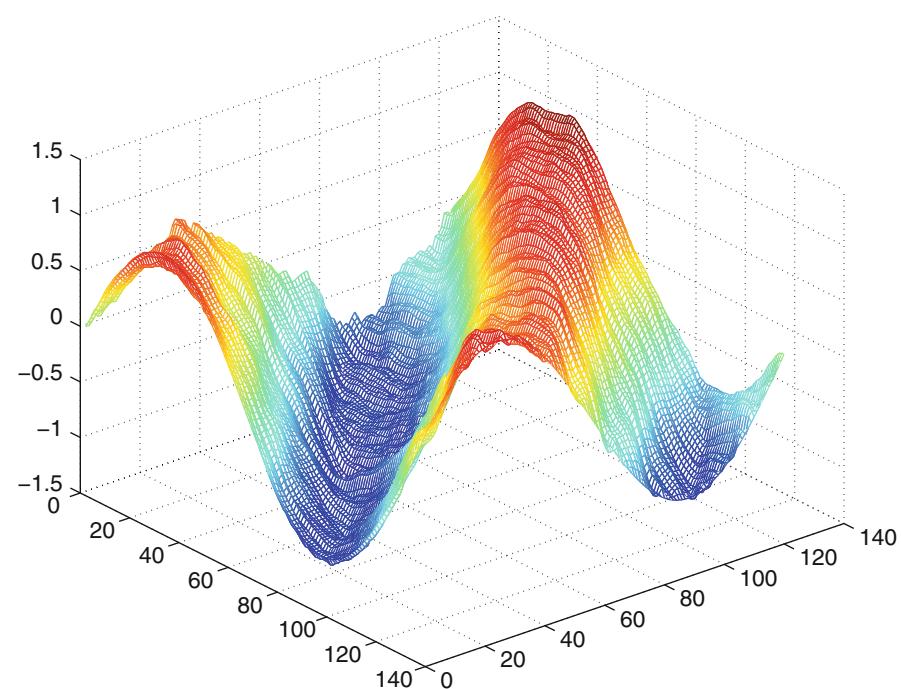

To illustrate what an SPDE is and where to use it for, two figures are included. Figure 1 shows two simulated paths, i.e., $\omega \in \Omega$ was chosen and a finite element method in space and a Euler–Maruyama scheme in time were used. On the left-hand side, the heat equation with additive noise and Dirichlet boundary conditions, i.e.,

$$du(t) = \Delta u(t) \, dt + dW(t)$$

on the space and time interval $[0, 1]$ with initial condition $u(0, x) = \sin(\pi x)$ is displayed,

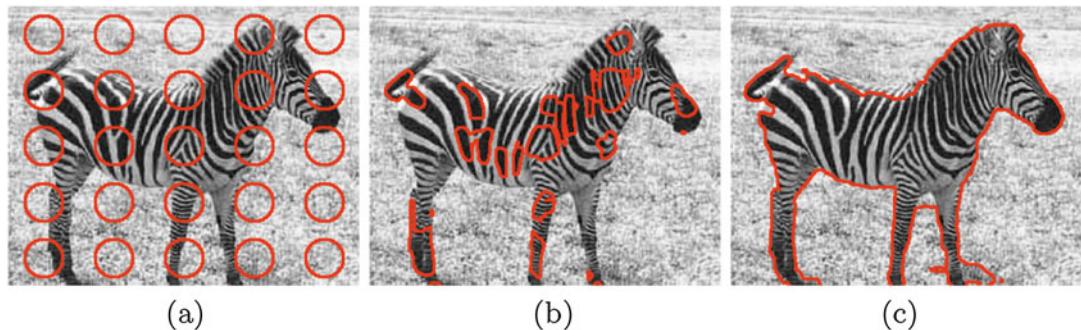

(a)

(b)

Stochastic Partial Differential Equations, Fig. 1 Simulation of one path of an SPDE with additive noise on an interval. (a) Parabolic equation. (b) Hyperbolic equation

Stochastic Partial Differential Equations, Fig. 2 Segmentation using an SPDE and stochastic active contours. (a) Initial condition. (b) Intermediate step. (c) Segmentation result

where W is a Wiener process with space correlation given by the kernel function $q(x, y) = \exp(-2|x - y|)$. On the right-hand side, a hyperbolic equation with additive noise is presented. It is given by

$$du(t) = \nabla u(t) dt + dW(t)$$

with initial condition $u(0, x) = \sin(2\pi x)$ and inflow boundary condition $u(t, 0) = -\sin(2\pi t)$. The other parameters are the same as for the heat equation. In both figures, time evolves from left to right. This and more simulation and convergence results can be found in [1].

One example for an application of SPDEs in computer vision is segmentation. This approach was suggested by Juan et al. [11]. Using level set methods and variational calculus, one possible SPDE to be simulated is

$$du(t, x) = \nabla \frac{\nabla u(t, x)}{|\nabla u(t, x)|} dt + |\nabla u(t, x)| dW(t, x)$$

where the initial condition is, e.g., a weighted distance function as in Fig. 2a. The red circles are the zero level sets. Different types of noise than the coupling with the size of the gradient can be found in [11] and [13]. An example of the segmentation of a zebra from [13] is shown in Fig. 2.

Definition

Subpixel estimation is the process of estimating the value of a geometric quantity to better than pixel resolution even though the data was originally sampled on an integer quantized pixel space. A closely related topic is *superresolution*, which is discussed in another chapter.

Background

It is naively assumed that information at a scale smaller than the pixel level is lost when continuous data is sampled or quantized into pixels from, e.g., time-varying signals, images, data volumes, and space-time volumes. However, in fact, it is generally possible to estimate geometric quantities to better than the original pixel accuracy. The underlying foundations of this estimation are the following:

- *Models of expected spatial variation:* Discrete structures, such as edges or lines, produce characteristic patterns of data when measured, allowing fitting of a model to the data to estimate the parameters of the structure.

- *Spatial integration during sampling:* Sensors typically integrate a continuous signal over a finite domain (space or time), leading to measurements whose values depend on the relative position of the sampling window and the original structure.
- *Point-spread function:* Knowledge of the PSF could be used, e.g., by deconvolution of a blurred signal, to estimate the position of the signal.

Applications commonly benefiting from subpixel estimation are (1) camera calibration and triangulation (e.g., in stereo and structured light depth estimation) and (2) image motion estimation for improved image stabilization and compression.

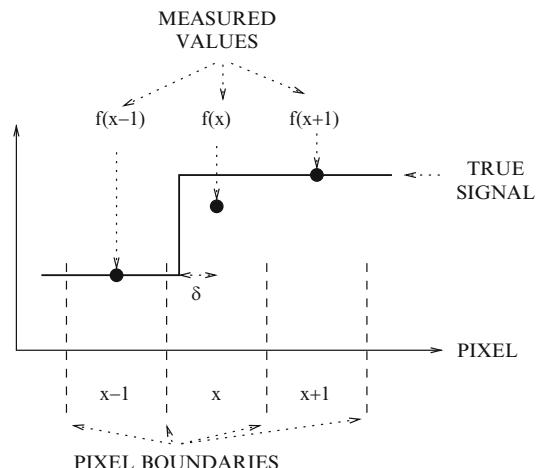

One of the earliest instances of subpixel edge detection in computer vision research was by MacVicar-Whelan and Binford [1] in 1981.

The accuracy of subpixel estimation depends on a number of factors, such as the image point-spread function, noise levels, and spatial frequency of the image data. A commonly quoted rule of thumb is 0.1 pixel, but lower is achievable, e.g., about 0.02 pixel is shown for stripe position detection in [2].

Theory

There are four common theory-based approaches to estimating subpixel positions and now also a data-driven approach using deep neural networks:

1. *Interpolation:* An example is in subpixel edge position estimation, which is demonstrated here in one dimension in ideal form in Fig. 1. One can see that measured intensity $f(x)$ is a function of the edge's actual position within a pixel and the values at adjacent pixels. Here we assume that the pixel "position" refers to the center of the pixel. Let δ be the offset of the true edge position away from the pixel center. Then, one can model the value $f(x)$ at x in terms of the values at the neighbors, assuming

Subpixel Estimation, Fig. 1 The values of $f(x)$ created by integrating the continuous signal over the whole pixel

a step function:

$$f(x) = \left(\frac{1}{2} + \delta\right) * f(x-1) + \left(\frac{1}{2} - \delta\right) * f(x+1)$$

from which we can solve for the subpixel edge position $x + \delta$ by:

$$\delta = \frac{2f(x) - f(x-1) - f(x+1)}{2(f(x-1) - f(x+1))}$$

Another approach is to interpolate a continuous curve (or surface) and then find the optimal position on the reconstructed curve (e.g., by using correlation for curve registration). As well as interpolating raw image data, interpolation can also be applied to a cost function, e.g., disparity estimates as computed by a deep neural network stereo matching algorithm [3].

2. *Integration:* An example is the estimation of the center point of a circular dot, such as required for control point localization in a camera calibration scheme. The assumption is that the minor deviations from many boundary pixels can be accumulated to give a more robust estimate. Suppose that $g(x, y)$ are the gray levels of a light circular dot on a dark background, where (x, y) are in a neighborhood N closely centered on the circle. Assume also that the mean dark background level has

been subtracted from all values. Then, the center of the dot is estimated by its gray-level center of mass:

$$\hat{x} = \frac{\sum_{(x,y) \in N} x g(x, y)}{\sum_{(x,y) \in N} g(x, y)}$$

and similarly for \hat{y} .

3. *Taylor series approximation*: An example is the subpixel feature point position estimation in the SIFT [4] operator. Given the difference of Gaussian function $D(x)$, where x represents the two spatial and one scale dimensions, the Taylor series expansion is:

$$D(x+\delta) = D(x) + \frac{\partial D(x)}{\partial x}^\top \delta + \frac{1}{2} \delta^\top \frac{\partial^2 D(x)}{\partial x^2} \delta$$

Differentiating with respect to δ and setting to 0 gives the subpixel (and subscale) estimate:

$$\delta = -\frac{\partial^2 D(x)}{\partial x^2}^{-1} \frac{\partial D(x)}{\partial x}$$

There are a number of different methods for estimating the first and second derivatives. Although the standard limit-based definition is clear, most image-based sampling is on an integer grid, so the typical formulas using “ $\lim h \rightarrow 0$ ” end up with $h = 1$. There are several methods for estimating the derivatives using either local samples [5] or fitting an algebraic curve or surface to local data and then differentiating the continuous function [6].

4. *Phase correlation*: The key principle behind phase correlation is the assumption that the pattern of data across a whole window is more distinctive than the individual pixel values. The technique is also independent of intensity, so it can be used for multispectral or illumination-varying registration. Assume that we have two image windows f_a and f_b and their discrete Fourier transforms $F_a = \mathcal{F}(f_a)$ and $F_b = \mathcal{F}(f_b)$. Compute the cross-power spectrum as $F_a F_b^*$ (by elementwise multiplication) where $*$ is the complex conjugate, normalize elementwise by $|F_a F_a^*|$, and finally

apply the inverse Fourier transform:

$$T = \mathcal{F}^{-1} \left(\frac{F_a F_b^*}{|F_a F_a^*|} \right)$$

The peak position in T is the desired offset. For subpixel alignment, the above method can be used to remove the integer component of the registration. Thereafter, one can estimate the subpixel peak position of the original registration or repeat the process on an upsampled version of the image windows once the integer portion of the offset has been removed.

5. *Deep Neural Networks*: As with many other computer vision applications, deep network methods are now being used in subpixel applications. The general scheme of these networks uses input images of a given size and outputs result images of a larger size (e.g., 2 or 4 times larger). Example applications include stereo matching [3, 7] and superresolution [8]. The above applications estimate numerical quantities, but one can also do semantic labeling at subpixel resolution. An example of this is the unmixing into different land class labels of pixels observed from a remote sensor [9, 10].

Application

Subpixel methods have been developed to analyze the following:

- *Shape parameters*: circle and other “blob” shape parameters [11], ellipse parameters for improved camera calibration [12], photometric stereo [13], superresolution [14], and decomposition of mixed pixels formed by imaging two or more source types [15]
- *Feature positions*: point-like signals [16], “interest” points [4], “edge” transitions [17], “line” transitions [18]
- *Shape matching and registration*: image registration using phase analysis [19, 20] or spatial domain matching [21], motion estimation prior to image compression [22], stereo matching [23] and disparity estimation [3, 24], feature tracking [25], optical flow [26], and image and video stabilization [27].

Definition

Subspace analysis in computer vision is a generic name to describe a general framework for comparison and classification of subspaces. A typical approach in subspace analysis is the subspace method (SM) that classifies an input pattern vector into several classes based on the minimum distance or angle between the input pattern vector and each class subspace, where a class subspace corresponds to the distribution of pattern vectors of the class in high-dimensional vector space.

Background

Comparison and classification of subspaces have been one of the central problems in computer vision, where an image set of an object to be classified is compactly represented by a subspace in high-dimensional vector space.

The subspace method is one of the most effective classification method in subspace analysis, which was developed by two Japanese researchers, Watanabe and Iijima around 1970, independently [1,2]. Watanabe and Iijima named their methods the CLAFIC [3] and the multiple similarity method [4], respectively. The concept

of the subspace method is derived from the observation that patterns belonging to a class form a compact cluster in high-dimensional vector space, where, for example, a $w \times h$ pixels image pattern is usually represented as a vector in $w \times h$ -dimensional vector space. The compact cluster can be represented by a subspace, which is generated by using Karhunen-Loëve (KL) expansion, also known as the principal component analysis (PCA). Note that a subspace is generated for each class, unlike the Eigenface Method [5] in which only one subspace (called eigenspace) is generated.

The SM has been known as one of the most useful methods in pattern recognition field since its algorithm is very simple and it can handle classification of multiple classes. However, its classification performance was not sufficient for many applications in practice, because class subspaces are generated independently of each other [1]. There is no reason to assume a priori that each class subspace is the optimal linear class subspace in terms of classification performance.

To deal with this problem, the SM has been extended. Two typical extensions are the orthogonal subspace method and the learning subspace methods. The orthogonal subspace method [6] executes the SM to a set of class subspaces that are orthogonalized based on the framework proposed by [7] in learning phase. The orthogonalization is known as a useful operation to boost the performance of angle-based method, such as SM, since class subspaces are usually close to each other in many classification problems.

The learning subspace methods [1,8,9] execute the SM to a set of class subspaces, the boundaries between which are adjusted to suppress classification errors for the learning pattern vectors. This adjustment is performed based on the following procedure. First, a learning vector \mathbf{x} is classified by using the SM. Then, if \mathbf{x} is wrongly classified into an incorrect class subspace L_r , which is not corresponding to the class of \mathbf{x} , subspace L_r is slightly rotated into the direction away from \mathbf{x} , and in contrast the correct class subspace L_c of \mathbf{x} is slightly rotated to the direction close to \mathbf{x} . This adjustment is repeated

several times for a set of learning vectors until a minimum classification error is achieved.

Moreover, to deal with the nonlinear distribution of pattern vectors, the SM had also been extended to the kernel nonlinear SM [10, 11] by introducing a nonlinear transformation defined by kernel functions.

These extensions aim mainly to improve the classification ability. In addition to such extensions, the generalization of the SM to classification of sets of patterns is also important for many computer vision problems. In order to handle a set of multiple pattern vectors as an input, the SM has been extended to the mutual subspace method (MSM) [12]. The MSM classifies a set of input pattern vectors into several classes based on multiple canonical (principal) angles [13, 14] between the input subspace and class subspaces, where the input subspace is generated from a set of input patterns as class subspaces. The concept of the MSM is closely related to that of the canonical correlation analysis (CCA) [13]. Actually, the cosine of the i -th smallest canonical angle corresponds to the i -th largest canonical correlation.

The MSM has achieved high performance in recognition of complicated 3D object such as face, using a set of images from image sequence or multi-view images. This success can be mainly explained by the fact that the MSM implicitly utilizes 3D shape information of objects in classification. This is because the similarity between two distributions of various view images of objects reflects the 3D shape similarity between the two objects. To boost the performance of the MSM, it has been further extended to the constrained mutual subspace method (CMSM) [15, 16] and the whitening (or orthogonal) mutual

subspace method (WMSM) [17], where the relationship among class subspaces is modified to approach orthogonalization in the learning phase. In CMSM, the orthogonalization is performed by projecting the class subspaces onto a generalized difference subspace [16], which represents difference components among the class subspaces. In WMSM, it is performed by whitening all the class subspaces. These extensions have boosted the classification ability of the MSM. The MSM and its extensions have been further extended to kernel nonlinear methods [18–21] by kernel trick.

Theory

Subspace Method

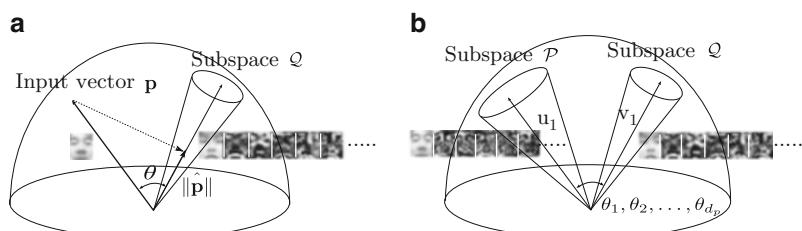

Assume an input vector \mathbf{p} and k class subspaces in f -dimensional vector space. The similarity S of the pattern vector \mathbf{p} to the i -th class is defined based on either of the length of the projected input vector $\hat{\mathbf{p}}$ on the i -th reference subspace [3] or the minimum angle [4] between the input vector \mathbf{p} and the i -th class subspace as shown in Fig. 1a. The length of an input vector \mathbf{p} is often normalized to 1.0. In this case, these two criteria coincide. In the following explanation, therefore, the angle-based similarity S defined by the following equation will be used:

$$S = \cos^2 \theta = \sum_{i=1}^{d_q} \frac{(\mathbf{p} \cdot \boldsymbol{\phi}_i)^2}{\|\mathbf{p}\|^2}, \quad (1)$$

where d_q is the dimension of the class subspace and $\boldsymbol{\phi}_i$ is the i -th f -dimensional orthogonal normal basis vector of the class subspace, which are obtained from applying the principal component analysis (PCA) to a set of patterns of the class.

Subspace Methods,

Fig. 1 Conceptual illustrations of SM and MSM. (a) Subspace method (SM). (b) Mutual subspace method (MSM)

Concretely, these orthonormal basis vectors can be obtained as the eigenvectors of the correlation matrix $\sum_{i=1}^l \mathbf{x}_i \mathbf{x}_i^\top$ calculated from the l learning patterns $\{\mathbf{x}\}$ of the class.

Process Flow of the SM

The whole process of the SM consists of a learning phase and a recognition phase.

In the Learning Phase All k class d_q -dimensional subspaces are generated from a set of pattern vectors of each class by using PCA.

In the Recognition Phase The similarities S of an input vector \mathbf{p} to all the k class subspaces are calculated by using Eq. (1). Then, the input vector is classified into the class of the class subspace with highest similarity. If the highest similarity is lower than a threshold value fixed in advance, the input vector is classified into a reject class.

Mutual Subspace Method

Assume an input subspace and class subspaces in f -dimensional vector space. The similarity of the input subspace to the i -th class subspace is defined based on a minimum canonical angle θ_1 [13, 14] between the input subspace and the class subspace, as shown in Fig. 1b.

Given a d_p -dimensional subspace \mathcal{P} and a d_q -dimensional subspace \mathcal{Q} (for convenience, $d_p \leq d_q$) in the f -dimensional vector space, the canonical angles $\{0 \leq \theta_1, \dots, \theta_{d_p} \leq \frac{\pi}{2}\}$ between \mathcal{P} and \mathcal{Q} are uniquely defined as [14]

$$\cos^2 \theta_i$$

$$= \max_{\substack{\mathbf{u}_i \perp \mathbf{u}_j (i \neq j, i, j = 1 \sim d_p) \\ \mathbf{v}_i \perp \mathbf{v}_j (i \neq j, i, j = 1 \sim d_p)}} \frac{(\mathbf{u}_i \cdot \mathbf{v}_i)^2}{\|\mathbf{u}_i\|^2 \|\mathbf{v}_i\|^2}, \quad (2)$$

where $\mathbf{u}_i \in \mathcal{P}$, $\mathbf{v}_i \in \mathcal{Q}$, $\|\mathbf{u}_i\| \neq 0$, $\|\mathbf{v}_i\| \neq 0$, (\cdot) and $\|\cdot\|$ represent an inner product and a norm, respectively.

Let Φ_i and Ψ_i denote the i -th f -dimensional orthonormal basis vectors of the subspaces \mathcal{P} and \mathcal{Q} , respectively. A practical method of

finding the canonical angles is by computing the matrix $\mathbf{X} = \mathbf{A}^\top \mathbf{B}$, where $\mathbf{A} = [\Phi_1, \dots, \Phi_{d_p}]$ and $\mathbf{B} = [\Psi_1, \dots, \Psi_{d_q}]$. Let $\{\kappa_1, \dots, \kappa_{d_p}\}$ ($\kappa_1 \geq \dots \geq \kappa_{d_p}$) be the singular values of the matrix \mathbf{X} . The cosines of canonical angles $\{\theta_1, \dots, \theta_{d_p}\}$ can be obtained as $\{\kappa_1, \dots, \kappa_{d_p}\}$. The original MSM uses only a minimum canonical angle θ_1 to define the similarity. However, since the remaining canonical angles also have information for classification, the value, $\tilde{S} = \frac{1}{t} \sum_{i=1}^t \cos^2 \theta_i$, defined from the smallest t canonical angles is often used as the similarity in many computer vision problems. The value \tilde{S} reflects the structural similarity between two subspaces. The whole process of the MSM is the same as that of the SM except that an input vector is replaced by an input subspace.

Constrained Mutual Subspace Method

The essence of constrained mutual subspace method (CMSM) [15, 16] is to conduct MSM on a generalized difference subspace (GDS), where the GDS is generated from the sum of the orthogonal projection matrices of all the class subspaces [16]. This can be performed by applying MSM to a set of an input subspace and class subspaces, which are projected onto the GDS. For the projection, there are two ways that give equivalent results. One is to project the basis vectors of each class subspace onto GDS and then normalize the projected basis, which is further followed by Gram-Schmidt orthogonalization after the orthonormality is lost by the projection. The alternative is to first project the images for each class subspace and then generate a class subspace from the projected images.

Application

The subspace methods and their extensions have been applied to various problems [1, 10, 11] of computer vision due to their high general versatility and low computational cost. In particular, the extended SMs have produced remarkable results in optical character recognition (OCR), such as handwriting Chinese character recognition [2, 4], in Japanese industry.

The mutual subspace method has also been demonstrated to be extremely effective for 3D object recognition. In particular, the MSM has been known to be suitable for face recognition [15, 17, 22] because the subspace (called “illumination subspace”), which includes any face image patterns under all possible illumination conditions, can be generated from face images under more than three different illumination conditions [23]. The nonlinear extensions of the MSM, CMSM, and WMSM have been shown to be further effective for 3D object recognition using image sequences and multi-view images [18–21, 24, 25]. These methods work well together with CNN features, which are extracted through a pre-trained Convolution neural network [26].

Definition

Surface roughness is structure on the microscale of object surfaces. The illumination of such rough surfaces causes shading, shadowing, interreflections, and occlusion effects on the microscale, resulting in 3D texture, which depends strongly on the viewing direction and on the illumination conditions.

Background

Most natural surfaces are rough on the microscale. This microscale structure can be described mathematically with exact geometrical models, with statistical surface height or attitude (slope) distributions.

Surface roughness causes 3D texture in images, which varies over objects as a function of the local viewing angle and illumination conditions. They can be described by the bidirectional texture function or BTF [3]. Thus, textures of rough objects cannot be texture-mapped, in contradistinction to flat, wallpaper-type textures. They need to be synthesized using surface models or photographed BTFs [6]. Even unresolved 3D texture in an image affects material appearance, through effects on the bidirectional reflectance distribution function (BRDF [7]).

S

Theory

Since the optical effects due to surface roughness are quite complicated, it is hard to formally derive models for 3D textures. Physics-based optical models can be of a geometrical or a statistical nature. Physically exact geometrical models are scarce, because for most surface roughness structures the shadowing and interreflections calculations are intractable. As a

summary description of surface roughness, one may use such measures as the probability density of heights, the autocorrelation function of heights, and the probability density of orientations of local microfacets. For example, “bump mapping” techniques [4] in computer graphics regard only the distribution of orientations and ignore differences in height. Indeed much of the image structure generated by 3D texture is due to the fact that surface microfacets differ in orientation and thus receive different illuminances according to Lambert’s law [5]. The bidirectional texture contrast function (BTCF [9]) provides robust guesstimates of the attitude distribution. However, the height distribution is also important because it causes such important effects as vignetting, shadowing and occlusion on the microscale.

The field of surface metrology is concerned with surface roughness measurements and descriptions. Using profilometers, surface profiles of real surfaces can be measured, from which roughness parameters can be derived. Roughness parameters usually are statistical measures over lines or areas of the height profile. Many different parameters are in use and can easily be found in engineering literature and via the Internet [11]. Photometric surface metrology from single images suffers from the bas-relief ambiguity [1] and is in computer vision usually referred to as texture analysis [6].

Open Problems

3D texture provides information which is additional to shading; shading is often primarily dependent on the normal component of the illumination, while 3D texture is primarily dependent on the tangential component of the illumination. The spatial structure of 3D texture gradients, e.g., the “illuminance flow,” allows inferences about shape and illumination. Formal solutions to the question how exactly shading and 3D texture combine and interact might further the field of shape from shading.

Experimental Results

Several databases of images of rough surfaces can be found on the Internet [2, 8, 10].

Definition

The Swendsen-Wang (SW) algorithm [1] is an efficient Markov chain Monte Carlo algorithm for sampling from the Ising/Potts model:

$$\pi_{\text{Potts}}(X) = \frac{1}{Z} \exp\left\{\sum_{\langle i,j \rangle \in E} \beta_{ij} \delta_{X_i=X_j}\right\} \quad (1)$$

where δ_A is a Boolean function, equal to 1 if condition A is true, and 0 otherwise. The Ising/Potts model is defined for a graph $G = \langle V, E \rangle$ and a labeling $X : V \rightarrow \{1, \dots, L\}$. The obtained

model is called Ising model [2] when $L = 2$ and Potts model [3] when $L \geq 3$.

Most computer vision applications use $\beta_{ij} = \beta > 0$, also named the ferromagnetic model, preferring similar colors for neighboring vertices. The Potts models and its extensions are used as prior probabilities in some Bayesian inference tasks.

Background

The SW algorithm was developed in [1] to overcome some of the limitations of the Gibbs sampler [4] in obtaining samples from the Ising/Potts model (1). If one sets $\beta_{ij} = 1/kT$ where T is a parameter called *temperature* and k is a constant, the Gibbs sampler was observed to slow down, obtaining highly correlated consecutive samples, around a certain temperature named the critical temperature.

In contrast, consecutive samples obtained by the SW algorithm exhibit much smaller correlation at the critical temperature.

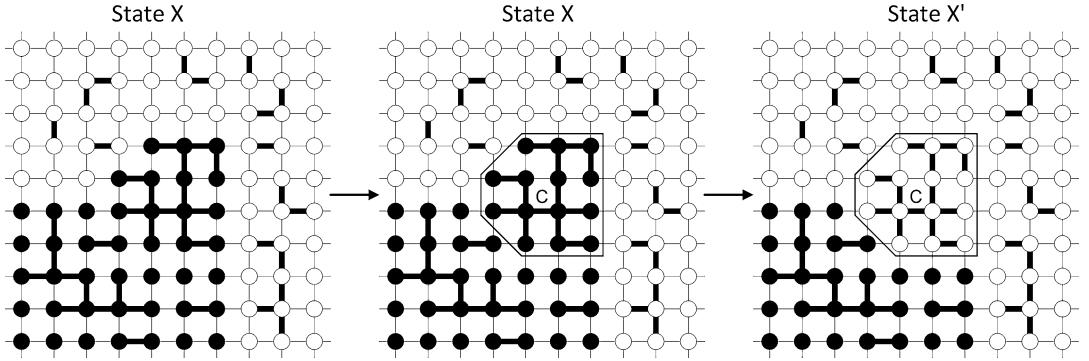

Theory

As opposed to the Gibbs sampler [4] that relabels one node at a time, the SW algorithm changes the label of a cluster of nodes in a single move.

The SW algorithm is illustrated in Fig. 1. At each step, the SW method constructs a new set $F \subset E$ of graph edges, also called the active or “on” edges. This is done by initializing $F = \emptyset$ and adding to F any edge $\langle i, j \rangle \in E$ such that $X_i = X_j$ with probability $1 - e^{-\beta_{ij}}$. A connected component of the new graph $G' = (V, F)$ is selected at random, a new label l is chosen at random among the possible labels $\{1, \dots, L\}$, and all nodes in C are relabeled to l . For more details, see Algorithm 1 below.

Alternatively, the labels of all connected components C of the graph $G' = \langle V, F \rangle$ can be flipped independently.

The SW algorithm is run for many iterations, and after a burn-in period that depends on the number of nodes and the coefficients β_{ij} , the

Swendsen-Wang Algorithm, Fig. 1 The Swendsen-Wang method. Left: In the current labeling state X (left), the graph edges (shown with thin lines) between same label nodes are turned “on” with probability $p_{ij} = 1 - e^{-\beta_{ij}}$. Middle: A connected component C of the graph of “on” edges is randomly selected, a new label l is randomly chosen. Right: All nodes in C are relabeled with label l , obtaining the new labeling state X'

Algorithm 1 The Swendsen-Wang Algorithm

Given: Graph $G = \langle V, E \rangle$, $V = (V_1, \dots, V_n)$ and the Ising/Potts model from Eq. (1).

Input: Current labeling state $X = (X_1, \dots, X_n)$.

Output: New labeling state X' .

Set $F = \emptyset$

for all edges $e = \langle i, j \rangle \in E$ with $X_i = X_j$ **do**

 Sample $u_{ij} \sim \text{Bernoulli}(p_{ij})$ with $p_{ij} = 1 - e^{-\beta_{ij}}$

if $u_{ij} = 1$ **then**

$F \leftarrow F \cup \{\langle i, j \rangle\}$

end if

end for

Pick a connected component C of $G' = (V, F)$ at random.

Sample $l \sim \text{Unif}\{1, \dots, L\}$

Set $X'_i = l, \forall i \in C, X'_i = X_i, \forall i \notin C$

labeling states X will follow the posterior probability (1).

In a modified version by Wolff [5], one may choose a vertex $v \in V$ and grow a connected component C starting at $C = \{v\}$ and following Bernoulli trials on edges adjacent to C that have not been visited yet. This saves some computation in the clustering step, and bigger components have a higher chance to be selected.

The SW method described above is different from what was presented in the original paper [1]. This description follows the interpretation of Edward and Sokal [6], where the variables $u_{ij}|_{\langle i,j \rangle \in E}$ are collected into the vector U , and the set of active edges is $F(U) = \{\langle i, j \rangle \in E, u_{ij} = 1\}$. The SW algorithm is explained as

an auxiliary variable method that samples from the joint model:

$$\begin{aligned} p_{ES}(X, U) &\propto \prod_{\langle i,j \rangle \in E} [(1 - p_{ij})\delta_{u_{ij}=0} \\ &\quad + p_{ij}\delta_{u_{ij}=1} \cdot \delta_{x_i=x_j}] \\ &\propto (1 - p_{ij})^{|E \setminus F(U)|} \cdot p_{ij}^{|F(U)|}. \end{aligned} \quad (2)$$

$$\prod_{\langle i,j \rangle \in F(U)} \delta_{x_i=x_j}.$$

The SW algorithm samples from the above joint model $p_{ES}(X, U)$ by alternatively sampling $p_{ES}(U|X)$ and $p_{ES}(X|U)$. Note that the sampling of $p_{ES}(U|X)$ is exactly the part of the SW algorithm that constructs the random edges F , while the sampling of $p_{ES}(X|U)$ is the part that flips the labels of one or all the connected components C of the graph $G' = \langle V, F \rangle$. By sampling (X, U) from the joint model $p_{ES}(X, U)$, the labelings X will follow the marginal $p_{ES}(X)$ which is exactly the Potts model $p_{Potts}(X)$. On the other hand, the random edges U follow the marginal $p_{ES}(U)$ which is the random cluster model.

Another explanation of the SW algorithm is due to Higdon [7] through the perspective of slice sampling and decoupling. He also introduces partial decoupling, which gives a data-driven clustering step.

The SW algorithm was generalized to arbitrary probabilities in [8], by interpreting it as a Metropolis-Hastings [9,10] step. This generalization is named the Swendsen-Wang Cut algorithm.

An exact sampling method for the Potts model using the SW algorithm was developed by Huber [11], based on coupling from the past [12]. This method eliminates the need for the burn-in period for obtaining samples; however, it is quite conservative and can only be used in practice for small graphs.

Application

Due to being restricted to the Ising/Potts model, there are only a few applications of the SW algorithm to computer vision.

Higdon [7] introduced partial decoupling and presented an application of SW to image reconstruction from positron emission tomography (PET) data. The SW algorithm with partial decoupling was also used in [13] for texture segmentation using a model with Potts prior and a data term. The SW algorithm was compared with the Gibbs sampler and SW with partial decoupling in [14].

Morris [15] introduced a higher-order prior model named the “chien” model that is not based on pairwise interactions but on 3×3 cliques. He used the SW algorithm with partial decoupling for obtaining samples from this model.

The SW Cut algorithm, a SW generalization to arbitrary probabilities and edge weights, has seen many applications to image, motion, and object segmentation as well as stereo matching and curve grouping, to name only a few. For more details, see the SW Cut entry of the encyclopedia.

Definition

The Swendsen-Wang cut algorithm is an efficient Markov chain Monte Carlo (MCMC) algorithm for sampling arbitrary distributions $p(X)$ defined on partitions X of a graph $G = \langle V, E \rangle$. It uses a set of weights on the graph edges to form data-driven clusters and change the label of an entire cluster in one move.

Background

Many computer vision problems can be formulated as the optimization of an energy or probability function defined over the space of partitions or labelings of a graph. Efficient algorithms such as graph cuts [1], belief propagation [2], or dual decomposition [3] can be used for certain types of energy functions.

However, for general forms of the energy or probability functions, many times one has to resort to stochastic relaxation (Gibbs sampler) [4] methods that relabel one node at a time. Such algorithms can be very slow in practice, especially when strong regularization is imposed on the partitions.

For Ising/Potts models [5, 6], the Swendsen-Wang (SW) algorithm [7, 8] was designed to overcome some of the limitations of the stochastic relaxation. The SW algorithm achieves speedup by relabeling a cluster of adjacent nodes of the graph in a single move.

Theory

The Swendsen-Wang cuts algorithm is a generalization of the Swendsen-Wang algorithm to arbitrary distributions by adding an acceptance step for the proposed MCMC cluster relabeling

move. The acceptance probability can be computed efficiently using Eq. (3).

Let $G = \langle V, E \rangle$ be a graph, $q_e \in [0, 1], \forall e \in E$ a set of weights on the graph edges and $p(X)$ a probability defined for any partition or labeling $X = (X_1, \dots, X_n)$ of the graph nodes $V = (V_1, \dots, V_n)$. The probability $p(X)$ can be defined up to a constant. Assume also given a probability mass function $q(l|C, X)$ defined over the set possible labels l , given a labeling state X and a set of nodes $C \subset V$. The function $q(l|C, X)$ could be as simple as a uniform distribution or can be driven by the image data.

For any labeling X of the graph nodes and any label l , define $V_l(X)$ to be the set of nodes with label l :

$$V_l(X) = \{i \in V, X_i = l\} \quad (1)$$

For any two subsets $C, D \subset V$, define the *cut* from C to D as the set of edges:

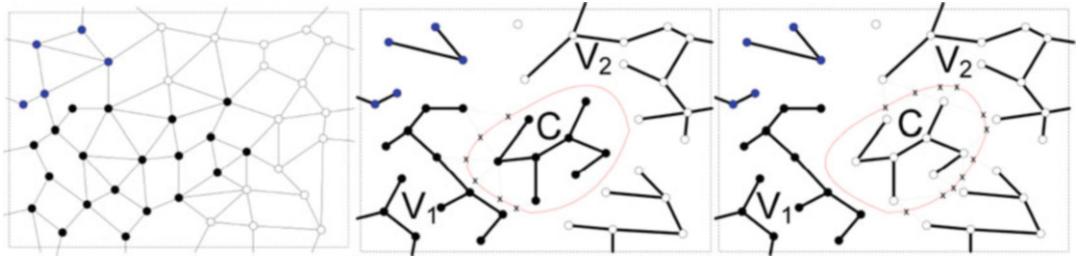

$$C(C, D) = \{e = \langle i, j \rangle \in E, i \in C, j \in D\}. \quad (2)$$

With these notations, one move of the SW Cut algorithm proceeds as follows, also illustrated in Fig. 1.

The acceptance probability $\alpha(X \rightarrow X')$ has a factor defined in terms of the cuts $C(C, V_l(X) \setminus C)$ and $C(C, V_{l'}(X) \setminus C)$ that contain the edges from C toward the nodes with the old label l and the proposed new label l' , respectively. These cuts are shown with dotted lines in Fig. 1.

The algorithm was observed to be hundreds of times faster than the Gibbs sampler when the edge weights q_e were chosen appropriately. The edge weights should approximate the probability that the two adjacent nodes belong to the same label. This can be achieved using the image information available at the graph nodes and could be learned in a discriminative way, for example, using Boosting or regression.

The SW cut algorithm can be used for maximum a posteriori (MAP) estimation using a simulated annealing schedule, in which the probability $p(X)$ is raised to increasingly larger powers,

Swendsen-Wang Cut Algorithm, Fig. 1 Illustration of the SW Cut algorithm. Left: A graph $G = \langle V, E \rangle$ with a labeling X . Middle: At each step, a new graph $G' = \langle V, F \rangle$ is formed by going through all edges between same label nodes and keeping an edge e with

probability given by its weight q_e . Right: Then a connected component C of G' is selected at random, a new label l' is chosen for C , and if the move is accepted, the new labeling state has $X_C = l'$

Algorithm 1 The Swendsen-Wang Cut Algorithm

Given: Weighted graph $G = \langle V, E \rangle$, $V = (V_1, \dots, V_n)$ and a probability $p(X)$.

Input: Current labeling state $X = (X_1, \dots, X_n)$.

Output: New labeling state X' .

Set $F = \emptyset$

for all edges $e = \langle i, j \rangle \in E$ with $X_i = X_j$ **do**

 Sample $u \sim \text{Bernoulli}(q_e)$

if $u = 1$ **then**

$F \leftarrow F \cup \{\langle i, j \rangle\}$

end if

end for

Pick a connected component C of $G' = (V, F)$ at random, with some label $X_C = l$.

Sample a new label $l' \sim q(l'|C, X)$

Sample $u \sim \text{Bernoulli}(\alpha(X \rightarrow X'))$ where $X'_i = l', \forall i \in C, X'_i = X_i, \forall i \notin C$ and

$$\alpha(X \rightarrow X') = \min(1, \frac{\prod_{e \in C(C, V_{l'}(X) \setminus C)} (1 - q_e)}{\prod_{e \in C(C, V_l(X) \setminus C)} (1 - q_e)} \cdot \frac{q(l|C, X') \cdot p(X')}{q(l'|C, X) \cdot p(X)}). \quad (3)$$

if $u = 0$ **then**

 Reject the move i.e., make $X' = X$.

end if

forcing the sampling to focus on the labelings X of highest probability.

A Wolff [9] version of the SW cut algorithm has also been proposed [10, 11], which grows a connected component from a seed node. This version reduces the amount of computation required

for the clustering step, and larger connected components have a higher chance to be selected.

Application

The SWC algorithm has many applications in computer vision. One application was image segmentation [10, 12], where the graph had image superpixels as nodes and edges based on the superpixel adjacency. The edge weights q_e were based on the similarity between the intensity histograms of the corresponding superpixels. The probability $p(X)$ was a Bayesian model with a prior based on connected components and was maximized by SW cut with simulated annealing. Experiments showed that the SW cut algorithm was two orders of magnitude faster in total CPU time when compared to the Gibbs sampler tuned to obtain the same optimal result.

Other applications of the SW cut algorithm include curve grouping [12], dense stereo matching [10, 13], motion segmentation [11, 14] and estimation [15], object segmentation [16], and task allocation [17] in robotics. Furthermore, the SW cut algorithm was used for discovering composite features for object detection [18] and for graph matching [19].

Open Problems

In problems, higher-level objects can sometimes be detected only when at least three components

are considered simultaneously. For such cases, it is an open question how to generalize the SW cut algorithm to use higher order cliques instead of graph edges to construct the clusters.

For example, finding lines in point clouds can be seen as the problem of labeling the points that belong to each line and the remaining points as background. But since nontrivial collinearity exists only between at least three points, it is difficult to define edge weights directly between the points. A generalization of the SW Cut algorithm could use triplets of collinear points instead of graph edges to form point clusters that are likely to be on the same line. It is not known how exactly to form the clusters from such higher order cliques and what is the acceptance probability for relabeling such a cluster.

Definition

Texture classification deals with classification of images or regions based on the computational representations of their underlying texture.

Background

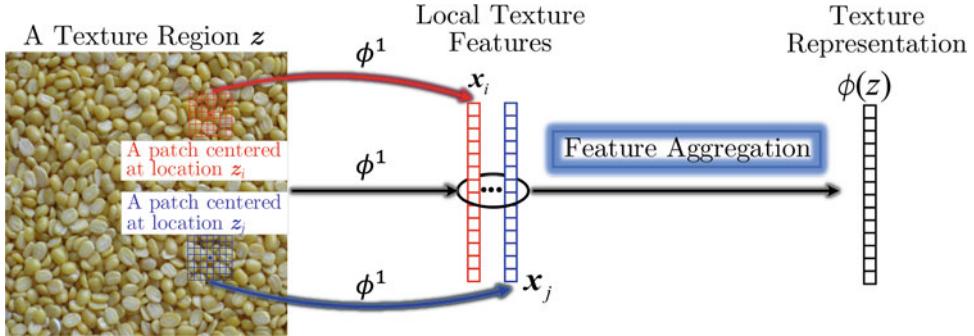

As an important visual cue, texture is a fundamental characteristic of many types of images ranging from multispectral satellite images to microscopic images of tissue samples (see Fig. 1). For instance, texture appears to be a stronger cue to object identity than global shape information. It is easy to recognize and hard to define. Although it lacks a generally agreed definition, texture has the following important characteristics. (1) The unique property of repetition: similar visual patterns (texture primitives or textons) with some degree of variability in their appearances and relative positions appear repeatedly. (2) A regional property with stationarity: unlike color, it is a phenomenon of a region and cannot be defined on a single pixel. The probability density functions that characterize the distribution and variation of the repeating structure are consistent. (3) Scale dependent: whether an effect is referred to as texture or not relies on the scale at which it is viewed. Different types of texture are visible at different scales.

Analysis of visual patterns and texture plays a central role in mining knowledge from visual data. Feature representations of image patterns and texture enable us to abstract, store, classify, search, and generate in order to understand the physical world. As a longstanding, fundamental, and challenging problem in the fields of computer vision and pattern recognition, texture analysis has been a topic of intensive research since

Texture Classification, Fig. 1 Texture is an important characteristic of many types of images. (a) gold coins, (b) zebra, (c) purple orchids, (d) image by Van Gogh, (e)

facial texture, (g) an aerial image, (h) a synthetic aperture radar image of sea ice, (i) prostate cancer tissue, and (j) honeycombing fibrosis in lung CT

Texture Classification, Fig. 2 The goal of texture representation is to transform the input image or region into a feature vector that describes the properties of the texture, facilitating subsequent classification task. Usually a tex-

ture image is firstly probed with local texture operators to obtain a pool of local features, which are then aggregated into a global representation for an entire image or region

the 1960s [1] due to its significance both in understanding how the texture perception process works in human vision and in the important role it plays in a wide variety of applications. Texture analysis embraces several problems including classification, segmentation, synthesis, retrieval, and physics from texture [2,3]. Texture representation (see Fig. 2), i.e., the extraction of computational features that measure texture information, is at the core of these texture analysis problems. In addition, texture representations are found to be useful in a wide variety of recognition problems in computer vision, such as recognizing objects, scenes, faces, etc. The enormous growth in

image and video data due to surveillance, mobile devices, medical imaging, robotics, etc. requires sophisticated computational texture representations [2,3].

The goal of texture classification is to design algorithms for declaring an unknown region or image as belonging to one of a set of known texture categories of which training samples have been provided. As a classical pattern recognition problem, texture classification primarily consists of two critical subproblems: texture representation and classifier design. It is generally agreed that the extraction of powerful texture representations plays a relatively more important role and thus is the focus of attention. A recent

comprehensive survey on texture representation and classification can be found in [2], where a taxonomy of texture representation methods is presented.

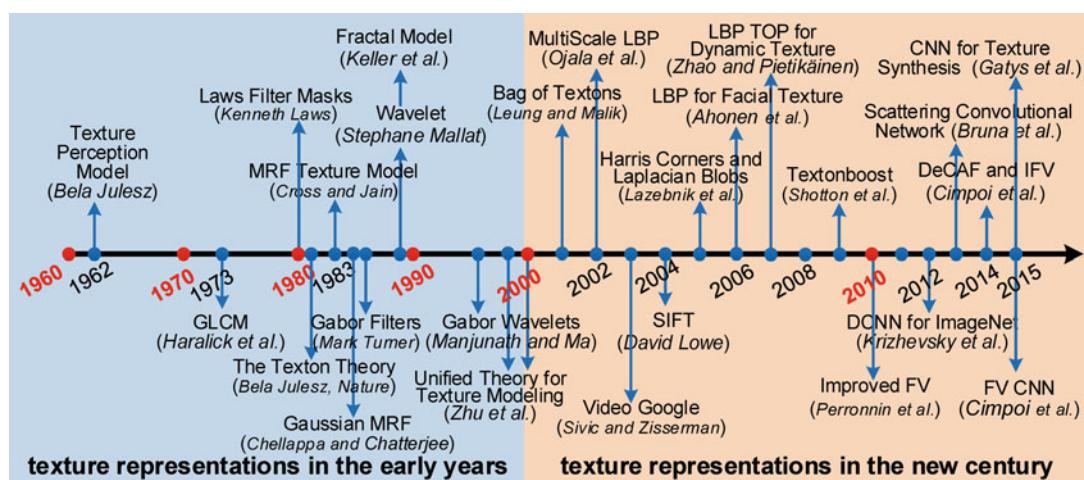

Theory

The goal of texture representation in texture classification is to transform an image or region into a feature vector that encodes texture information, facilitating the subsequent classification task. When deriving texture representations, the three aforementioned texture characteristics should be taken into consideration, especially the unique property of repetition. The standard texture representation process is illustrated in Fig. 2. Since texture is a spatial phenomenon, texture representation cannot be based on a single pixel and generally requires the analysis of patterns over local pixel neighborhoods. Usually an image or region is firstly probed with local texture operators to obtain a pool of local features. Since local patterns repeat, a summarization or aggregation is necessary to obtain an efficient global representation for the whole region. The global representation should characterize the distribution of and the variation of the repeating

structure. This type of representation is often referred to as an “orderless” texture model.

As with image representations for objects and scenes, in addition to distinctiveness, texture representations should have robustness against intraclass variations caused by illumination change, geometric transformation, nonrigid deformation, degradation in image quality, etc. in order to support recognition in real-world environments. For many applications such as resource-limited platforms like embedded and handheld devices, computational efficiency for computing representations is very critical. The desired requirements for texture representations are task related. The inherent difficulty in obtaining powerful texture representations lies in balancing two competing goals: high-quality representation (distinctive and robust) and high computational efficiency.

A large number of different approaches for texture representation have been proposed, and a recent comprehensive survey can be found in [2]. Milestones in texture representation over the past decades are summarized in Fig. 3. In the past two decades, remarkable progress has been witnessed in texture representation and learning, which mainly consist of two important development stages. In the first stage from 1995 to 2012 (i.e., the predeep learning era), the field was dominated by milestone handcrafted texture

Texture Classification, Fig. 3 A tour of algorithm evolution in texture representation over the past decades. Relevant references in this figure can be found in [2]

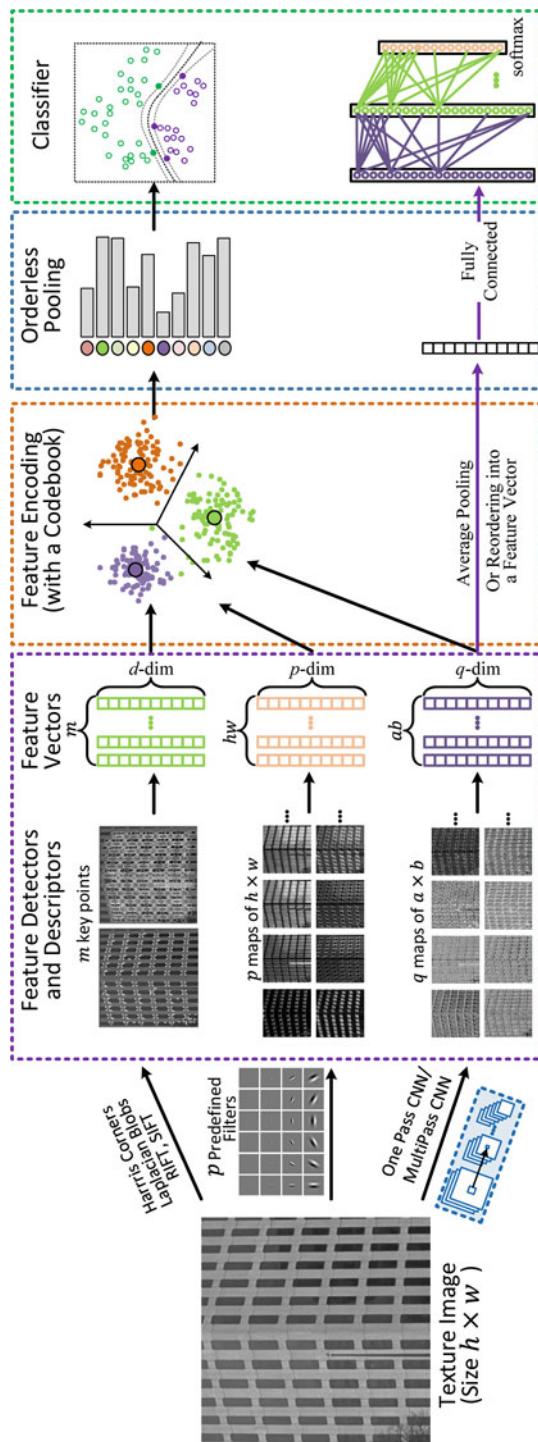

descriptors such as SIFT [4], HOG [5], LBP [6, 7], Bag of Visual Words (BoW) [8, 9], Fisher Vector [10], etc. The second stage, i.e., the deep learning era, starts from 2012 when a team led by Hinton won the prestigious ImageNet Challenge using deep learning techniques [11]. In the past several years, the field of computer vision has been able to take great leaps in recent years due to advances in deep learning. In texture classification, research focus has also begun to transfer to deep learning-based methods [12], especially Deep Convolutional Neural Networks (DCNNs). However, researchers still face the fundamental problem of finding the best computational texture representation for a given task [7, 13]. Liu et al. [2] divided modern texture representation methods since 2000 into three categories, Bag of visual Words (BoW) based, Deep Convolutional Neural Network (DCNN) based, and texture attribute based, with the first two categories being extensively studied.

BoW-based Texture Representation The BoW pipeline is sketched in Fig. 4, consisting of the following basic steps. (1) Local Patch Extraction. For a given image, a pool of local image patches is extracted over a sparse set of points of interest, over a fixed grid, or densely at each pixel position. (2) Local Patch Representation. For each extracted image patch, local texture descriptors are applied. High-quality local texture descriptors play a critical role in the BoW model. Representative local texture descriptors include MR8, SIFT, LBP, HOG, and pretrained DCNN. (3) Codebook Generation. The objective of this step is to generate a codebook (i.e., a texton dictionary) based on training data. The key here is how to generate a compact and discriminative codebook so as to enable accurate and efficient classification. (4) Feature Encoding. Given the generated codebook and the extracted local texture features from an image, feature encoding represents each local feature with the codebook, usually by mapping each local feature to one or a few codewords, resulting a feature coding vector. Of all the steps in the BoW pipeline, feature encoding is a core component which links local representation and feature pool-

ing, greatly influencing texture classification in terms of both accuracy and speed. Commonly used feature encoding methods include BoW, VLAD, Fisher Vector, etc. (5) Feature Pooling. A global feature representation is produced by using a feature pooling strategy to aggregate the coded feature vectors. Classical pooling methods include average pooling, max pooling, and Spatial Pyramid Pooling (SPM). (6) Feature Classification. The global feature is used as the basis for classification, for which many approaches are possible, e.g., Nearest Neighbor Classifier (NNC) and SVMs.

DCNN-based Texture Representation A key to the great success of DCNNs is their ability to leverage large labeled datasets to learn powerful feature representations with multiple levels of abstraction, which have demonstrated good generalization ability. DCNNs pretrained on very large datasets were found to transfer well to many other problems, such as texture classification [14] and object detection [15], with a relatively modest adaptation effort. In general, the current literature on texture classification includes examples of both employing pretrained generic DCNN models or performing fine-tuning for specific texture classification tasks. In the recent survey [2], DCNN-based texture classification methods can be classified into three categories: using pretrained generic DCNN models [14], using fine-tuned DCNN models [16], and using handcrafted deep convolutional networks [17].

Among various texture representation methods, LBP [6] which adopts a predefined codebook is well known for its computational efficiency and good texture classification performance. A taxonomy of LBP features and benchmark of the most promising variants was presented in [18]. It presents an extensive experimental evaluation of LBP variants and deep learning-based features. The experiments were designed to measure features' robustness against different classification challenges, including changes in rotation, scale, illumination, viewpoint, number of classes, different types of image degradation, and computational complexity. The best overall performance was obtained for the Median Robust Extended

Texture Classification, Fig. 4 General pipeline of the Bow model. Features are computed from handcrafted detectors for descriptors like SIFT and RIFT and densely applied local texture descriptors like handcrafted filters or CNNs. The CNN features can also be computed in an end-to-end manner using fine-tuned CNN models. These local features are quantized to visual words in a codebook

Local Binary Pattern (MRELBP) operator [19]. With the advance in DCNN architectures, texture representations based on DCNNs (e.g., VGGNet [20] and ResNet [21]) have quickly demonstrated their strengths in texture classification [14], especially for recognizing textures with very large appearance variations. The sensitivity to image degradations and computational complexity are among the key problems for most of existing methods [18].

Application

Typical applications of texture recognition methodology include medical image analysis (e.g., quantitative dermatology), industrial quality inspection, image search, analysis of satellite or aerial imagery, face analysis, biometrics, object recognition, texture synthesis for computer graphics and image compression in e-commerce applications, and road analysis for automated driving. Internal imaging using CT and MRI has been advanced significantly in recent years. The use of texture recognition for various biomedical applications using different types of images has increased rapidly in recent years. Texture analysis can support detection of small changes, anomalies, and other perturbations in medical images. For example, a small texture change in a medical imagery may mean the early start of a disease. On the contrary, a small texture change may mean the early response to a treatment.

Open Problems

Despite significant progress in recent years, most texture descriptors, irrespective of whether hand-crafted or learned, have not been capable of performing at a level sufficient for real-world applications. Researchers still face the fundamental problem of finding the best computational texture representations for a given task. Recently, many approaches have used DCNNs to build texture representations. Nevertheless, it is still unclear how these models represent texture and

invariances. The goal of the community is to develop texture representations that can accurately and robustly discriminate massive image texture categories in all possible scenes, at a level comparable to the human visual system. In practical applications, factors such as significant changes in illumination, rotation, viewpoint and scale, nonrigid transformations, and image degradations such as occlusions, image blur, and random noise call for more discriminative and robust texture representations. Another challenging issue is the computational burden concerning many existing methods, since many real-world applications either require real-time processing (e.g., mobile applications) or have to deal with huge amounts of data. Therefore, compact and efficient texture representations are required.

Definition

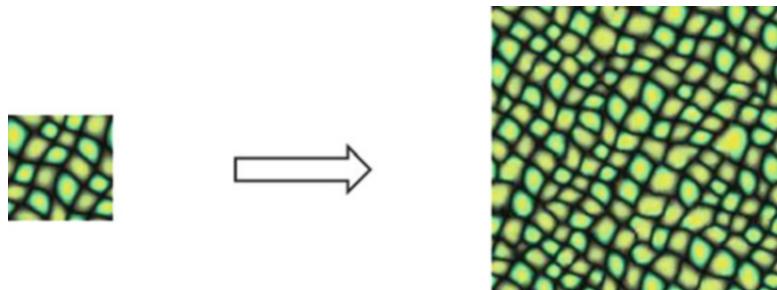

Texture synthesis is the process of producing an image of a certain texture pattern from either a model governing the variation of the texture patterns or a small number of samples of the texture pattern, as illustrated in Fig. 1. The model could be either learned from training samples or composed of a set of placing rules or procedural steps.

Background

Texture is an important characteristic of the appearance of objects or things in natural scenes. A texture image has two unique properties: *stationarity* and *locality*. *Stationarity* implies that different regions of a texture image often appear to be similar, and *locality* indicates that each pixel can largely be predicted from a small set of neighboring pixels without the need of considering the rest of the image. Following [1], in two extremes, texture could either be *deterministic* (Fig. 2a) or *stochastic* (Fig. 2b). The former often consists of a set of deterministic primitives (i.e., textons) with certain placement

Texture Synthesis, Fig. 1

Given the left sample, texture synthesis is to generate a new texture image which follows the same underlying process governing the texture pattern

rules, while the appearance of the latter is random in nature (i.e., no explicitly visible textons in the image space), governed by a stochastic process. As the world is never too extreme, most real-word textures (Fig. 2c) are a mixture of *deterministic* and *stochastic* patterns with different mixture ratios.

Texture synthesis has been an active research topic in computer vision and graphics for decades, and a lot of methods have been proposed with different objectives and assumptions. They can be roughly classified into two categories: procedure-based [2–4] and sample-based [1, 5, 6]. Nevertheless, in computer vision, texture synthesis often refers to the latter one.

Many classical procedure-based methods were proposed from the graphics research community. They often use preset physical or biological procedures and parameters to simulate their underlying formation process. For example, reaction-diffusion equations [2] were adopted to generate the textures on animal skin. Desbenoit et al. [3] adopted an open diffusion-limited model for lichen. And a clonal mosaic model is proposed for the synthesis of mammalian coat patterns in [4]. Procedure methods can be very fast and memory efficient because they can render the textures on the fly. However, they are often limited to very specific textures and need careful parameter tweaking.

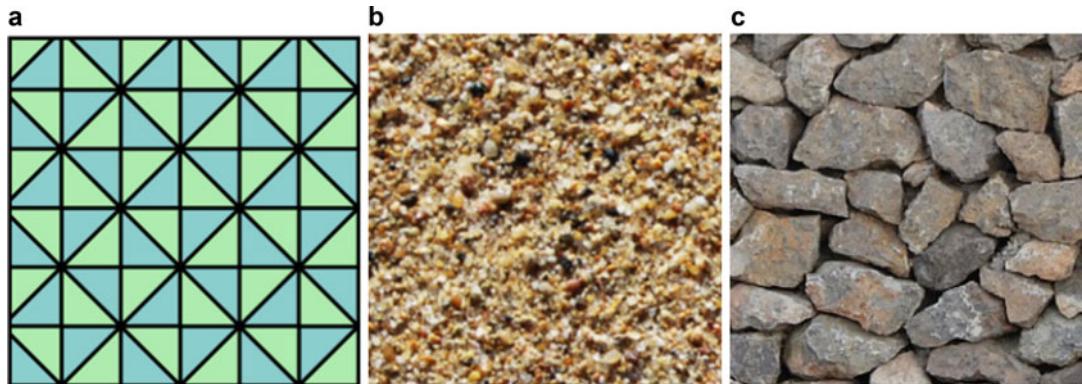

Sample-based methods can handle more general textures, which can be broadly categorized as *model-based method* [5, 7, 8] and *direct method* [6, 9–12]. Model-based methods explicitly construct a statistical model of the texture patterns (texture modeling step) and then adopt some sampling strategies to obtain the final texture (sampling step), while direct methods sample

pixels or small texture patches from the provided examples with certain local density functions or matching criteria and then grow or stitch them together to form a bigger texture image.

Theory and Application

In computer vision, the theoretic foundation of many model-based methods for texture synthesis is provided by the Julesz ensemble [13], which is the maximum set of images sharing the same feature statistics (i.e., the values of the first to the k th order statistics of some filter responses are the same). Much of later work adopted the principle of the Julesz ensemble but differed in what specific image features and set of statistics are used in modeling the texture. For example, Heeger and Bergen [1] matched the filter response histograms at different spatial scales using an image pyramid. First- and second-order statistics of joint wavelet coefficients are explored in [7]. A texture feature extraction technique involving autocorrelation function measurement of a texture field, combined with a histogram representation of a statistically decorrelated version of the texture field, was introduced by Faugeras and Pratt [8].

Along the statistical modeling side, Zhu et al. [5] proposed the *FRAME* model, a seminal work that combines filtering theory and Markov random field modeling together through the maximum entropy principle. The *FRAME* model provides a unified view and interpretation of many previous concepts and methods in texture modeling. The texture modeling part consists of two steps: (1) the feature extraction step to compute the features of the textures with a filter bank and (2) the feature fusion step to derive an estimated

Texture Synthesis, Fig. 2 Textures could be (a) deterministic, (b) stochastic, or (c) a mixture of both

distribution which has the same marginal distributions on the features extracted in step (1). Once the *FRAME* model is built, Gibbs sampling is adopted to synthesize new texture images. Wu et al. [14] proved the equivalence of the Julesz ensemble and the Gibbs texture ensemble. One drawback of texture synthesis using Gibbs sampling over the *FRAME* model is that computationally it is rather slow.

The success of deep learning brings new means of modeling textures with nonlinear filters. Gatys et al. [15] presented one of the first convolution neural network (CNN)-based texture synthesis methods. Instead of using linear filter banks, Gatys et al. [15] leveraged the deep learning features from the intermediate layers of a pre-trained neural network (on image recognition tasks) and characterized the textures with the correlation matrix (Gram-matrix) between feature responses in each layer. To generate a new texture image, a randomly initialized noise image is refined with gradient descent to produce the target image that matches the Gram-matrix representation of the given sample texture image. Inspired by Gatys et al. [15], Chen et al. [16] proposed StyleBank, which defines textons on the nonlinear filtered maps from an encoder network and successfully demonstrated how rendering textons of different styles through a decoder network can produce different stylized images. Li et al. [17] learn *FRAME* models using convolutional neural network (CNN) filters, which is able to leverage the highly expressive

CNN features to generate rich object and texture patterns in natural scenes.

Alternatively, without explicitly establishing a model of the target texture, direct methods focus on growing a new texture image from an initial seed and regard the given texture example as a source pool to constantly sample similar pixels or patches. Efros and Leung [6] synthesized textures through a nonparametric sampling from a local density function, which was shown to work well for a wide variety of textures ranging from deterministic to stochastic. Though much faster than [5], this method is still too slow since it produces textures by sampling at the pixel level. Wei and Levoy [11] significantly accelerated Efros and Leung's algorithm [6] using a tree-structured vector quantization. However, it is still not real-time.

Due to the greedy nature, one limitation of [6] and [11] is that the algorithms may be trapped in suboptimal local minimum in the search space and hence start growing undesired texture pattern or verbatim copying the seed image. By using a patch-based sampling algorithm, Liang et al. [10] proposed a real-time texture synthesis algorithm, which was orders of magnitude faster than previous methods and avoided the quality problem in [6, 11]. However, one notable issue of patch-based texture synthesis is the presence of broken features at the boundary of adjacent textures when neighborhood search cannot find satisfactory candidates in the sample texture due to inaccurate similarity measure. To alleviate this

problem, a new local curvilinear feature matching and texture warping method is further proposed in [12].

Another dimension of texture synthesis is along the temporal dimension or synthesizing textures in motion. Such kind of dynamic textures can be found in videos of water waves, fire, smoke, wavy trees, or grasses. To synthesize dynamic textures, the modeling or sampling needs to be defined over space and time. One way of establishing such generative models is using a linear dynamic system such as an ARMA model [18]. Since an open-loop linear dynamic system is prone to be unstable and hence makes the synthesized dynamic texture diverge, Lu et al. [19] borrowed knowledge from control systems and adopted a closed-loop linear dynamic system to model dynamic textures for stable synthesis. Similar to the findings in [15], it was revealed that for many (but not all) dynamic textures, the temporal statistics can also be captured by second-order dependencies between spatial features from a pre-trained CNN for visual recognition.

Texture synthesis has a lot of applications. The most obvious one is to render texture maps for 3D environments, which are widely used in video games and movies. Other applications include material recognition and segmentation, texture transfer [9], style transfer [16], image and video editing/completion, and image compression, to list a few.

Open Problems

Texture synthesis has been extensively studied with well-established theory and application systems. Recent advances in deep learning have facilitated better solutions to a lot of computer vision problems including texture synthesis. The family of deep generative models, represented by generative adversarial networks (GANs) and variational auto-encoder (VAE), has produced remarkable results in synthesizing objects and things in natural scenes. This brings new insights for texture modeling, such as the benefit of the rich nonlinear features extracted from the CNNs

in facilitating better matching of texture statistics. Yet we are still striving for building a better theoretic framework for texture modeling with CNNs. The deep FRAME model made a nice stab, but more work along this line may be needed to push the frontiers for texture modeling and synthesis.

Definition

A 3D *shape descriptor* is a compressed representation of the geometry of a surface. The estimation of a descriptor can be applied to a single point, considering only the points belonging to its neighborhood, or to the entire object involving all points of the surface.

Background

The estimation of similarities between surfaces represents the cornerstone of most 3D computer

vision applications. A typical way of solving surface matching is to establish point-to-point, or shape-to-shape, correspondences obtained by matching local or global descriptors. Several metrics can be used to compare them, the most common arguably being the Euclidean distance in the descriptor space. Designing an effective descriptor is far from being an easy task. Their fundamental role has, over the years, fuelled intense activity in this field. According to [1] two essential traits of 3D shape descriptor are *descriptiveness* and *robustness*. Descriptiveness refers to the capacity to embed predominant characteristics of the set of points being described. The more distinctive the information incorporated within it, the easier it will be to distinguish it from the same descriptor related to different shapes or different neighborhoods on the same shape. As far as robustness is concerned, it can be defined as the ability to be not sensitive to a large set of nuisances, like rotation, point density variations, sensor noise, viewpoint changes, occlusions, and clutter. The information encoded within a descriptor should be as independent as possible from the noise affecting the data.

According to the region of the surface involved, descriptors can be grouped in *global* or *local*. Global methods encode the entire 3D model in the descriptor, while local focus on a small part of the surface (i.e., a neighborhood around a keypoint), with the latter usually being preferred to the first, thanks to their higher robustness to partial occlusions of the surface and to the presence of clutter.

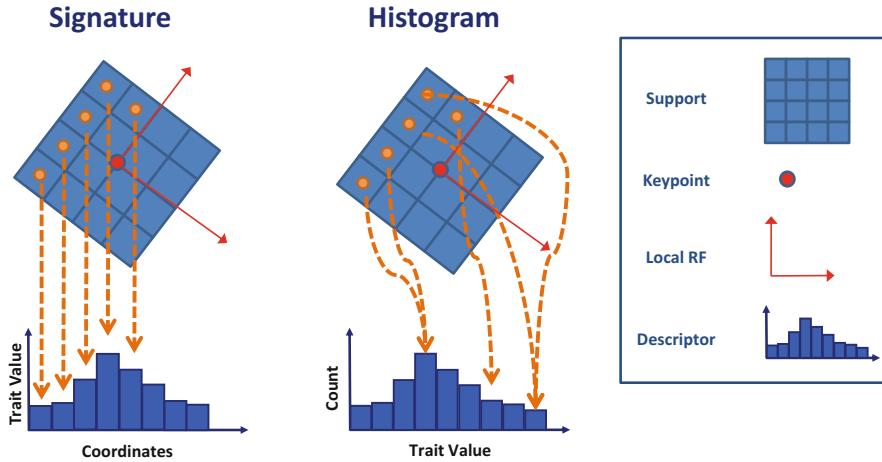

An important characteristic of a descriptor is the ability to be invariant to certain recurring nuisances in the data, such as specific 3D transformations, noise, and topology changes. Most 3D descriptors aim to be invariant to 3D rotations, either by using a local reference frame (LRF) prior to the computation of the descriptor [2, 18, 19] or, in case of certain learned approaches, by employing specific training procedures [9, 10].

In the following section, we will focus more on local descriptors. We will refer to p as the point for which we are computing the descriptor, n_p as the normal at p , and *support* as the region surrounding p .

Theory

Scholars have studied different ways to create feature descriptors for 3D surfaces. The first attempts were *handcrafted*, meaning that geometric or topological measurements were collected into histograms. Recently, advances in deep learning have given rise to several data-driven methods, which will be referred to as *learned*. According to [2], local approaches can be subdivided into two main categories defined as *histograms* and *signatures* (see Fig. 1 for a graphical explanation). Based on this classification, a histogram-based descriptor accumulates local geometrical or topological measurements (e.g., point counts, mesh triangle areas, etc.) into histograms according to a specific discretized domain (e.g., point coordinates, curvatures, etc.). Differently, a signature-based descriptor encodes one or more geometric measurements computed individually on each point within the support. This encoding has to be ordered in an invariant manner with respect to the point coordinates. To achieve this, usually an LRF is computed over a spherical support centered on the point, and then each measurement is encoded by means of an order expressed via the point coordinates of the LRF itself.

One of the first examples of histogram-based descriptor is *spin images*(SI) [11], under which the surface representation for p is created using a 2D array, the *image*, constructed by *spinning* a 2D plane around the normal at the feature point, n_p (hence the name spin images). First each point inside the support is projected to a 2D cylindrical coordinate system centered on the feature point, then this space is discretized into a 2D array, and the number of points falling in each bin is counted to build the final representation. To achieve rotation invariance, the cylinder is aligned using n_p . *3D Shape Context*(3DSC) [12] captures the geometry around a keypoint using the distribution of the points in a spherical grid support. Similar to SI, n_p serves as *reference axis*(RA), to align the north pole of the grid, while the degree of freedom on the azimuth direction is addressed by computing multiple descriptors, each of them with a

Three-Dimensional Shape Descriptor, Fig. 1

According to [2], most local descriptors can be divided between signatures and histograms. The former class encodes one or more geometric traits computed on each point of the support according to local coordinates, and

the latter accumulates the number of points or the triangle area according to a specific quantized domain. Signatures always require an LRF to define the coordinates within the support, while histograms only if their domain is based on coordinates

randomly chosen vector on the tangent plane at n_p . An improved version of 3DSC is proposed in *Unique Shape Context*(USC) [18], where the ambiguity on the azimuth direction is removed by leveraging a definition of a repeatable and unambiguous local reference frame [2]. Richer information can be extracted from point density by computing statistics on it, as has been done in *Rotational Projection Statistics*(RoPS) [19], which combines plane projection and statistics on the point distribution to design a local 3D descriptor that operates on meshes. RoPS starts by defining a novel LRF. Then, the points within the support are rotated around the x axis by a given angle and projected onto three planes xy , yz , and xz . For each projection a distribution matrix is built, and five statistics, including the central moments and Shannon entropy, are computed. The same procedure is repeated considering the y and z axes. The final histogram is obtained by concatenating the statistics of all rotations.

Most of the signature-based methods rely on surface normals to build their own descriptions. *Point Feature Histogram*(PFH) [16] constructs a graph with all the possible pairs among the points inside the support region of p . For each couple, three angular features expressing the relationship

between the normals are then encoded. Due to the construction of the dense graph between the points, PFH is computationally expensive. Therefore, a simplified version which constructs the graph for each of the points in the support considering only a subset of neighbors has been introduced in *Fast Point Feature Histogram*(FPFH) [17]. Another relevant example in this category is *Unique Signatures of Histograms for Local Surface Description*(SHOT) [2]. SHOT computes a set of local histograms over the 3D volumes defined by a 3D spherical grid superimposed on the support. The grid is aligned with the axes given by the estimated LRF, and each local histogram counts the number of points falling into each bin according to the cosine of the angle between the normal at each point and the z axis of the estimated LRF. In [27] a method that creates a global model description using an oriented *point pair feature*(PPF) is proposed.

As far as learned descriptors are concerned, the application of artificial neural networks to 3D data, such as point cloud, is a very challenging topic due to the unstructured nature. Researchers over time have experimented with different methodologies to arrange a set of Euclidean coordinates into a regular grid structure [20–22].

One of the first methods aimed at learning a 3D local feature descriptor by means of deep learning is *3DMatch* [3]. Similar to what has been done to learn embeddings for the images, a standard 3D ConvNet is trained minimizing the *contrastive loss* [24] between descriptor triplets. Local 3D patches, representing the support of p , are encoded using a voxel grid based on the *Truncated Signed Distance Function*(TSDF) [25]. On the same wavelength, *3DSmoothNet* [8] employs a voxelized smoothed density value representation oriented according to a local reference frame. The descriptiveness of the learned descriptor is increased through the use of the hardest-in-batch method [26]. Other state-of-the-art approaches learn how to robustly compress specific existing handcrafted 3D descriptors, instead of learning a new one. In *Compact Geometric Features*(CGF), the feature point is represented by a high-dimensional input parameterization similar to [18], and a fully connected network acts as dimensionality reduction upon it to reduce the input dimensionality without discarding the most important information. In *PPF-FoldNet* [5] the network is trained in an *unsupervised* way to encode and decode the point pair features [27] computed on the support region of a feature point. Analogously, 3D Point Capsule Networks [7] learn to compress the four-dimensional point pair features with a 3D Capsule-Encoder; the latent capsule codeword then serves as learned descriptor. A great challenge in learning feature descriptors is how to achieve invariance to rotation; all the proposals just discussed so far rely on a reference axis or a local reference frame. In [9] an *equivariant* [28] descriptor is learned from unoriented input data, and an LRF is required only at test time to obtain an invariant descriptor. In *Fully Convolutional Geometric Features*(FCGF) [10], the use of a fully convolutional network together with an extensive data augmentation in training allows to obtain an invariant feature descriptor in a single forward pass for all points belonging to a point cloud.

Deep learning has been recently used also to learn global descriptors for 3D surfaces, espe-

cially on point clouds. A general framework to learn features directly from raw point clouds data (e.g., point coordinates) is proposed in *PointNet* [14]. PointNet is designed in a permutation invariant manner, a group of shared *multilayer perceptron* treat each point individually, and a symmetric function, *max pooling*, is applied to achieve invariance to permutation. The proposed architecture is suitable for *3D object classification* and *3D semantic segmentation*. Taking point clouds as input, the network produces either the class labels for the entire cloud or per point part label, learning a mapping from 3D data to latent feature which can be viewed as a global descriptor. An attempt to use PointNet as a local descriptor was made in [6].

One of the key aspects behind the success of *Convolution Neural Network* (CNN) is their ability to capture features on an increasing scale through multi-resolution hierarchy. Lower-level filters have a smaller receptive field that is enlarged as the depth of the network increases. This hierarchical structure allows for a better generalizability to unseen cases. However, PointNet treats each point individually without leveraging the local geometric structure. To cope with this issue, an improved version is presented in *PointNet++* [29], which mimics standard CNNs behavior introducing a hierarchical structure. Other learned global descriptors recently proposed are [32–34].

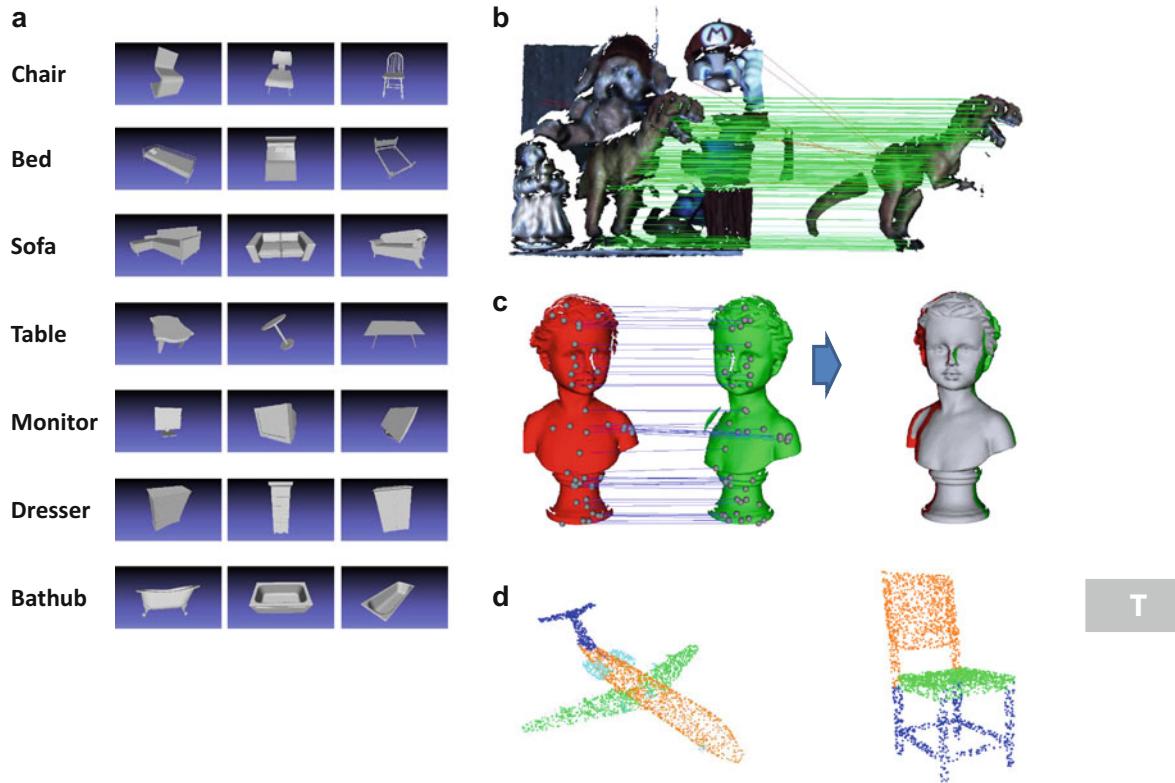

Application

Multiple applications require the analysis of similarities between 3D surfaces. Five well-established applications inherent to disciplines such as computer vision, computer graphics, and robotics are the following:

- *3D object recognition* verifies the presence of a set of objects within a scene. Typically the models to be recognized are taken from a model gallery, and there may be objects in the scene that are not included in the gallery. Once an object has been identified, its 6D pose is estimated.

- *3D surface reconstruction*, given a set of partially overlapping views of the same object, estimates the set of 6D transformations that bring all views within the same coordinate system, so as to reconstruct the object shape and appearance.
- *3D object retrieval* determines the most similar 3D models from a large database given a 3D shape as query (or a textual description of the object).
- *3D object classification* aims at identifying the correct category of an object. The main challenges are related to handling the intra-class variations related to object categories and the robustness with respect to viewpoint changes.
- *3D semantic segmentation*, given an object or a scene, aims at subdividing it into its different semantic parts/components.

Figure 2 shows some examples related to these applications. As previously mentioned, local methods are particularly suited to deal with clutter and partial occlusions; hence they are a general tool employed within 3D object recognition scenarios. In such an application, the general approach relies on determining point-to-point correspondences between each model of the database and the current scene based on matching 3D feature descriptors (see Fig. 2b). The 6D model pose can then be estimated by selecting a subset of correspondences based on consensus

Exemplars of 3D shape descriptors applications. (a) The Princeton ModelNet Benchmark dataset [35], commonly used for benchmarking 3D shape retrieval and shape classification algorithms. (b) Example of 3D object recognition in clutter and occlusion using local descriptors; left, current scene; right, recognized

model; red and green lines, correspondences yielded among keypoints by matching local descriptors. (c) 3D surface registration of two partial views performed via point-to-point correspondences obtained by matching local descriptors. (d) 3D object part segmentation on the ShapeNet part dataset [30]. Each point in the point cloud is colored by the corresponding ground-truth label

and/or geometrical constraints. Within the object recognition scenario, global methods generally need, instead, to be paired with a segmentation algorithm by computing a descriptor on each segment. Local descriptors are also commonly employed for 3D reconstruction from partial views, since they are suited to handle the presence of nonoverlapping parts of two surfaces that need to be registered together (see Fig. 2c). Finally, 3D semantic segmentation (Fig. 2d) is performed feeding an artificial neural network and obtaining a class label for each of the point in the point cloud.

Open problems

Although it is a mature field of research, many problems concerning 3D shape descriptors still remain open. The use of deep learning algorithms has boosted the performance of local 3D descriptors, but, analogously to what happens with images, they suffer from the domain shift problem since they are trained and tested under different working conditions and data domains. Algorithms have to be flexible enough to handle different nuisances such as viewpoint variations, clutter, and occlusions. In particular handling point density variation in data acquired with different sensors will be a key aspect to evaluate the performance of learned approaches. With the high diffusion of low-cost mobile devices, applications based on augmented reality are becoming increasingly important; for this reason the computational load associated with computing and matching shape descriptors is also an important issue. Finally, state-of-the-art methods are injecting supervision during the train process which requires a large amount of labeled data, and collecting this information is often a very time-consuming and costly effort. Novel unsupervised methods are currently being investigated which could offer a meaningful solution with respect to this problem.

Three-Dimensional View Integration

Denis Laurendeau

Department of Electrical and Computer
Engineering, Laval University, Quebec City,
QC, Canada

Synonyms

Geometric fusion; Surface reconstruction

Definition

View integration consists of integrating several 3D views (images) in a non-redundant model, one that describes each part of the surface of an object or a scene with a single geometric primitive.

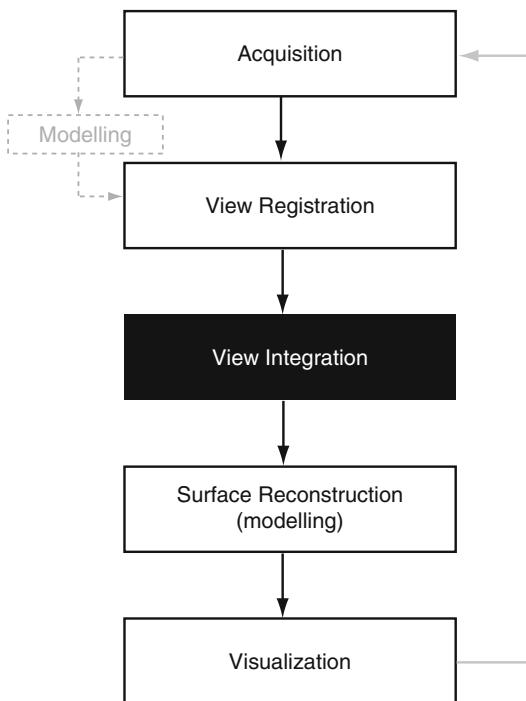

Background

The availability of accurate 3D cameras in the early 1980s has opened a new field of investigation in computer vision, namely, the acquisition and processing of 3D images [3]. The development of this field has been spectacular in the last three decades, and the use of 3D sensors, and the images they provide, is now common practice in a wide spectrum of human activities such as assembly, inspection, Computer-Aided Design (CAD), reverse engineering, medicine, and entertainment to name just a few.

In comparison with standard cameras which provide images of the appearance – either black and white or color – of the surface of objects, 3D cameras provide images containing information on the geometry of the surface of these objects. Some modern 3D sensors now even capture both appearance and geometric images of objects at the same time.

For the sake of brevity, in the following, the word “object” will be used to designate indifferently single objects or scenes made of more than one object. The problem of 3D view integration is concerned with the task of building the model of an object using three-dimensional data captured from several vantage points. The model should represent, in one form or another, the surface of the object from all directions of observation.

Equation 1 shows the steps usually adopted by 3D computer vision applications: acquisition, registration, integration, reconstruction, and visualization. A modeling step (shown in gray shade in the figure) is often executed before the registration step since registration and integration often use local models (e.g., triangulations) instead of raw data. In the case of interactive modeling applications, one can loop dynamically through these steps since the model of the object is pro-

Three-Dimensional View Integration, Fig. 1
Processing steps of 3-D vision applications

gressively built as new data is acquired with the 3D sensor. Except maybe for visualization, all steps have a direct or indirect outcome on view integration.

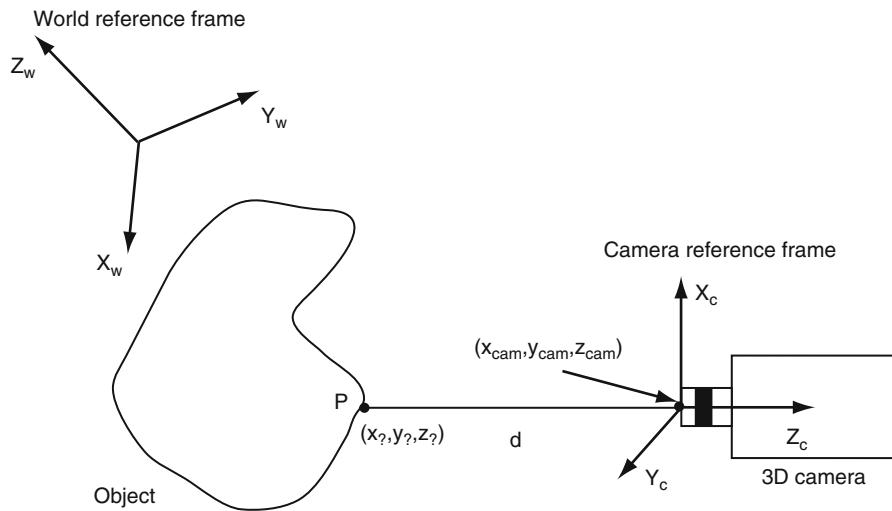

In the following, the steps shown in Fig. 1 are discussed in the context of view integration.

Theory and Application

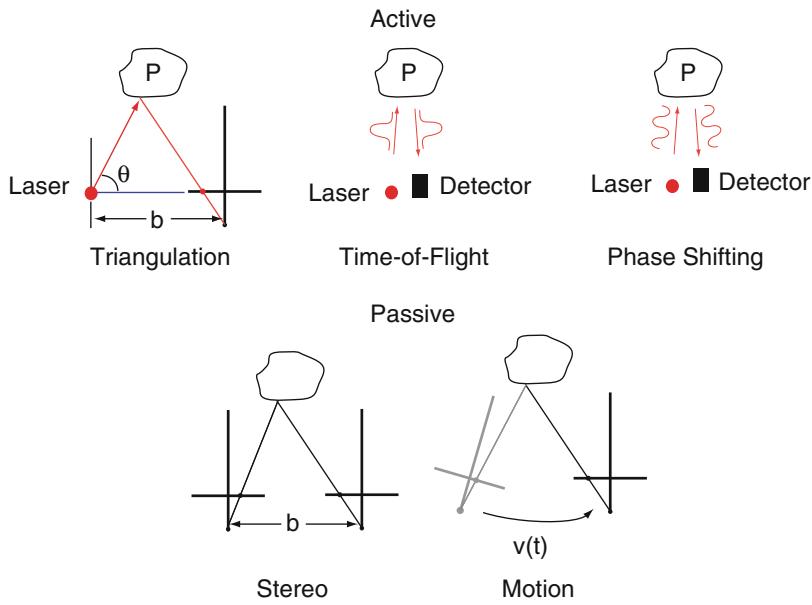

3D Data Acquisition and View Integration

As mentioned above, 3D cameras acquire image data that conveys information on the surface geometry of objects. Figure 2 shows an object with a complex shape located in reference frame $X_w - Y_w - Z_w$ called the “World” reference frame. A 3D sensor, with its own reference frame $X_c - Y_c - Z_c$, observes this object from location $(x_{cam}, y_{cam}, z_{cam})$ in the “World” reference frame. For a given point P at the surface of the object, the 3D camera measures the coordinates $(x_?, y_?, z_?)$ of the point (some cameras compute the

distance “d” between P and the origin of frame $X_c - Y_c - Z_c$). The reason for using “?” in the measured coordinates of P is that some cameras provide these coordinates in frame $X_c - Y_c - Z_c$ while others provide these coordinates in frame $X_w - Y_w - Z_w$ or some other frame in the “World” reference frame used for calibrating the camera. Several types of 3D cameras exist and use different approaches (active or passive) for measuring 3D coordinates of surface points and provide different types of raw data. Figure 3 shows some of these techniques (see [3] for a good coverage of range sensing technologies). On one hand, active techniques use some sort of light source, often a laser, for projecting a point or pattern (light stripe, grid) on the surface of the object. The pattern reflected by the surface is observed by a camera and, knowing (or calibrating) the baseline b (i.e., the distance between the source and the camera) and the orientation θ of the source, the coordinates of point P in the reference frame of the camera can be obtained by triangulation. Dense 3D images can be obtained by sweeping the pattern on the surface and capturing a large number of points. Another popular active approach computes the time of flight between the emission of a light pulse and its detection by a light sensitive sensor (an ultrasound pulse and microphone are also used in cheap 3D cameras). The distance between the sensor and point P can be obtained from $d = 2t \times c$, where c is the speed of light. A similar approach, which uses a continuous wave (sine for example) instead of a pulse, computes the distance between the source and the sensor from the phase shift between the emitted and received signal. On the other hand, passive techniques do not use any external light source for measuring surface geometry. The most well-known passive approach is stereovision which computes the coordinates of point P by triangulating the rays produced by its images captured by 2 (or more) cameras. A variant of stereovision uses only one camera that moves in front of the object and captures two (or more) images of it from different locations. Although it is not absolutely required that the scale of the object be known [7], the stereo pair of cameras is usually calibrated before

Three-Dimensional View Integration, Fig. 2 Acquisition of a 3-D image

Three-Dimensional View Integration, Fig. 3 Different types of range finders

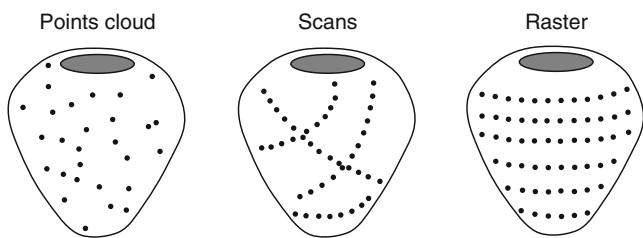

image acquisition in order to provide accurate 3D coordinates at real scale.

Depending on the approach used, 3D cameras provide different types of raw data such as point clouds, scans, or rasters. As shown in Fig. 4, point clouds, also called “unorganized sets of points,” do not show any specific spatial organization and the connectivity between points is not available directly. Such images are often

provided by techniques such as stereo vision. A second type of 2D image is shown in the middle diagram of Fig. 4 and consists of points organized as lines (the lines or scans need not be parallel). This type of image often results from the use of a light stripe scanned over the object during data acquisition by an active 3D camera (for instance, a handheld 3D scanner). The connectivity between neighboring points on

Three-Dimensional View Integration, Fig. 4

Different types of range images

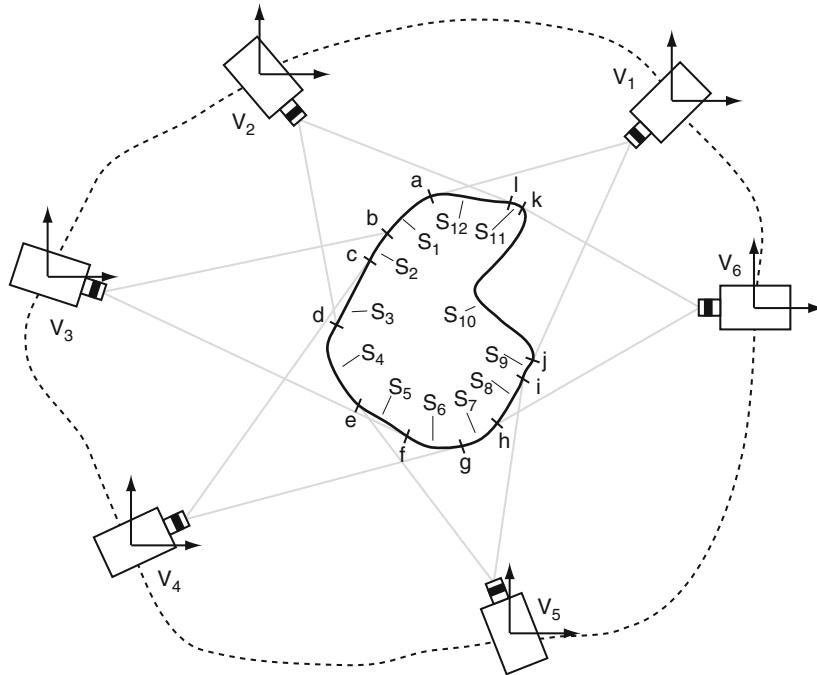

a scan is generally available (in smooth areas of the surface), but the connectivity of points on different scans may not be available explicitly. Finally, a third type of 3D image, known as a “raster” and which generally provides dense 3D data, results from the acquisition of dense 3D images on a parametric grid for which the connectivity (4-neighbor or 8-neighbor) is directly available in the image. The availability or not of connectivity information as well as the density and accuracy of the 3D points in the images has a significant impact on view registration and view integration as discussed later.

View Registration in the Context of View Integration

All 3D cameras, no matter what the approach used for measuring the 3D points, have a finite field of view, and, as shown in Fig. 5 for a 2D case, several images are thus required for gathering information on all parts of the surface of an object. The use of several views implies that (i) some parts of the surface of the object are observed in more than one view (segment S_3 between c and d in Fig. 5 is visible in views V_2 , V_3 , and V_4); (ii) parts of the surface are observed at a grazing angle in some views (segment S_5 between e and f in V_3), meaning that the 3D data in this part of the view is sometimes not accurate; and (iii) concavities on the surface (such as segment S_{10} between k and j) are present and may require a large number of views if the entire surface is to be sampled. Acquiring multiple views implies that either the camera or the object must be moved during the acquisition process. In earlier days of 3D vision (and in many current applications), sensors were mostly static and objects were installed on a turntable while 3D images of the surface were captured.

The advent of handheld 3D sensors [8] or sensors mounted at the end of a robotic arm now allows the object to remain static while the camera is moving during data acquisition. As mentioned above, the 3D information in each view is often expressed in a reference frame $X_c-Y_c-Z_c$ attached to the camera. This means that the data acquired by the camera at each position (on its path around the object) is local to this position. Once the entire surface of the object has been covered, the data acquired in each local camera reference frame (V_i , $i = 1 \dots 6$ in Fig. 5) must be transformed in a common reference frame which can be the “World” reference frame, the reference frame of one of the views, for instance, V_1 , or any other frame that is relevant for the application. The task of finding the rigid transformation (translation and rotation) required to express the data in local reference frames in a common global reference frame is called “view registration.” View registration is a very complex problem that has received a lot of attention in the 3D vision research community, and several approaches for finding the rigid transformation between views have been proposed in the literature, the most well-known being the Iterative Closest Point (ICP) algorithm for pose refinement [2]. These approaches will not be discussed here but it suffices to say that all approaches that use the data alone (in opposition to methods that make use of an external positioning device) for computing the registration are based on the overlap between views (i.e., the data common to two or more views) to estimate the parameters of the rigid transformation between views by minimizing the distance between the overlapping regions. The computational complexity of the registration step, which needs to find the nearest neighbors of points on overlapping views in its distance minimization cost function, becomes a

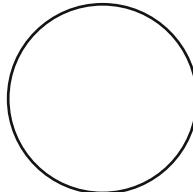

Three-Dimensional View Integration, Fig. 5 Capturing capture of the entire geometry of an object requires multiple views acquired from different overlapping vantage points

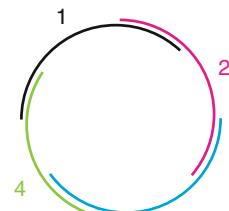

Three-Dimensional View Integration, Fig. 6

Different view registration approaches: pair wise (*top right*), simultaneous (*bottom*)

Original shape

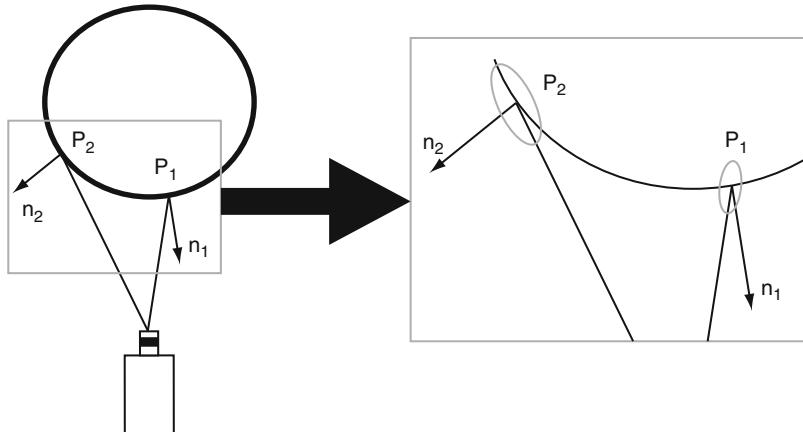

Pair-wise registration

Simultaneous registration

major hurdle when the amount of 3D data is large, although some solutions have been proposed for achieving real-time performance on common-off-the-shelf computers for man-made objects of reasonable size [16]. The accuracy with which

view registration can be achieved (meaning that the error in the estimation of the parameters of the rigid transformation is small) has a direct impact on the view integration step since the quality and conformity of the integrated data is

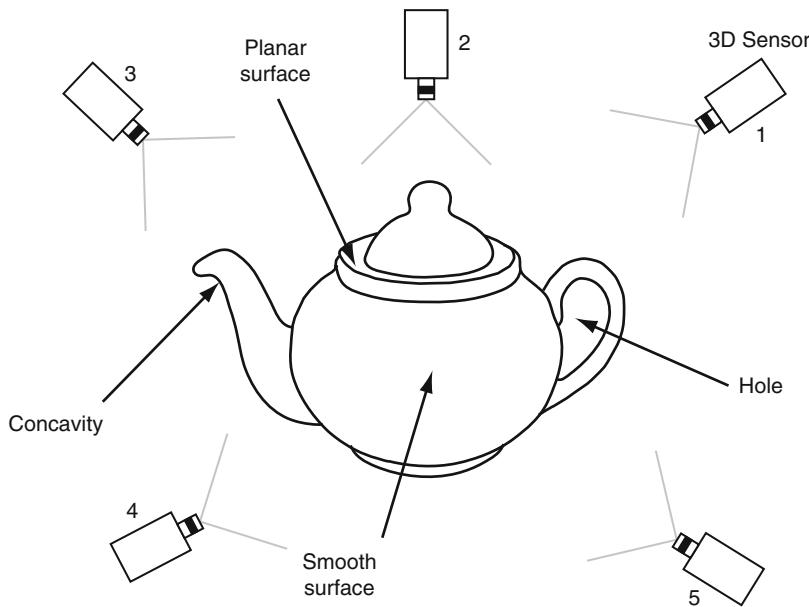

Three-Dimensional View Integration, Fig. 7 Illustration of the acquisition error on range points. The error is usually larger when the camera observes the surface at a grazing angle

closely related to registration errors. Three main approaches exist for view registration, two of which are illustrated in Fig. 6. Pair-wise registration estimates the rigid transformation two views at a time (for instance, 1–2 are registered first and yield 1/2, view 3 is then registered with 1/2 leading to 1/2/3 that is finally registered with view 4 leading to the final registered set of views 1/2/3/4). The main advantage of this approach is that it is both conceptually and computationally simple. Its main drawback is that registration errors accumulate in the sequential process, and the final result may often be far from the exact shape of the object as shown in the figure. A better approach, which is more computationally demanding, consists of registering all views simultaneously. This means that the parameters of all rigid transformations are estimated at once by minimizing the global registration error. This imposes that all available data be processed simultaneously, which may lead to important memory requirements and long processing times when a large number of views containing huge amounts of 3D points need to be considered. The reward for the extra memory and computational cost is that registration accuracy is much better than for the pair-wise process because of global optimization. A last approach that is not illustrated in the figure and which is a compromise between the two other approaches, consists of registering a view with a

computer model built from previously registered (and potentially integrated) views.

The need for registering several views in order to capture the geometry of the whole object raises the problem of choosing the next-best views that will bring the most relevant data and help in reducing the number of images required for surface coverage [1].

The accuracy of the 3D data has a significant impact on the view registration. As illustrated in Fig. 7, 3D measurements are obtained with different accuracy over different parts of a surface. For areas where the surface normal makes a large angle with respect to the direction of observation of the camera (point P_2 with normal n_2), measurements are less accurate than for the parts where the surface normal and direction of observation are mostly parallel (point P_1 with normal n_1). For active systems using a laser, for instance, a smaller light energy reaches the sensor which causes measurement to be less accurate at P_2 . The measurement error is often modeled as a Gaussian distribution with its main axis aligned with the direction of measurement as shown on the right hand side of the figure. The Gaussian model is far from being ideal since it fails to describe the “impulsive” nature of the acquisition noise in areas such as P_2 , but it is a convenient approach for taking measurement errors into account in the registration process. Some measurements which cannot be modeled by a Gaussian error model

Three-Dimensional View Integration, Fig. 8 Acquisition of the geometry of a complex object with concavities, self-occlusions in some views, and holes

are completely unreliable and are labeled as “outliers.” Such outliers have a dramatic effect on the minimization process in view registration and must be eliminated (RANSAC-based approaches can help in the elimination process [6]). Outliers also occur at step discontinuities (parts of the surface where there is a large variation of range over a small patch of the surface).

3D View Integration

With the above material on 3D data acquisition and registration, the problem of 3D view integration can now be approached as such. In the following, it is assumed that 3D data has been acquired in enough views to cover the whole surface of an object and that view registration has been performed with enough accuracy to allow reliable integration. For the sake of simplicity, the focus will be put on the integration of 3D raster images acquired by active range finders. Raster images will be called “range views” or “range images.” Integration of color information often acquired simultaneously with range information will not be addressed since it is a research problem of its own.

Ideally, a view integration approach should meet the following requirements [4] (see Fig. 8):

1. Be able to deal with multi-part objects with holes and concavities such as the teapot shown in the figure. For instance, parts of an object may occlude another part in a given view creating step discontinuities in the range image (the handle of the teapot occludes the body in view 1).
2. Be independent of the number of views and be able to cope with the large number of views (and 3-D points) needed to capture the full geometry of an object.
3. Be able to perform incremental reconstruction meaning that new views can be added to an existing model.
4. Be “order independent” meaning that the resulting integrated model should not depend on the order with which the views were integrated.
5. Be able to take data accuracy into consideration in the integration process and be robust to outliers.

6. Be able to take into consideration the connectivity of the data when it is available as well as the redundancy of the data (i.e., data acquired on the same area of the object's surface in different views).
7. Be able to fill gaps in the integrated model caused by lack of 3D data on small parts of the surface.
8. Be computationally efficient with respect to CPU and memory requirements. Although real-time view integration performance is not always requested, processing a large number of views must be executed in a reasonable amount of time on COTS computers. Ideally, complexity should be linear with respect to the number of points (and triangles when a local triangulation model is used for describing each view) as well as the number of views.

At this point, it is important to mention that the process of view integration is also called “surface reconstruction” or “geometric fusion” in the relevant literature. All terms will be used in the following.

Before going further, let us define more formally what is meant by the term “range image.” This definition is proposed in [14]. A range image is a function which associates domain points to image points. Domain points p_p are sampled on a reference surface S_p while image points p_s are located on the surface of 3D objects in a scene. The range image function results from the projection of domain points p_p onto object surfaces. The projection can be directed along curved lines called projectors as shown in Fig. 9a. Objects are assumed to be solids of finite volume bounded by a manifold, orientable, and closed surface. Imposing that the surface be closed implies that view integration must be able to fill holes resulting from an imperfect integration process, a feature that is in line with requirement section “Open Problems” above.

There are basically two main approaches to view integration: surface based and volume based. Both approaches share the property that they can generally generate an integrated surface model at several resolutions. The generated model is usually a linear approximation of the

integrated surface. This means that the integrated model approximates the surface locally by small planar patches such as triangles organized in a connected mesh, and each area of the surface is described by one and only one model. More sophisticated representations such as bicubic splines, superellipsoids, or generalized cylinders can also be used as a model of the integrated surface.

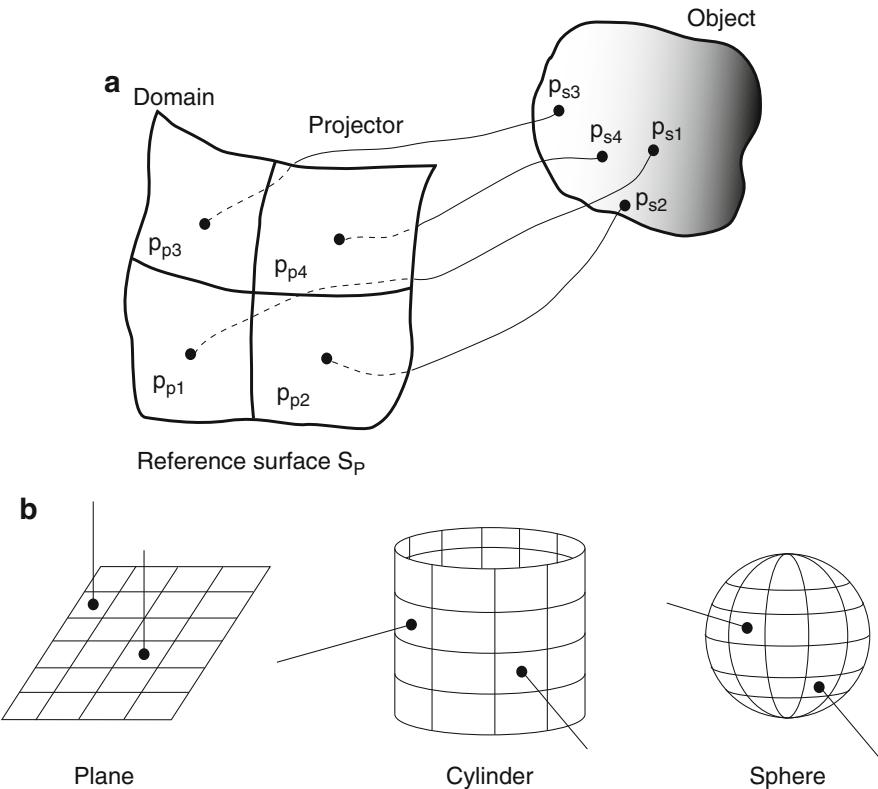

Both approaches also make the assumption that the resolution of the range images used in the integration process is high enough to deal with objects showing large curvature in some areas of their surface otherwise, too small a resolution would cause curved areas to appear as step discontinuities.

Surface-based approaches are addressed first followed by volume-based approaches.

Surface-Based View Integration

The definition of a range image given above is operational and quite general since no specific shape is specified either for the reference surface or the projectors. In practice, the reference surface can be a plane, a cylinder, or a sphere, and the projectors are straight lines as shown in Fig. 9b. Although cylindrical and spherical reference surfaces can prove useful in some situations, they also have significant drawbacks. For instance, the elements of a spherical grid do not have the same area. In addition, projectors may intersect for both the cylindrical and spherical grids. For a planar reference surface, the elements of the grid can be made square, and the projectors are parallel with each other and perpendicular to the reference surface. Planar reference surfaces are thus preferred over cylindrical or spherical grids for obvious reasons. The advantage of using a reference surface is that connectivity information between image data is directly available from the connectivity between grid elements except at step discontinuities.

The first step in view registration consists of eliminating outlier data from the range image. Outliers frequently appear near step discontinuities or occlusion contours when laser scanners attempt to acquire samples where the laser impinges the object surface at grazing angles.

Three-Dimensional View Integration, Fig. 9 General definition of a range image (a). Planar, cylindrical, and spherical reference surfaces with straight line projectors (b)

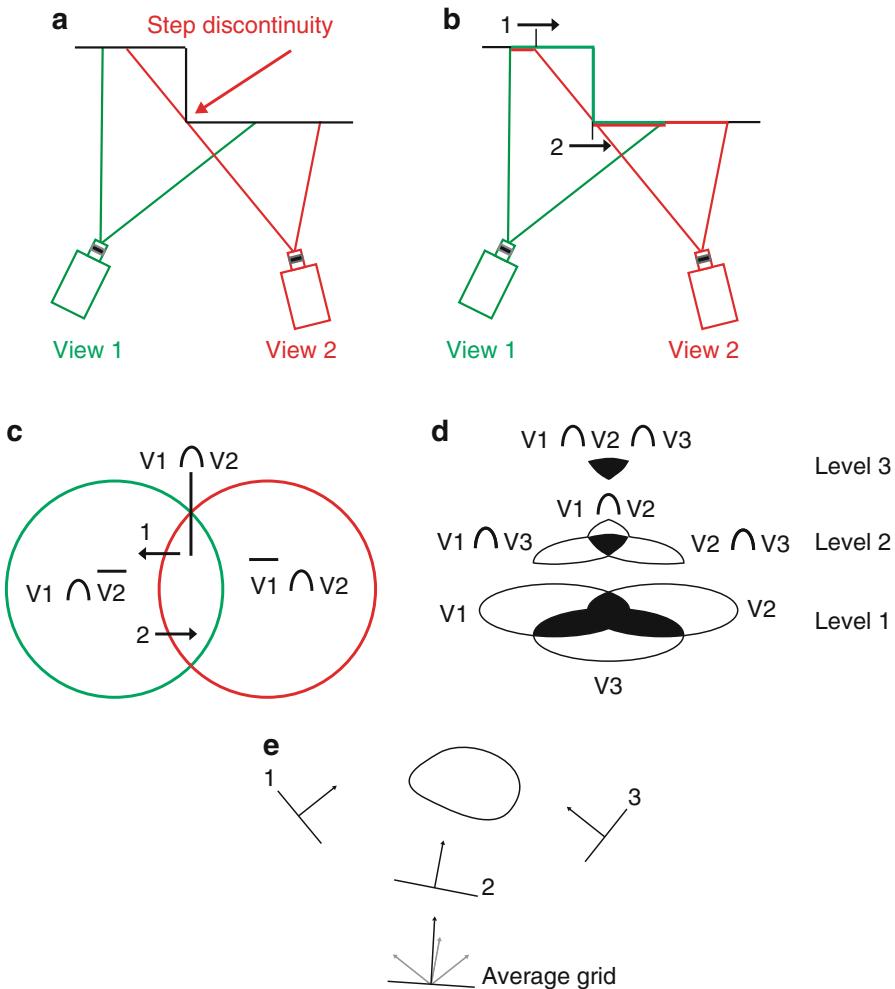

Outliers appear as if they were “floating” in space and are often very far from other points. A simple thresholding operation applied on the range image is generally all that is needed to eliminate outliers.

A second processing operation that is frequently performed on range images is the detection of step discontinuities in the different views. An example of such a step discontinuity is shown in Fig. 10a. The scene shows a surface orientation discontinuity in View 1 but this discontinuity is seen as a step discontinuity in View 2. Many approaches can be used for detecting step discontinuities, the simplest one being to implement a thresholding operation on the 3D data corresponding to horizontal and vertical neighbors on the grid of the reference surface. Although it is a simple operation from the conceptual standpoint, it is not so easy to implement a robust step discontinuity algorithm since range data is sometimes

noisy near the steps, and false alarms and non-detections can occur and may cause problems for some integration algorithms [14].

The view integration task begins as such once the three pre-processing steps described above have been performed for all views. The first goal is to detect the redundant information in the views, i.e., the parts of the scene that are observed in more than one view. Redundant information is a key element for view registration but once registration is performed, redundancy in the data must be eliminated in order to produce the model.

Set theory has been proposed as a framework for addressing the view integration problem [14]. If a view is seen as a set of points as in Fig. 10c, then, finding redundant information reduces to finding subsets of the Venn diagram which are the intersection between sets, in this case $V1 \cap V2$. Figure 10b shows the parts in the scene which are visible in $V1$ (green), $V2$ (red), both

Three-Dimensional View Integration, Fig. 10 Step discontinuity in a view (view 2) (a). Crossing a step discontinuity in a view (b). Membership discontinuity in

V1 and V2 (green and red), or not visible in any view (black) for the simple scene in Fig. 10a. It is important to note that there is a link between the presence of a step discontinuity in a range image and a membership discontinuity in the Venn diagram. In the figure, when one crosses the step discontinuity in View 1 reported in the reference frame of View 2 (marked as “1” on the figure), one crosses the frontier between subset $V1 \cap V2$ and subset $V1 \cap \overline{V2}$. The same situation occurs when one crosses the step discontinuity in View 2 (marked 2 on the figure) since one crosses the frontier between subset $V1 \cup \overline{V2}$ and $V1 \cap \overline{V2}$.

V1 and V2 (green and red), or not visible in any view (black) for the simple scene in Fig. 10a. It is important to note that there is a link between the presence of a step discontinuity in a range image and a membership discontinuity in the Venn diagram. In the figure, when one crosses the step discontinuity in View 1 reported in the reference frame of View 2 (marked as “1” on the figure), one crosses the frontier between subset $V1 \cap V2$ and subset $V1 \cap \overline{V2}$. The same situation occurs when one crosses the step discontinuity in View 2 (marked 2 on the figure) since one crosses the frontier between subset $V1 \cup \overline{V2}$ and $V1 \cap \overline{V2}$.

By processing pairs of views in turn, one ends up building the Venn diagram of N views and thus finding the redundant information corresponding to subsets of the Venn diagram. The information contained in only one view can thus be modeled while the information contained in more than one view can be merged and then reconstructed as a single model. This procedure is described next.

Finding the information common to a pair of range views consists of taking each 3D point in one view and finding whether or not, when transferred in the reference frame of the other view using the frame transformation obtained

from view registration, it is close to a triangle in the mesh of the first view. This first operation is called a “neighborhood test.” When the 3D point is indeed close to a triangle in the second view, a second test is run to check whether or not this point is “visible” from the planar parametric grid of the second view. This “visibility test” is required since a point may be close to the surface of a view but may not be visible from this view. This happens for instance near the rim of a cup where points in one view may have been sampled on the interior of the cup, while points in the other view have been sampled on the exterior of the cup. Such points are close in space, but they do not belong to the same part of the object. The “visibility test” checks if the scalar product between the normal to the surface at the point being processed and the direction of the optical axis of the camera is positive (i.e., the angle between the two directions is smaller than 90°). If it is so and the point is close to the surface, then this point is labeled as being common to the two views.

The two tests described above yield poor results near step discontinuities because it is (i) difficult to define a surface patch near a discontinuity which causes the spatial neighborhood test to fail and it is (ii) also difficult to estimate the normal to the surface near a discontinuity, causing the surface visibility test to fail.

This is where step discontinuities come into play. Steps discontinuities detected in one view are reported in the second view (again using the frame transformation obtained from the view registration process). The points labeled as common to two views and forming a connected component on the parametric grid of this view are used as seed regions for a region-growing process which expands the regions until they reach a contour of step discontinuity. Knowing that a step discontinuity marks a membership discontinuity in the subsets of the Venn diagram, when the expanded region makes contact with a step discontinuity, the region growing stops, and the points which were merged to the regions are labeled as being common to both views.

The above procedure described how data common to two views can be detected. However, complex objects require much more views if their geometry is to be captured with details. Consider the hierarchy of subsets of the Venn diagram shown in Fig. 10d. These subsets are called redundant subsets. The integration procedure begins at the top of the hierarchy and finds a description of the surface for points belonging to $V_1 \cap V_2 \cap V_3$. The strategy consists of defining a new parametric grid whose orientation is the average of the orientation of the grids of the views participating in the subset as shown in Fig. 10c. Each range view is modeled by a step discontinuity constrained Delaunay triangulation. A Delaunay triangulation ensures that triangles in the model are as equiangular as possible. Stopping the triangulation at step discontinuities ensures that triangles do not overlap a discontinuity and do not model two parts of the surface separated by a large step [14, 17]. The triangulation of each participating view is projected on the new parametric grid and is resampled on this grid. This reparameterization can be seen as acquiring a new image from the vantage point of the average parametric grid. Now, since several views participate in a subset, each view can contribute a range value to the “synthesized” image of this grid. This means that these range values can be merged in order to take advantage of the redundancy brought by the multiple views. The resulting range value of the average grid is a weighted average of the range value in each view. The weight for each contributing range value is obtained from the square of the cosine between the direction of the sensor and the surface normal at that point. This ensures that a range value acquired at normal incidence in a view will contribute more to the synthesized view than one obtained at a grazing angle in another view. Finally, once the synthesized image has been generated, a Delaunay triangulation is built to describe the subset at a given level of the hierarchy.

Then, levels lower in the hierarchy are processed similarly. Processing at all levels of the hierarchy means that several Delaunay

triangulations exist for the same part of the surface and redundancy must be eliminated. This redundancy is useful though because it helps in eliminating errors near membership discontinuities at the higher level of the hierarchy (remember that it is difficult to build a model near these discontinuities). Redundancy between triangulations is eliminated by finding the overlap between them starting from the top of the hierarchy to the bottom.

Once the overlap has been eliminated, each canonical subset of the Venn diagram is modeled by a single triangulation. The next step consists in stitching the triangulations in order to fill small gaps between them.

In the procedure described above, data fusion between range values coming from different views and elimination of the overlap between redundant models of the same part of the surface are operations that are performed before stitching the resulting triangulations. Due to errors in view registration, the stitching may cause small ridges to appear in the integrated model. An improvement of the procedure consists of eliminating the overlap and stitching triangulations first and then to improve the final geometry by finding a consensus position of the triangle vertices based on the contributions of all participating views (again, a weighted average is used). Since it is better to avoid lateral movement of the vertices in the triangulation, the consensus position is computed for the direction along the average surface normal at each vertex [17] or by re-tessellating the mesh using redundant data [13].

Volume-Based View Integration

Signed Distance Fields

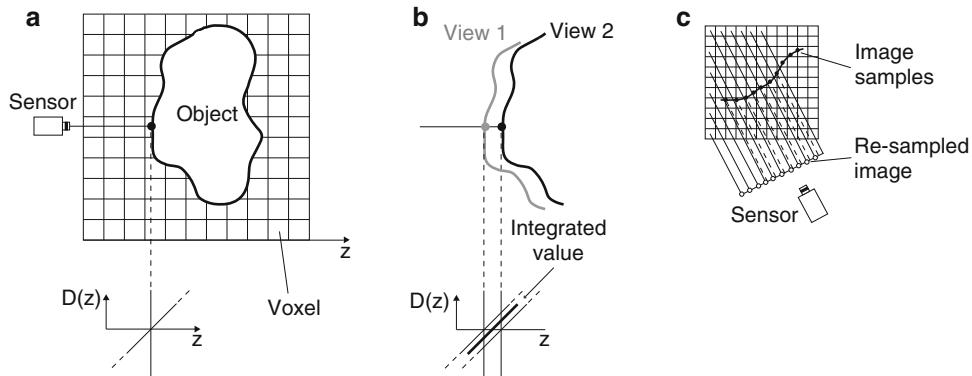

Volume-based view integration approaches make use of the fact that objects occupy a volume in 3D space. Since range images provide samples of the frontier between the “outside” and the “inside” of the object, combining registered volume information implicitly contained in range images is a way of integrating the different views.

The world of robotics has made use of volume-based representations of surfaces through the

concept of probabilistic “occupancy grids” [5]. An occupancy grid is one that encodes the probability of the presence of an object in each cell of the grid. The evidence of the presence or absence of an object is derived from the probabilistic model of the range sensor, the range measurements provided by the sensor, and Bayesian updating of the cell’s occupancy probability based on repeated measurements. Occupancy grids have been used mostly for path planning and collision avoidance in robotics but have not generally been used for surface reconstruction because of the difficulty of transforming the probabilistic model stored in the grid into an accurate surface description.

The most general volumetric approaches for view integration make use of a continuous objective function to combine range data [4, 11]. The range data points in the images are considered as samples of this objective function. A very popular objective function that is used by volume-based view integration approaches is the signed distance function $D(z)$. Function $D(z)$ is an implicit representation of the surface, and, as discussed in the following, a triangular mesh built from the zero-crossings of this function is the explicit representation of the surface.

Let us assume that the volume in which the object is located is represented as a grid of cubic voxels as shown in Fig. 11a. When a range image is acquired, it is first modeled as a triangular mesh. The mesh must not overlap step discontinuities for the same reasons as those mentioned above for surface-based approaches. Each vertex in the mesh is assigned a weight according to a weighing function that takes into account the accuracy of the measurement. Several approaches have been proposed for modeling this accuracy [9]. The signed distance between the weighted mesh and each voxel center in the direction of the ray between the sensor and the surface is computed and stored in the voxel grid structure. When a second view is acquired, the signed distance function is computed once again as shown in Fig. 11b, and the two views are integrated by computing the weighted distance resulting from the previous view and the current

Three-Dimensional View Integration, Fig. 11
Illustration of the signed distance between a surface and the centers of the cells of a volumetric grid (a). Merging

view. More formally, the surface is located at the zero-crossing of the weighted objective function $D(z)$ at the voxel. This approach is obviously order independent and is also independent of the number of views. It takes data accuracy into account since the signed distance function and the weighing function can be computed separately as images are acquired and the zero-crossing of the cumulative weighted signed distance function can be computed last. When pushed forward, the approach also allows “hole filling” to be implemented in a straightforward manner. As a matter of fact, when casting a ray between the sensor and the surface, the ray can be cast back toward the sensor, and voxels crossed by the ray are assigned the label “empty” (with $D(z) = D_{\min}$ and weight zero). Voxels on the surface are labeled as “near” the surface, and the remaining voxels are assigned the “unseen” label (with $D(z) = D_{\max}$ and weight zero). “Hole filling” is performed implicitly by finding the zero-crossing of the resulting distance function [4]. Final surface extraction of the integrated model is obtained with the well-known “Marching Cubes” algorithm [10] adapted to the above procedure [12].

Despite the conceptual simplicity of using distance fields, practical implementations face some challenges. The first challenge is of course the computer memory requirements for storing the signed distance field. A coarse resolution helps in reducing memory space and processing time

of the distance field for two views (b). Re-sampling of the range images for speeding up the integration process (c)

but the resulting model is not faithful to the object surface geometry. A fine resolution for the volumetric grid yields a high-quality surface model, but computational costs explode. Encoding the volumetric grids in clever data structures (run-length encoding [4], kd-trees [11]) has been proposed to reduce both memory space and computer time requirements.

A second issue that must be considered is the distance to which the weighing function should extend on both sides of the surface. Ideally, the function could extend indefinitely, but, as it is the case for surface-based approaches, this would cause integration to fail for thin parts of the object’s surface such as the rim of a cup since functions on the sides of both surfaces would interfere when computing the resulting weighted distance function for a voxel. Choosing the extension of the weighing function to be half the maximum uncertainty interval of the range measurements is usually a good rule of thumb since the generated model cannot be more accurate than the measurements themselves. Other error models can also be considered as well [9, 13].

Another important algorithmic issue is the updating of the content of the volume with a new range image since it rarely happens that both are aligned (as a matter of fact, the orientation of the volume in 3D space can be chosen arbitrarily as far as it circumscribes the volume of the object). Ray casting between the sensor and a

voxel for finding the intersection is very costly in terms of computing time and is tractable only for volumes with coarse resolution. Consequently, range images can be re-sampled along the volumetric grid prior to volume updating. This resampling can be compared with the computation of a reparameterized surface grid mentioned for the surface-based approaches described above. Range image re-sampling is shown in Fig. 11c.

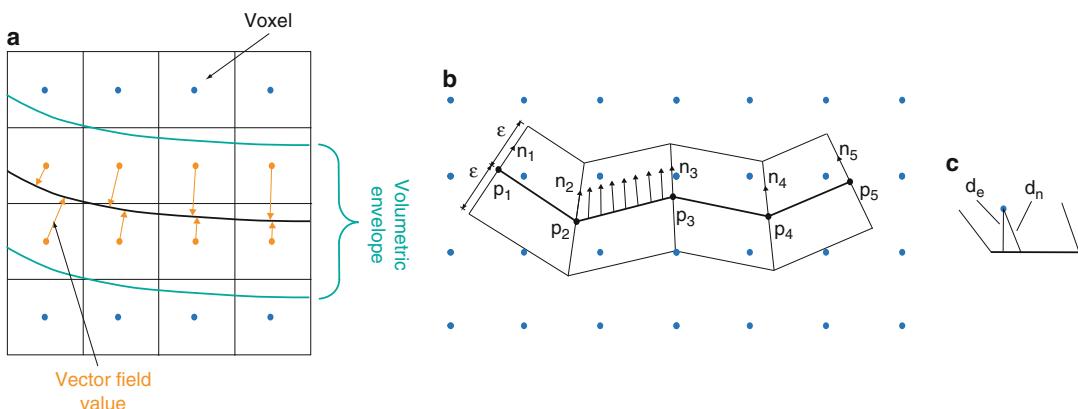

Vector Fields

Another powerful representation has been proposed for describing surfaces and for performing surface reconstruction from a set of range images: the “vector field” [16]. The “vector field” representation also uses a volume for integrating range views and for extracting a unique surface reconstruction from the marching cubes algorithm. However, the entry in each voxel is the distance between the voxel center and the closest point on the surface (the definition of “closest point” will be given below) as well as the direction of the vector toward the closest point (see Fig. 12a for a 2D cut of the volume). For each surface, the field is computed only for voxels located inside a region of space called the “volumetric envelope” which is defined by the iso-surfaces located at a positive distance ε on both sides of the surface. The volumetric envelope plays the same role as the limited extent for the weighing function of the approach using the distance function. It allows

the vector field approach to cope with registration errors between views and to limit the computational cost of computing the field. Several constraints guide the choice of the value for ε : size of the voxel, error of the registration between views, as well as other geometric considerations [15]. Although vector fields can be computed for point clouds, scans, and range images, only the case of range images will be covered in the following.

More formally, assuming a set $A = \{a_i \in R^3, i = 1, \dots, N\}$ of N 3D points in a range image, the “vector field” representation of set A is the field $F: VCR^3 \rightarrow R^3$ such that $F(v) = \arg \min_{a \in A} d(a, v) - v$. Where $V = \{V_{i,j,k}\}$ is a set of $N_x N_y N_z$ voxel centers $V_{i,j,k}$ and $d(a, v)$ is some distance measure between a and v . The choice of the distance measure is key to the concept of vector field.

Figure 12b shows a 2D view of how the vector field is computed for a range image for which a triangular mesh has been constructed beforehand. First, the normal to the surface of each triangle in the mesh is computed and the normal at a vertex is computed as the average vector of the normals of all triangles containing this vertex. The direction of the normals should be consistent with the position of the sensor (i.e., reside on the same side of the surface). Then, the normal to each point on the triangle is obtained by interpolating average normals at the vertices, each normal being weighted by the barycentric

Three-Dimensional View Integration, Fig. 12 Basic principle of the vector field representation (a). Closest point along the interpolated normals (b). Difference

between the Euclidean distance and the distance along the interpolated normal (c)

coordinates of the point on the triangle. For a lattice point of the volumetric grid, the distance stored in the corresponding voxel is d_n , the distance along the interpolated normal (see Fig. 12d) instead of the classical Euclidean distance d_e . In addition, the direction of the interpolated normal is also stored in the voxel.

Integrating N range views simply consists of computing the normalized vector field resulting from the combination of all contributing images. The normalized vector field is one for which each vector is divided by its norm. This can be expressed by the following equations:

$$F_{\text{int}}(p) = \left[\sum_{i=1}^N F_i(p) w_i(p) \right] / \sum_{i=1}^N \omega_i(p)$$

and

$$d_{\text{int}}(p) = \left[\sum_{i=1}^N d_i(p) w_i(p) \right] / \sum_{i=1}^N \omega_i(p).$$

The weight ω represents the confidence in the data and is given by the cosine of the angle between the direction of the sensor and the surface normal. The weights ω_i are also interpolated using the barycentric coordinates. The final surface model (i.e., the reconstructed surface) is obtained by the marching cubes algorithm.

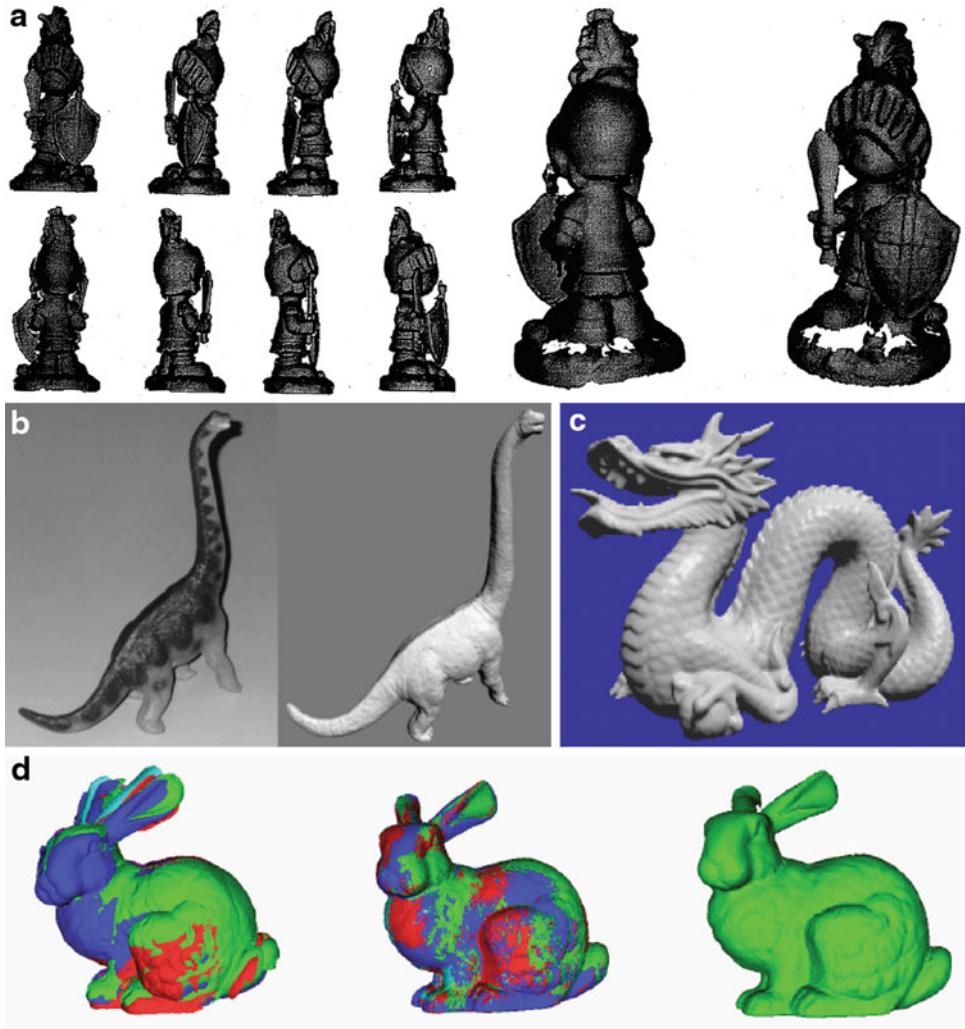

Clearly, the surface reconstruction approach using vector fields is independent of the number of views. It makes use of connectivity information in a view since the computation of normals at vertices uses this connectivity. It is order independent since the field for each view is computed separately and fields of all views are combined. The approach is also incremental in that it allows a view to be integrated with an existing field. Sensor noise is taken into account in the integration process as it is the case for all view integration approaches presented so far. However, the vector field requires more storage space than the classical signed distance field described above so what is the gain of storing direction information in the volumetric model in addition to distance information? Could the vector field be obtained from the signed distance field? In a volumetric lattice of infinite resolution (i.e., voxel size = 0),

the vector field could be obtained by computing the gradient of the distance field which provides the direction of the surface normal everywhere in the lattice. However, this does not hold for a finite resolution lattice since the gradient of the signed distance field must be estimated by finite differences, an approach that is not accurate enough to yield useful direction information. Another gain offered by vector fields over signed distance fields is when the final surface model is obtained by the marching cubes algorithm [15].

But the major gain of using the vector field over signed distance fields is that this representation can be used for all steps of the surface reconstruction process (registration, integration, reconstruction, and visualization) with linear complexity with respect to the number of points making real-time surface reconstruction possible. The reason for this is that storing distance to and direction toward the surface in the field results in solving the nearest neighbor problem implicitly, something that is not the case with the signed distance field (with the same resolution). Using the same representation – the vector field – for all steps of the surface reconstruction process avoids conversion between representations, an operation that is sometimes computationally expensive and numerically inaccurate.

Open Problems

The surface reconstruction approaches presented above, both surface based and volume based, allow a significant number of range images to be integrated in a non-redundant surface representation. The main issue common to all approaches is still the ability to cope with huge amounts of data (i.e., several millions of points) in a reasonable amount of time and with limited memory space. The increasing power of modern computers and the low cost of memory help in allowing more and more views to be integrated in a single surface representation. More research is required on approaches for compressing the representations without too much increase in computational complexity while still minimizing the error in

Three-Dimensional View Integration, Fig. 13 Surface reconstruction with surface-based and volume-based approaches. Final polygonal mesh of a soldier figurine produced by the surface-based approach exploiting the Venn diagram formalism. (Taken from [14]) (a). Final polygonal mesh of a dinosaur figurine using the “zippered polygon” meshes surface-based approach. (Taken from

[17]) (b). Final polygonal mesh obtained by the volume-based approach based on the signed distance field formalism. (Taken from [14]) (c). Final polygonal mesh of a duck generated from the volume-based approach exploiting the vector field formalism. View registration is also achieved with the same vector field model. (Taken from [15]) (d)

the compressed model. Compression approaches suitable for transmission over the Internet would be a significant asset.

Another important problem to be addressed that is closely related to view integration is the accuracy with which view registration can be achieved. All view integration approaches described above make the assumption that view registration is accurate. However, although

accurate view registration approaches are available for finding the rigid transformation between views before integration, most of these approaches are pose refinement techniques, meaning that they can estimate the parameters of the rigid transformation between views that are already close to each other. Initial pose estimation (i.e., estimation of the rigid transformation between views when they are far apart) is a much

more complex problem, and further research is needed on this topic.

One of the goals of view registration is to produce reliable and accurate geometric models of complex objects. Including appearance information (i.e., color) in the models is an interesting problem which has received attention, but research still needs to be conducted in this direction. For instance, one may ask the following question: Can the data structures used for surface-based or volume-based view integration be extended to include color information? Can these enhanced data structures be compressed efficiently?

Experimental Results

Figure 13 shows the results obtained with four view integration approaches. Figure 13b shows eight 256×256 range images of a toy soldier (left) with two views of the resulting model made of 70,842 triangles provided by the surface-based approach in [14]. Figure 13b presents the polygon mesh of a plastic dinosaur model [17]. The mesh contains 360,000 polygons.

Figure 13c shows the model of a dragon built from the volume-based approach using a signed distance field [4]. This model, made of 1.7 million triangles, was produced from the integration of 61 scans totalizing 15 million triangles.

Finally, Fig. 13d presents the model of a duck built from 12 range images and using the vector field representation [15]. The lattice is made of $128 \times 128 \times 128$ voxels with a volumetric envelope of 3 voxels. The left image shows a superimposition of the original range images. The center image shows a superimposition of the same range images after registration using the vector field approach. The right image shows the reconstructed surface built from the integration of the vector fields built with the original images.

Total Variation

Bastian Goldluecke

Department of Computer Science, Technische Universität, München, München, Germany

Definition

The total variation (TV) is a nonnegative, convex, and lower semicontinuous functional on the space of integrable functions. For a function $u \in L^1_{\text{loc}}(\Omega)$ on a domain $\Omega \subset \mathbb{R}^n$, it is defined as

$$J(u) := \sup \left\{ - \int_{\Omega} u \cdot \operatorname{div}(\xi) \, dx : \xi \in C_c^{\infty}(\Omega, \mathbb{R}^n), \|\xi\|_{\infty} \leq 1 \right\}. \quad (1)$$

For differentiable functions $u \in C^1(\Omega)$, this definition can be reduced to the familiar expression

$$J(u) = \int_{\Omega} |\nabla u|_2 \, dx \quad (2)$$

with the help of Gauss' integral theorem. A function with $J(u) < \infty$ is called of *bounded variation*; the space of all functions on Ω with bounded variation is denoted by $\mathcal{BV}(\Omega)$.

Background

The total variation is a favorite prior term and regularizer in variational models for image processing. Since it is a convex functional, it allows to formulate convex variational models which can be efficiently globally minimized. Furthermore, while it favors smoother functions, abrupt discontinuities are not penalized stronger than slow transitions, and discontinuous solutions are possible. For this reason, the total variation can be viewed as an edge-preserving regularizer.

Since the length of the boundary of a set can be expressed as the total variation of its characteristic function, total variation can also successfully be employed to formulate variational

segmentation problems. In particular, it can be used to express weighted minimal surface problems, which leads to further applications in, for example, 3D reconstruction.

Theory

Total variation and convex analysis In computer vision applications, J is usually employed as a regularizer for a *variational model* of the form

$$\operatorname{argmin}_{u \in \mathcal{V}} J(u) + F(u), \quad (3)$$

where F is a data fidelity term which measures how well u fits the given data, while \mathcal{V} is chosen as a subspace of the Hilbert space $L^2(\Omega)$. The Hilbert space setting is necessary to apply optimization methods from *convex analysis* and certainly general enough for most practical applications. Any minimizer is necessarily of bounded variation. On $L^2(\Omega)$, the total variation can be rewritten as the support functional of a convex set K ,

$$J(u) = \sup_{v \in K} (u, v) \text{ with } K = \left\{ \operatorname{div}(\xi) : \xi \in C_c^{\infty}(\Omega, \mathbb{R}^n), \|\xi\|_{\infty} \leq 1 \right\} \subset L^2(\Omega), \quad (4)$$

as one can see immediately from definition (1). From the fact that J is a support functional, one can deduce that J is convex, one homogenous, and lower semicontinuous on $L^2(\Omega)$. Furthermore, the convex conjugate of J is given by the indicator function of the closure of K ,

$$J^*(v) = \begin{cases} 0 & \text{if } v \in \operatorname{cl}(K), \\ \infty & \text{otherwise.} \end{cases} \quad (5)$$

It also follows that if, in addition, the data fidelity term F is convex, lower semicontinuous, and coercive, the model (3) has a minimizer, which is unique if F is strictly convex [2].

The perimeter of a set Perhaps the most remarkable fact about the total variation is its

geometric properties, which become apparent when one computes the total variation of a *characteristic function* 1_U of a subset $U \subset \Omega$. If U is a “sufficiently nice” set, it can easily be shown with Gauss’ integral theorem that $J(1_U)$ is equal to the $(n - 1)$ -dimensional Haussdorf measure $\mathcal{H}^{n-1}(\partial U)$ of the boundary of U . For $n = 2$, this corresponds to the length of the boundary of U , for $n = 3$, to the surface area. This observation motivates the definition of the *perimeter* of an arbitrary set U in Ω as

$$\text{Per}(U, \Omega) := J(1_U). \quad (6)$$

Sets of finite perimeter are known as *Caccioppoli sets*, by definition $1_U \in \mathcal{BV}(\Omega)$ if and only if U is a Caccioppoli set. The geometric insight that $\text{Per}(U, \Omega)$ measures boundary surface area is leveraged to reformulate weighted minimal surface problems in terms of minimization problems over binary functions of bounded variation.

Co-area The co-area formula in its geometric form says that the total variation of a function equals the integral over the $(n - 1)$ -dimensional area of the boundaries of all its lower level sets, see Fig. 1. More precisely [8],

$$\begin{aligned} J(u) &= \int_{-\infty}^{\infty} J(1_{\{u \leq t\}}) dt \\ &= \int_{-\infty}^{\infty} \text{Per}(\{u \leq t\}, \Omega) dt. \end{aligned} \quad (7)$$

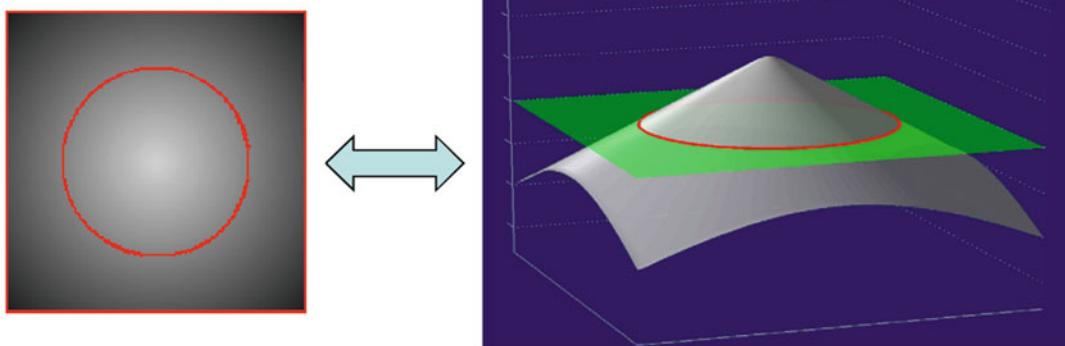

It is an important tool to analyze convex relaxation techniques in labeling problems [15], where it can sometimes be employed to show global optimality of a method.

Variants Interesting variants of the total variation used in image processing include nonlocal TV [9] which replaces the gradient operator with interactions across the whole image domain as well as total generalized variation [4] which incorporates higher-order derivatives of the test functions. Total variation can also be defined for vector-valued functions [1, 2] and used as a regularizer for color image processing problems [7] or geometric penalizer in multi-label problems [12].

Application

There are several important problems in image processing and computer vision which make use of the total variation. One application is to use J as a prior term in inverse problems; others leverage the geometrical properties of J to formulate segmentation problems. Weighted minimal surfaces can be viewed as a special class of segmentation problems and are heavily used in 3D reconstruction. Total variation can also be formulated for scalar fields on manifolds, which makes it possible to solve image processing problems on curved surfaces.

TV as a prior Assume one observes an image $f \in \mathcal{L}^2(\Omega)$, which is related to an unknown

Total Variation, Fig. 1 *Co-area formula:* The total variation of a function can be computed by integrating the boundary length of all lower level sets; (red lines)

variable $u \in \mathcal{L}^2(\Omega)$) by a linear operator A and the ideal model $f = Au$. Typically, the problem is ill-posed and the observation f is noisy, so a regularization is required. Instead of trying to solve the linear model directly, one minimizes

$$\operatorname{argmin}_{u \in \mathcal{L}^2(\Omega)} \left\{ J(u) + \frac{1}{2\sigma^2} \|Au - f\|_2^2 \right\} \quad (8)$$

This can also be interpreted as the maximum a posteriori estimate [18] for the unknown u under the assumption that f is contaminated with pointwise independent Gaussian noise with standard deviation σ . In this probabilistic interpretation, the total variation has taken the place of the negative log probability for the unknown u . Since this prior probability distribution is rarely known in practice, an objective prior like TV has to be used. Equation (8) describes a typical inverse problem in image processing formulated as a *variational model* and has been intensively studied. A recent overview of minimization methods is given, for example, in [5]. In the case that A is the identity, problem (8) is known as the Rudin-Osher-Fatemi (ROF) model for image denoising, named after the authors of [17], in which total variation made its first appearance as a regularizer in image processing. If A is instead a convolution with a blur kernel, one arrives at total variation deblurring models [6]. Similar models are also used for super-resolution [13].

TV in segmentation problems The archetypical binary segmentation problem can be formulated as an optimization problem over the space of binary functions of bounded variation

$$\operatorname{argmin}_{u \in \mathcal{BV}(\Omega, \{0, 1\})} \left\{ J(u) + \int_{\Omega} c \cdot u \, dx \right\}. \quad (9)$$

If $u(x) = 1$, the point x belongs to region 1 and vice versa. The real-valued function c denotes the assignment cost given by the model, where a negative cost $c(x) < 0$ indicates a preference of x to be assigned to region 1. For example, if probabilities p_1, p_2 are given for each point to belong to region 1 or 2, respectively, then a typical choice is $c = \log(p_2/p_1)$. The use of the

total variation of u as a regularizer corresponds to a penalization of the length of the interface between the regions, as discussed for Eq. (6).

The simple binary model above can be viewed as the piecewise constant two-region case of the famous Mumford-Shah functional [14], which is very hard to minimize. In contrast, the model (9) can be minimized globally by relaxation to a convex model and subsequent thresholding [15]. The proof relies on the co-area formula (7), which allows to write the energy as an integral over the energies of all level sets of u . A global solution is also available for the generalization from binary labeling to a continuous interval of labels with linear penalizer [16].

TV in 3D reconstruction. In variational approaches to 3D reconstruction, one looks for a surface which minimizes the local photo-consistency error ρ , given as a nonnegative function on a domain $\Omega \subset \mathbb{R}^3$. This is modeled as a weighted minimal surface problem, where the desired surface minimizes the surface integral over ρ . Finding a weighted minimal surface is a special case of binary segmentation in the sense the space Ω is partitioned into a region inside and outside the surface, respectively. A more general form of the co-area which includes a positive weight function ρ states that the weighted total variation of a characteristic function 1_U equals the weighted surface area of ∂U . Formally [8],

$$\int_{\Omega} \rho |\nabla 1_U|_2 \, dx = \int_{\partial U} \rho \, d\mathcal{H}^{n-1}.$$

One noteworthy application of this relationship is to formulate 3D reconstruction with a convex functional, such that globally optimal solutions can be obtained [11].

Total variation and related image processing problems can also be defined and solved on manifolds [3].

In the context of 3D reconstruction, a total variation super-resolution model on the surface can be employed to reconstruct high-resolution texture maps from multiple views [10].

Definition

Transfer learning is a methodology in machine learning that exploits the representation and/or features previously learned from some other tasks to better learn a target task. Generally, transfer learning makes learning target task faster, and when the target task lacks training data, transfer learning improves performance. Formally, a *domain* $\mathcal{D} = (\mathcal{X}, P(X))$ consists of both the input space \mathcal{X} and a probability distribution $P(X)$ where $X \in \mathcal{X}$. Given a domain \mathcal{D} , a *task* $\mathcal{T} = (\mathcal{Y}, f(\cdot))$ includes both the label space \mathcal{Y} and an objective predictive function $f(\cdot)$. In this entry, we consider transfer learning in the form of transferring from a *source* domain and task ($\mathcal{D}_S, \mathcal{T}_S$) to a *target* domain and task ($\mathcal{D}_T, \mathcal{T}_T$). T

With the aforementioned notations, transfer learning aims at improving the learning of the target predictive function $f_T(\cdot)$ over domain \mathcal{D}_T given the knowledge gained while learning $(\mathcal{D}_S, \mathcal{T}_S)$, where $\mathcal{D}_S \neq \mathcal{D}_T$ or $\mathcal{T}_S \neq \mathcal{T}_T$.

Background

Transfer learning is common when human learns novel ideas. For example, children can learn to generalize the concept of giraffe from a book. Similarly, people may find chess much easier to learn if they know how to play checkers. Unlike traditional machine learning, where the probabilistic distributions $P(X)$ and $P(Y|X)$ are often assumed to be stationary, in transfer learning they are nonstationary. Researchers have focused on two types of transfer learning: (1) *inductive transfer learning* where $\mathcal{T}_S \neq \mathcal{T}_T$ and (2) *transductive transfer learning* where $\mathcal{T}_S = \mathcal{T}_T$ but $\mathcal{D}_S \neq \mathcal{D}_T$. Specifically, $\mathcal{T}_S \neq \mathcal{T}_T$ implies that either $\mathcal{Y}_S \neq \mathcal{Y}_T$ or $f_S(\cdot) \neq f_T(\cdot)$. Similarly, $\mathcal{D}_S \neq \mathcal{D}_T$ implies that either $\mathcal{X}_S \neq \mathcal{X}_T$ or $P(X_S) \neq P(X_T)$.

In inductive transfer learning, there exist scarce labelled data in the target domain, and there are more labelled data in the source domain. The goal of inductive transfer learning is to leverage the scarce labelled data in the target domain to *induce* target predictive function. On the other hand, in transductive transfer learning, there exist some unlabelled data in the target domain. *Domain adaptation* often involves transductive transfer learning. For a comprehensive survey in transfer learning, we refer the readers to [1].

Theory

Inductive Transfer Learning

There are several ways to achieve inductive transfer learning including instance-based [2] and parameter-based methods [3]. Specifically, instance-based methods assume that *although the two domains and tasks are different, samples from one domain might be beneficial for the other*

domain. The goal for instance-based methods is to identify samples that are helpful for the target task from the source domain. Focusing on the scenario where $\mathcal{Y}_S = \mathcal{Y}_T$, TrAdaBoost [2] iteratively re-weights the contribution of a sample from \mathcal{D}_S to the process of training target predictive function $f_T(\cdot)$. In each iteration, it trains the predictor with the weighted source domain data and then evaluates the mistakes made by the predictor with samples in the target domain. The re-weighting strategy for data in the target domain is identical to that of *AdaBoost*. In addition, data in the source domain are also re-weighted such that the samples that are wrongly classified will have less impact to training in the next iteration. The intuition behind such a strategy is that the misclassified source domain samples may likely conflict with the data in target domain.

Parameter-based methods assume that *related tasks share model parameters or prior distribution*. The goal for parameter-based methods is to identify which parameters should be adapted to the new task and by how much. Yosinski et al [3] empirically studied the effect of parameter sharing between tasks across different layers in deep neural networks. They found that the effectiveness of parameter sharing depends on (1) the specialization of the shared parameters to tasks and (2) optimization difficulties related to splitting networks between coadapted parameters. Since the parameters of deeper layers tend to be more task-specific, sharing parameters in the deeper layers (and all the layers earlier) leads to performance degradation. However, using the parameters obtained by training on $(\mathcal{D}_S, \mathcal{T}_S)$ as a prior to further conduct fine-tuning on $(\mathcal{D}_T, \mathcal{T}_T)$ produces better performance for \mathcal{T}_T .

To deal with cases where label space $\mathcal{Y}_S \neq \mathcal{Y}_T$, *selective joint fine-tuning* [4] was proposed as an approach that is both parameter-based and instance-based. It first uses k nearest neighbors based on image descriptors to search data from the source domain that are similar to the ones in the target domain. For instance, given an image in the target domain, a certain number of images with similar low-level characteristics from the source domain are found. Here the low-level characteristics of an image are determined

by the histogram of the response of filters (e.g., convolutional filters in the first or second layer of a convolutional neural network). Afterward, the searched data together with the target domain data are used to jointly fine-tune a deep neural network using two branches of task-specific linear classifiers, each representing the loss in its respective domain.

Transductive Transfer Learning

As mentioned in Background, transductive transfer learning assumes $\mathcal{D}_S \neq \mathcal{D}_T$ and $\mathcal{T}_S = \mathcal{T}_T$, which implies that one can adapt the predictive function learned in the source domain for use in the target domain. Most literature in transductive transfer learning study the setting where $P(X_S) \neq P(X_T)$. Multiple transductive transfer learning schemes exist in the literature, including instance-based [5, 6] and representation-based [7, 8].

Instance-based methods are motivated by *importance sampling*. To see the connection between the two, let $\mathbb{P}_S = P(X_S, Y_S)$ be the distribution that governs the source data and label; similarly $\mathbb{P}_T = P(X_T, Y_T)$ denotes the distribution for target data and label. The end goal of learning a predictive function in the target domain is formally stated as follows:

$$\theta^* = \operatorname{argmin}_{\theta} \mathbb{E}_{(x,y) \sim \mathbb{P}_T} L(f(x|\theta), y), \quad (1)$$

where θ is the parameter for the target predictive function $f(\cdot)$ and (x, y) is a training example sampled from the target data distribution. Since there is no labelled data available on the target domain, (1) cannot be optimized directly. Instead, we use importance sampling by probing the source data distribution D_S :

$$\theta^* = \operatorname{argmin}_{\theta} \mathbb{E}_{(x,y) \sim \mathbb{P}_S} \frac{p_T(x, y)}{p_S(x, y)} L(f(x|\theta), y) \quad (2)$$

$$= \operatorname{argmin}_{\theta} \mathbb{E}_{(x,y) \sim \mathbb{P}_S} \frac{p_T(y|x)p_T(x)}{p_S(y|x)p_S(x)} L(f(x|\theta), y) \quad (3)$$

$$= \operatorname{argmin}_{\theta} \mathbb{E}_{(x,y) \sim \mathbb{P}_S} \frac{p_T(x)}{p_S(x)} L(f(x|\theta), y) \quad (4)$$

$$\approx \operatorname{argmin}_{\theta} \frac{1}{n_S} \sum_{(x,y) \sim \mathbb{P}_S} \frac{p_T(x)}{p_S(x)} L(f(x|\theta), y), \quad (5)$$

where p_S and p_T denote the probability density function for the source and target domain, respectively. And n_S denotes the number of samples in the training set of the source domain. The simplification step from (3) to (4) stems from the assumption of transductive transfer learning, i.e., $\mathcal{T}_S = \mathcal{T}_T$, which implies $p_S(y|x) = p_T(y|x)$ and $f_S(\cdot) = f_T(\cdot)$. The approximation from (4) to (5) uses empirical distribution to approximate the true distribution, which is also known as *empirical risk minimization*.

From (5), we can observe that if one can estimate $\frac{p_T(x)}{p_S(x)}$, one solves the transductive transfer learning problem. Zadrozny [5] proposed to estimate $p_T(x)$ and $p_S(x)$ by learning simple classifiers. Huang et al. [6] proposed to estimate $\beta_i = \frac{p_T(x_i)}{p_S(x_i)}$ without density estimation for p_T and p_S . Specifically, they proposed *kernel mean matching* (KMM) that re-weights the source data points such that the means of the source and target data points in a reproducing kernel Hilbert space (RKHS) are close. Empirical KMM optimization is achieved by solving the following QP problem:

$$\beta^* = \operatorname{argmin}_{\beta} \frac{1}{2} \beta^T K \beta - \kappa^T \beta \quad (6)$$

$$\text{s.t. } \beta_i \in [0, B] \text{ and } \left| \sum_{i=1}^{n_S} \beta_i - n_S \right| \leq n_S \epsilon, \quad (7)$$

where $K_{ij} := k(x_i, x_j)$ with k being a kernel function. $\kappa_i := \frac{n_S}{n_T} \sum_{j=1}^{n_T} k(x_i, x_{Tj})$, where $x_i \in X_S \cup X_T$ and $x_{Tj} \in X_T$. B states the upper bound of the weights, and the second constraint states that $\beta_i, i = 1, \dots, n_S$ should form a probability distribution.

Representation-based methods [7, 8] aim at finding a representation that has no discrepancy between the two domains, and learning the target predictive function upon the resultant representation. Pan et al. [7] proposed *maximum mean discrepancy embedding* (MMDE) to minimize the maximum mean discrepancy

between the source and target domain in a low-dimensional RKHS space. Such a low-dimensional embedding is obtained via solving a semidefinite program (SDP). Later Pan et al. [8] proposed *transfer component analysis* (TCA) to reduce the computation complexity of MMDE. Long et al. [9] proposed *deep adaptation network architecture* (DAN) that adds multiple kernel variant maximum mean discrepancy (MK-MMD) losses to the last few layers of a deep neural network to conduct domain adaptation in the deep learning context. Sun et al. [10] proposed *correlation alignment* (CORAL), a frustratingly easy domain adaptation method that works effectively. In essence, CORAL first whitens the data from the source domain and then recolors it with the covariance of the data from the target domain. Such a simple method work effectively and can be applied with deep features (i.e., the output of a deep layer in deep neural networks.) Sankaranarayanan et al. [11] proposed domain alignment using *generative adversarial networks* (GAN). The key assumption underpinning this method is that a well-aligned feature representation should contain enough information to generate source-like images such that a trained classifier cannot distinguish between the images generated by source domain and target domain. Based on this idea, they developed a training procedure using *auxiliary classifier generative adversarial networks* (ACGAN) and achieved state-of-the-art domain adaptation results.

Application

Transfer learning is applicable to a wide variety of applications. For instance, Blitzer et al. [12] used transfer learning for sentiment classification to reduce the cost of labelling the large corpora every time a new domain is considered. Zheng et al. [13] adopted transfer learning to adapt models from time to time targeting Wi-Fi localization. Adaptation from synthesized image to

real-world images is another key application in transfer learning. For example, Mayer et al. [14] demonstrated that with transfer learning, predictive model can obtain better performance with the help of synthesized data targeting disparity, optical flow, and scene flow estimation. Kornblith et al. [15] showed that ImageNet-pre-trained deep neural networks can transfer positively to various image classification tasks including scene classification, fine-grained image classification, and texture classification.

Open Problems

While most transfer learning literature targets at classification tasks, recent work [16] reveals that transferring from synthetic data to real-world data is challenging for object detection and semantic segmentation tasks. Furthermore, transfer learning in video understanding, human pose estimation, action recognition, and 3D scene understanding are still under-explored. Another research direction is open-set transfer learning [17], as most prior arts considered transfer learning in a closed-set setting. In open-set transfer learning, the target domain contains images of additional unknown categories that were not present in the source domain, which is still very challenging.

Definition

Transparency is the property of some materials that allows light to be partially transmitted through. The proportion of light a material transmits through determines its transmittance, α . The term translucency is generally used in cases where light is transmitted through diffusely.

Background

When a surface is viewed through a partially-transmissive material, the optical contributions of the two layers in a given viewing direction are collapsed onto a single intensity in the projected image. If a computer vision system is to recover the scene correctly, it must be able to decompose or *scission* the image intensity into the separate contributions of the two material layers (see Fig. 1a).

The inverse problem of recovering layered surface structure is generally divided into two sub-problems: (1) the qualitative problem of inferring the *presence* of an interposed partially transmissive layer in parts of the image and (2) the quantitative problem of assigning surface properties – e.g., reflectance and transmittance – to the separate layers.

Theory

Physical Models

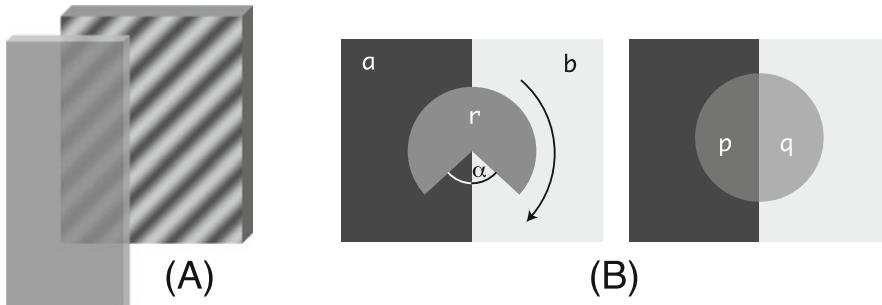

Metelli [18] used Talbot's equation for color mixing to model transparency: the "color" of the partially transmissive surface or filter (r) and that of the underlying opaque surface (a) are mixed linearly, with the mixing proportions determined by the transmittance α of the transparent layer:

$$p = (1 - \alpha)r + \alpha a \quad (1)$$

Metelli noted that this equation is consistent with a simple physical model of transparency involving an *episcotister* – a rapidly rotating disk with an open sector – placed in front of a background surface (see Fig. 1b, c). The same equation is also consistent with an opaque surface with a large number of holes that are too small to be resolved individually (e.g., a mesh). In the latter case, the "color mixing" takes place spatially, rather than over time. (Metelli himself considered only the achromatic case, so the colors he refers to are "achromatic colors," but his model has also been extended to the chromatic domain, e.g., [8, 10].)

Physically more accurate models of transparency incorporate the pattern of light reflection and transmission between a transparent filter and the underlying opaque surface (see Fig. 2a) [6, 7, 10, 12, 20, 25], leading to the following equation:

$$p = f + \frac{\alpha^2 a}{1 - fa} \quad (2)$$

Transparency and Translucency, Fig. 1 (a) Illustration of the problem of transparency: In each visual direction, the contributions of two distinct layers are collapsed onto a single pixel intensity. These contributions must

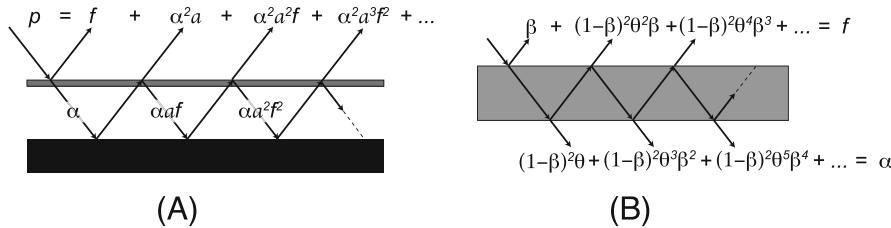

In this equation, reflectance f plays the same role as the product $(1 - \alpha)r$ in Metelli's model. Moreover, f and α can be further expressed in terms of intrinsic physical parameters of the partially transmissive filter (see Fig. 2b) – its *reflectivity* β (at the air filter interface) and *inner transmittance* θ (ratio of radiant flux that reaches the back surface of the transparent filter to the flux that enters the filter at its front surface), e.g., [10, 20, 25]. For models of sub-surface scattering within volumetric translucent materials, see, e.g., [15]. In such cases, background structure is often not visible through the translucent material, e.g., marble or cheese. In other cases, the background surface is visible but is greatly distorted due to variations in refractive index [11, 16].

It has been argued that, despite its simplicity, Metelli's linear equation provides a reasonable approximation to the more complete filter model [12], as well as to other more complex cases such as fog and haze [13]. Computer vision algorithms aimed at undoing the effects of fog and haze similarly employ a linear generative model, containing a multiplicative – i.e., attenuative – component due to absorption and scattering (a negative exponential of the fog extinction coefficient, generally taken to be a constant), plus an additive contribution of the airlight [9, 14, 19, 21, 24].

The Inverse Problem

Given a single equation such as (1) above, it is clearly impossible to determine transmittance α and reflectance r from knowledge of p and a

be disentangled if the scene structure is to be recovered. (b) Metelli's model of transparency based on a linear combination of the two contributions

Transparency and Translucency, Fig. 2 (a) Model of a transparent filter that takes into account the pattern of transmission and reflection between the filter and the

underlying opaque surface. (b) The overall transmittance and reflectance of the filter are functions of two intrinsic parameters: reflectivity β , and inner transmittance θ

alone. However, if the background surface contains two distinct “colors” a and b – both partly visible through the same transparent filter – the two equations:

$$p = (1 - \alpha)r + \alpha a \text{ and } q = (1 - \alpha)r + \alpha b \quad (3)$$

can be uniquely solved for α and r :

$$\alpha = \frac{p - q}{a - b}; \quad r = \frac{aq - bp}{a + q - b - p} \quad (4)$$

(Note that, more generally, with multiple colored patches visible through the transparent layer, a common solution may not exist and least squares methods may be required; see, e.g., [8].)

Transparent overlap of surfaces generically leads to X-junctions in the image (see Fig. 3). However X-junctions differ greatly in the degree of local support they provide for interpretations of transparency. Compare, for instance, the interpretations of perceived transparency elicited by the three displays in Fig. 3. In addition to making quantitative predictions for transmittance and reflectance, the above solutions also yield qualitative predictions for possible interpretations of transparent overlap and depth layering [6, 7, 18]. In order to have valid transparency, α must be non-negative with magnitude no larger than 1. Hence, based on the expression for α above, it follows that:

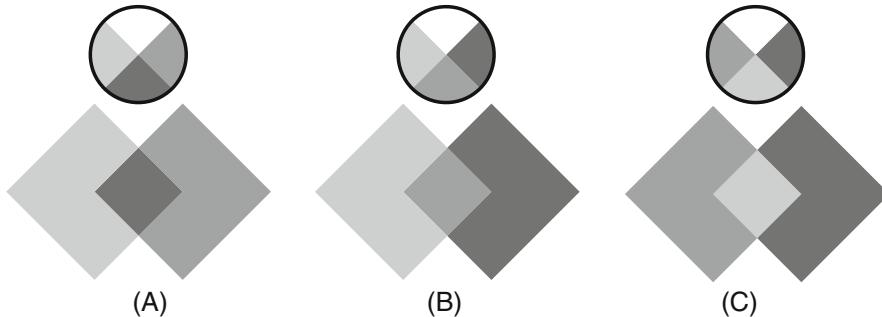

1. $\text{sign}(p - q) = \text{sign}(a - b)$. The contrast polarity must be the same inside and outside a putative transparency boundary.

2. $|p - q| \leq |a - b|$. The magnitude of the luminance difference must be no greater inside the transparency boundary than outside it.

Based on the polarity constraint above, researchers have classified X-junctions into three qualitative kinds [1, 2]. In a *non-reversing* junction, contrast polarity is preserved across both edges of the “X”; hence either edge could be the boundary of a transparent layer (Fig. 3a). In a *single-reversing* junction, contrast polarity is preserved across one edge only; hence there is only one possible interpretation of transparent overlap (Fig. 3b). Finally, in a *double-reversing* junction, neither edge preserves contrast polarity, so this junction type does not support an interpretation of transparency (Fig. 3c).

The above analysis provides local constraints for the interpretation of transparency. Local support is strongly influenced by configural factors, however [17], and may be even be overruled by global context. Mechanisms are needed to integrate local evidence across the image. In the achromatic domain, an integration algorithm was proposed by Singh and Huang [23], which propagates local junction information by searching for chains of polarity-preserving X-junctions with consistent sidedness (i.e., side with lower contrast) and then propagating the transparency labeling to interior regions. Despite its simple, deterministic nature, the algorithm performs well on synthetic images and simple real images with well-defined X-junctions.

In the chromatic domain, D’Zmura et al. [8] developed an algorithm for separating transparent overlays that (i) searches for chains of

Transparency and Translucency, Fig. 3 Classification of X-junctions based on their support for the interpretation of transparent overlap. (a) Non-reversing junctions. (b) Single-reversing junctions. (c) Double-reversing junctions.

X-junctions and (ii) tests for a consistent chromatic convergence across this chain. This algorithm is based on the finding that a convergence (possibly accompanied by a translation) in color space across a boundary tends to generate the percept of an overlying color filter, whereas other transformations such as shears and rotations do not. (This result is largely consistent with Metelli's model extended to the color domain – although some transformations that cannot be achieved with Metelli's equations, such as equiluminous translations in color space, can also generate a percept of transparency [8].)

Going beyond junctions The schemes reviewed above rely on the accurate extraction of junctions in images. A reliance on junctions may ultimately be too restricting, however, especially in images of natural scenes. For example, partially transmissive media with varying opacity, such as fog and haze, generate gradual changes in contrast along an edge in the background, without creating well-defined junctions. In order to deal with such cases, Anderson [3] proposed the *transmittance-anchoring principle* which states that, as long as contrast polarity is preserved across a contour, the visual system anchors the highest-contrast regions to full transmittance (i.e., surfaces seen in plain view), whereas lower-contrast regions are perceived as containing an overlying transparent layer with varying degrees of transmittance. Perceptual experiments suggest that human

observers do anchor transmittance in this way [4, 5].

Application

Work in computer vision has often focused on undoing the effects of fog and haze in images and recovering versions of these images that are free of atmospheric disturbance. One class of methods relies on having multiple images of a scene, taken either under different levels of atmospheric disturbance [19] or with different degrees of polarization [21]. Another approach uses image sequences to separate out an interposed reflective or occluding layer, such as a window or a fence [26]. Other methods, relying on a single image, have adopted a number of strategies, including maximizing local contrast in the restored image [24], the assumption that transmission and surface shading are uncorrelated [9], and the “dark-channel prior” – the assumption that in images of outdoor scenes taken under clear viewing conditions, most local patches tend to contain pixels with very low intensity in at least one of the color channels [14].

As noted above, another class of algorithms designed to separate transparent overlays from the background relies on the explicit extraction of X-junctions [8, 23]. These algorithms work well in simple images with well-defined junctions; it remains to be seen how well this approach scales up to complex natural images.

Physical versus perceptual models One issue that computer-vision systems must consider is whether they are aimed at recovering physically accurate estimates of the transmittance of a transparent material or obtaining estimates that are aligned with the way human observers perceive transmittance. One can readily imagine applications in which either may be more appropriate. Perceptual experiments have shown that the human perception of surface transmittance is not well-predicted by Metelli's equations and can deviate significantly from physical predictions. Specifically, these studies have shown that the visual estimate of transmittance is based on the *perceived contrast* within the region of transparency (suitably normalized by the perceived contrast in surrounding regions); and perceived contrast is not well predicted by the luminance differences (or luminance range) that appear in Metelli's solution for transmittance α ; see, e.g., [4, 20, 22]. Consistent with a perceived contrast model, a dark-colored surface can visually appear to be significantly more transmissive than a light-colored surface, despite the two having identical physical transmittance.

Definition

In computer vision, the term *transparent layers* refers to physical objects located at different depths from an imaging device, in such a configuration that irradiance coming from all these objects contributes to non-negligible portions of the final intensities of the *same* pixels, giving the perception of transparency.

Solving a *transparent layer problem* entails estimating a subset of the following values: intensity/color of each layer, depth of each layer, geometric parameters related to the camera pose and scene structure, and optical properties of the transparent layers.

Background

Phenomena of transparent layers can appear in many imaging processes. The most typical transparent layers occur due to *transparency*. For instance, objects seen through a textured and transparent material, for example, a tinted glass window or a thin curtain, where the layers include a front layer of transparent object and a rear layer of the background objects. Figure 1 illustrates this case.

Some transparent layers are caused by *reflection*, see Fig. 2. Specular surfaces, such as a

picture frame, reflect scene structures at a distance. A reflected image from a surface appears to be at a different depth from the reflecting surface itself. In the above example, the picture frame forms the closer layer and the reflected scene forms the more distant layer. The apparent depth of the reflected layer depends on multiple factors, including shape of the reflector and scene geometry.

Transparent layers can also appear because of *point spread*. Cameras have finite-sized imaging elements. In addition, due to imperfection in optical focusing, an observed image is usually a kernel-smoothed version of the scene radiance. The convolution kernel, known as the *point spread function* (PSF), is due to a combination of camera optics and the finite size of an imaging device. As a result of PSF blurring, pixels corresponding to boundaries of opaque objects at different depths contain contributions from both layers, giving the perception of transparency. Figure 3 illustrates two of such examples.

Penetrating electromagnetic radiation, such as X-ray or visible light, produces the perception of transparent layer. X-ray images are among the most sophisticated transparent effects, composed of many layers of objects that undergo non-rigid complex motions. Another prime example of this case is optical microscopy, where layers of cells at different depths are superposed into a final visible spectral image. Figure 4 shows such examples.

When the relative speed between a camera and an imaged scene is not negligible compared to the shutter speed, *motion blur* can cause blending of foreground and background scenes and give the impression of transparency. Blurring at a pixel is caused by integrating radiance contributions from scene points from different depths or different parts of an object. See Fig. 5 for an example.

Irradiance, i.e., light coming into a camera, travels through a *transmitting medium*, for example, air, water, and glass. Sometimes, the effects of the media in between are nontrivial, for example, due to excessively heated air, fog, milky water, or thick tinted glasses. The medium causes color shifts and distortion of the images, and sometimes, it is interesting to study the medium

Transparent Layers, Fig. 1 Transparent layers caused by *transparency*. *Left*, a photograph of a lake containing transparent layers: a layer composed of the water surface that is textured by ripples and a farther layer of pebbles on

Transparent Layers, Fig. 2 Transparent layers due to *reflection*. *Left*, a textured pitcher surface reflects objects in the scene. *Right*, photograph in a picture frame reflects a dodecahedron and a tea box

and background in the context of transparent layers. See Fig. 6 for two such examples.

People study transparent layers for many different reasons, for instance, to more accurately estimate motion or depth of a scene by separating the layers, thus removing non-Lambertian effects due to layer blending [3–9], to render images containing transparent layers from novel viewing angles [10, 11], for inexpensive content creation and manipulation in applications such as gaming and movies, and to enhance visualization of one or all component layers, such as in medical imaging [12, 13].

Theory

A linear superposition model of two layers can be summarized as

$$I(x) = T_1(\theta_1) \circ I_1(x) + \pi (T_2(\theta_2) \circ I_2(x), \alpha(x)), \quad (1)$$

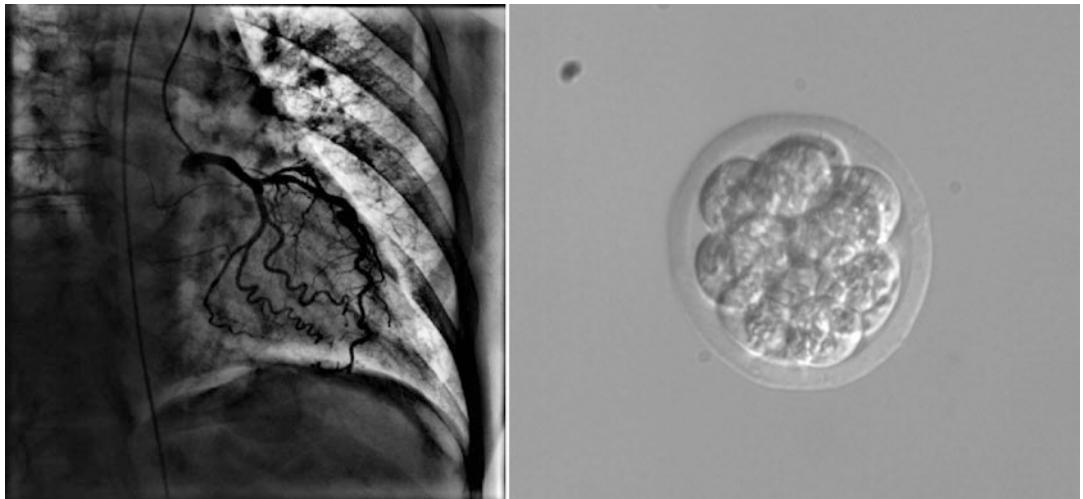

where:

- $I(x)$ is the observed image that is a superposition of different layers.

Transparent Layers, Fig. 3 Sub-pixel blending due to *point spread*. *Left*: sub-pixel blending occurring at boundaries of surfaces at different depths. The *insets* show boundary image regions. (Image courtesy of Scharstein and Szeliski [1]). *Right*: sub-pixel blending due to hairy

foreground objects. The *Inset* shows the α -map of the foreground object, where the intensity of the map is proportional to the opacity of a foreground pixel. (Image courtesy of Levin et al. [2])

Transparent Layers, Fig. 4 Penetrating electromagnetic radiation produces transparent layers. *Left*, the image shows an X-ray image (angiogram) of a human chest. Visible in the image are dye contrast-enhanced coronary arteries of the heart, ribs, spine bones, and soft tissues appearing at different distance to the X-ray machine.

Right, image shows transparent mouse embryo cells overlay on top of each other. (Image courtesy of Bill Warger and Judy Newmark and the Mouse embryos DIC image set is available from the Broad Bioimage Benchmark Collection (www.broad.mit.edu/bbbc))

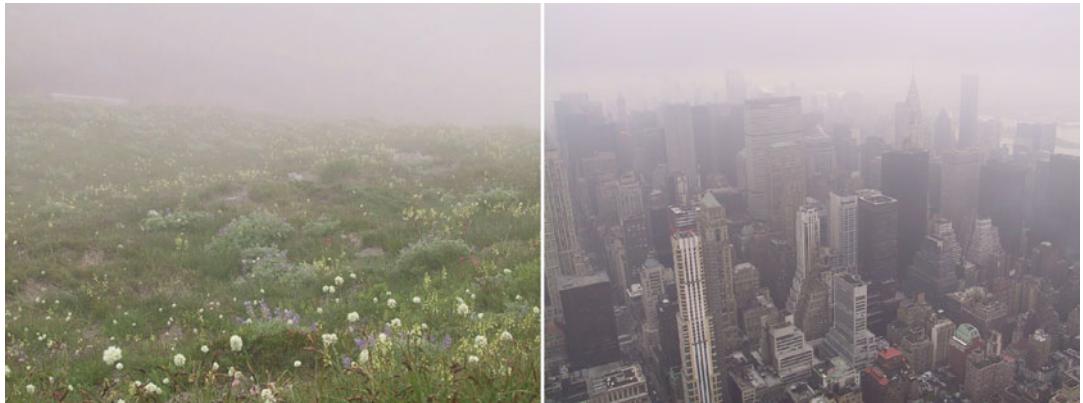

- I_l , $l = 1, 2$ represents radiance toward the viewing camera in the absence of the other layer. I_2 can itself be a superposition of layers, which generalizes (Eq. 1) to more than two layers in a recursive fashion.
- $\alpha(x)$ is a vector of blending parameter of the first layer, affected by properties such as con-

- stituent material types, distribution of material types, or thickness of the layer. In general, $\alpha(x)$ can be spatially varying.
- $T_l(\theta_l) \circ, l = 1, 2$ represents the function that warps a layer (I_1 or I_2) to the current camera view from a reference camera view. The warping function is parameterized by

Transparent Layers, Fig. 5 Transparent layers due to motion blur. *Left:* when the train is static. *Right:* when the train is moving very fast compared to the camera shutter speed, the train appears to be transparent due to the long

temporal integration process. The contribution of a point on a background object to the intensity/color of a pixel is proportional to the amount of time the point is visible

Transparent Layers, Fig. 6 Translucent Media can contribute nontrivial transparent layers. The above images show photographs of foggy days, when the transparent

layer due to the medium, i.e., air mixed with water droplets, becomes nontrivial

geometric parameters θ_l , $l = 1, 2$, for example, point depths or affine motion model parameters. The warping function $\mathcal{T}_{j\circ}$ can be parametric motions [8], nonparametric, pixel-wise motion such as in a stereo setting [9] or smooth, nonrigid motion such as in X-ray images.

- The function $\pi(\cdot)$ describes the physical process of composing a second layer given blending parameters of the first layer.

Note that the linear superposition model, i.e., by adding up (weighted) contributions from all layers, is a good approximation to many computer vision problems. For X-ray images, due

to the exponential decaying nature of radiation rays, the raw X-ray image I_x is not a linear superposition of layers. However, $\log I_x$ can be fairly accurately modeled by (Eq. 1).

In general, estimating all parameters of all layers is a *severely ill-posed problem*. For instance, for each pixel x in a single observed image, there is one set of observations $I(x)$ but many unknowns, i.e., geometric parameters θ_l , blending parameters α , and the colors of the constituent layers I_1 and I_2 . Fortunately, it is not always necessary to estimate all parameters at once. We are not confined to use a single image to solve a transparent layer problem either. In fact, in the majority of studies, researchers use multiple

images of the underlying scene. In specific problem settings, we can define well-posed problems.

There is a rich literature that studies transparent layers in computer vision. These methods utilize characteristics of transparent layers, such as physical model, statistical priors, or motion, to analyze transparent layers. The approaches range from explicitly separating the transparent layers to eliminating layers of no interest by means of integration or difference. The following is a summary of these approaches and how they constrain the problems to be well-posed:

Using defocusing and polarization cues. The first set of approaches utilizes physical properties of the image formation process to define well-posed layer separation problems. In these models, it is usually assumed that both layers can be approximated by fronto-parallel planes, and multiple images are taken from a *static camera*. As a result, scene points within the same layer share a single depth value, $\theta_l(x) = d_l$, $l = 1, 2$. The static configuration makes the warping functions \mathcal{T}_l trivial, i.e., identity transformations. Schechner et al. [14] showed that the depth values d_l can be estimated using defocusing cues. They utilized a set of photographs taken with different focuses. Using a “focus measure,” the two focal lengths that correspond to the sharpest focuses in both transparent layers are estimated. Knowing camera calibration *a priori*, the layer depths and PSF’s for each layer can be computed from the estimated focal lengths. The observed pair of images that correspond to the most sharply focused images can be written as

$$\begin{cases} I^{(1)} = I_1 + I_2 \otimes h_a \\ I^{(2)} = I_1 \otimes h_b + I_2 \end{cases}, \quad (2)$$

where \otimes means convolution; $I^{(k)}$, $k = 1, 2$ is the observed composite image when I_k is in focus. The above problem is still ill posed in that we can add a constant (or even a low frequency) component C to the solution of one layer and subtract the same from the other, and the resulting layer images, $I^{(1)} + C$ and $I^{(2)} - C$, are still valid solutions to (Eq. 2). However, if we fix the DC components of one layer, the problem can be solved by least squares. In the

same spirit, using a rotating polarizer in front of the camera lens, Schechner et al. [15] show that the observed image is a linear combination of the layers, where the linear combination coefficients are functions of inclination angles. The inclination angles can be estimated by minimizing the correlation between component layers. The key insights for formulating a well-constrained problem in both methods are using static cameras and geometric regularity of scenes to reduce the dimension of θ to 2, trivializing the warping functions \mathcal{T} , and estimating blending coefficients (PSF kernels or inclination angles) independent of layer radiances.

Utilizing an atmospherical scattering model. Unfavorable weather conditions can cause lowered visibility, due to floating particles in the air, including aerosols, water droplets, rain, or snow. In these conditions, atmospherical effects can no longer be ignored, and the atmosphere itself can be considered as a transparent layer: it alters and adds to the color of the scene radiance. Narasimhan and Nayar [16] conducted a thorough study of transparent layers due to atmospheric scattering. They showed that through reasonable assumptions and simplification of an atmospherical model, the transparent layer problem can be well constrained and solved: the depth from a scene point can be estimated up to a constant scale and the scene color can be estimated. For example, in its simplest form, images taken at *night* can be modeled as a simplified version of (Eq. 1)

$$I = \pi(I_2, \alpha) = g e^{-\beta d} I_2, \quad (3)$$

where g is a geometric constant; β being a constant attenuation coefficient, and d the scene depth. Eq. 3 implies that in the absence of sunlight or skylight that adds to the *air light*, i.e., color of the fog, the observed image, I is an attenuated version of the scene radiance I_2 . Given two images of the scene under different atmospherical conditions (clear nights, light fog, or dense fog), corresponding to different β , log ratio of the two observed images reveals that

$$\ln \left(\frac{I^{(1)}}{I^{(2)}} \right) = -(\beta^{(1)} - \beta^{(2)}) d. \quad (4)$$

As a result, we can estimate the scene depth up to unknown constant scale factor. In the presence of sunlight and skylight, the air light can no longer be ignored and the transmission layer composes the first layer, i.e., fog color is I_1 . In this case, an additional *dichromatic* model can be used to constrain the problem [16], resulting in well-posed problems. By utilizing a *dark channel prior*, He et al. [17] introduced a method that reconstructs the transparent layers and scene depth using a single image.

Statistical Approaches. Another effective way of transforming (Eq. 1) into a well-posed problem is by using statistical properties of I_1 and I_2 . Farid and Adelson [18] studied the case where an observed image is a linear mixture of two-component layers. By rotating a polarizer in front of the camera, they were able to capture images with different mixing parameters for different polarization angles. A simplified version of (Eq. 1) now has the form

$$\begin{cases} I^{(1)}(x) = a \cdot I_1(x) + b \cdot I_2(x) \\ I^{(2)}(x) = c \cdot I_1(x) + d \cdot I_2(x) \end{cases}. \quad (5)$$

The key assumption for their approach is that $I_1(x)$ and $I_2(x)$ are independent. As a result, the mixing coefficients should be sought such that after the inversion

$$\begin{pmatrix} I_1(x) \\ I_2(x) \end{pmatrix} = \begin{bmatrix} a & b \\ c & d \end{bmatrix}^{-1} \begin{pmatrix} I^{(1)}(x) \\ I^{(2)}(x) \end{pmatrix}. \quad (6)$$

$I_1(x)$ and $I_2(x)$ are maximally decorrelated (an approximation to the independence assumption). This is done by rotating and stretching the joint intensity distribution such that the resulting distribution is as separable as possible (the most decorrelated distribution). The parameters for rotation and stretching can be computed in close form if the observed joint distribution ($I^{(1)}(x), I^{(2)}(x)$) is approximated by a principal component analysis model. Schechner et al. [19] proposed a similar approach, where the mixture is caused by

focusing at one layer at a time. The point spread function of the defocused layer is estimated by minimizing mutual information between the two layers. Instead of using the original intensity, Bronstein et al. [20] convolve the input image pairs with high pass filters. The filtered images have mostly zero values and present sparse distributions. They show that sparse ICA can better separate the component layers. Levin et al. [21] demonstrate that for simple images the component layers can be recovered from just one image. From natural images, they learn the exponential density functions of several filter responses. The best separation of the input image is the one that maximizes the learned density function. However, their algorithm fails in more complicated images where texture is abundant.

Motion Analysis. Under certain conditions, by using images taken at multiple viewpoints (due to relative motion between the camera and the scene), we can transform (Eq. 1) into well-posed problems. In Szeliski et al. [8], the component layers are assumed to undergo parametric motions, for example, the motion observed between two frames can be parameterized by a 2D affine motion model. Furthermore, by assuming constant linear blending coefficients between the two layers, the linear superposition model (Eq. 1) can be simplified

$$\begin{aligned} I^{(i)}(x) &= T_1^{(i)}(\theta_1) \circ I_1 + T_2^{(i)}(\theta_{12}) \circ I_2(x) \\ &= I_1(T(x, \theta_1^{(i)})) + I_2(T(x, \theta_2^{(i)})), \end{aligned} \quad (7)$$

where $T(x, \theta)$ is the parametric transformation that maps a point in the i th observed frame to the reference frame. Given F frames from the motion sequence, assuming dimensionality (length) of θ being d and that there are N pixels in a frame, we have $2N + 2d(F - 1)$ unknowns and approximately $F \cdot N$ constraints (excluding boundary effects). Because $N \gg d$, the number of constraints grows much faster than the number of unknowns as more frames are observed. As a result, given a few frames, the problem can be well constrained.

However, solution to this well-constrained problem is not trivial. Szeliski et al. [8] took an iterative approach. An initial set of transformations θ_l^i was estimated using image alignment methods, assuming that one of the layers has dominant texture patterns. The images are warped back to the reference view, and by observing that image intensities are nonnegative, they used a *min-composite* algorithm to initialize intensity. Once an initialization is obtained, the algorithm then iteratively refines the motion and intensities of each layer.

Tsin et al. [9] studied the case for stereo matching when linear superposition of layers occurs. The unknowns in this case are per-pixel color and depth, i.e., $4N$ unknowns, $2N$ for intensities, and $2N$ for layer depths. In a first step, depths are estimated using a *nested plane sweep* for computing matching costs associated with a depth hypothesis pair, one depth for each layer. An optimization algorithm, i.e., graph-cut optimization, was used to find a strong minimum. The key observation in this step is that a cost associated with a depth hypothesis pair can be derived without knowing the layer intensities. After the depths are estimated, layer intensities can be solved using least squares in a second step.

There is a plethora of other work using motion sequences for layer separation. One of the earliest work on layer extraction is that of Wang and Adelson [22]. They compute per-pixel flow, perform K-means clustering in affine motion space, and assign each pixel to one of the sets of clustered affine parameters. Darrell and Pentland [23] improved on the formulation by having a direct connection between layers and robust estimation. Shizawa and Mase [3] provide a theoretically elegant solution to extract multiple flow from an image sequence. They formulate the constraint for double optical flow in space-time frequency domain and use it as the energy minimization function. In a follow-up work [24], the principle of superposition is applied to the multiple optical flow problem. Ju et al. [6] used a layered piecewise affine motion model to simultaneously estimate multiple motions in both occlusive and transparent motion sequences. Swaminathan et al. [25] handled the problem of highlight detection and removal by *epipolar plane image* (EPI) analysis, explicitly detecting the saturated highlights in a local EPI stripe. Bergen et al. [4] introduced a differencing technique to deal with transparency. In contrast to differencing techniques, the integration technique of Irani et al. [5] stabilizes one motion region and blurs all other regions by integration or averaging.

In summary, the transparent layer problems are in general ill-posed and hard to solve. However, we can define and solve well-posed transparent layer problems by adding additional information, for example, using multiple images, known calibration of the camera (PSF or camera pose), simplified scene geometry, and polarized observations or statistical priors. A reader is encouraged to study closely related topics, especially *matting* [2, 7] and motion *deblurring* [26], for dealing with transparent layers at opaque object boundaries.

Open Problems

Open problems for transparent layers are listed below.

1. Solving transparent layer problems in *general settings* robustly. The existing solutions dealt with specific cases of transparent layer problems, but a solution that works in general real-world applications is still elusive.
2. Robustly separating transparent layers from *a single image*. The difficulty comes from the fact that the problem is severely under-constrained. To solve the problem, unbiased, proper priors need to be added to the problem. Very insightful algorithms have been developed in the literature using priors derived from natural image statistics [21]. But to be able to robustly recover component layers to the degree of human capability, these priors are still insufficient.
3. Robustly separating *more than two layers or unknown number of layers*. The ability to recover transparent layers in these cases critically depends on the robustness of the algorithm in dealing with distractions from un-modeled layers and the ability to handle

- potentially very low signal-to-noise ratio of layers in the background, due to signal attenuation.
4. Robustly separating transparent layers *when the blending factor is unknown and spatially varying*.
 5. Motion-based separation of transparent layers undergoing *unknown and nonrigid motion*. The difficulties of layer separation and nonrigid motion estimation are coupled in this case.
- A good example of open problems is estimating motion and component layers in X-ray image sequences. The problem is complicated by the following factors: (1) unknown number of layers, depending on where an X-ray image is taken, it may contain images of many organs/bones superposed with each other; (2) Nonrigid motions of the layers, such as those caused by respiratory or cardiac motion. On the other hand, solving the problem has clinically important applications, for example, visualization enhancement and digital subtraction angiography [27].

Definition

Triangulation is a measurement method that estimates the position of an unknown 3D point.

When the positions of two vertices of a triangle are known, the position of the remaining vertex can be computed if the interior angles at these two vertices are known.

In computer vision, stereo reconstruction and active 3D measurement are achieved by using the triangulation.

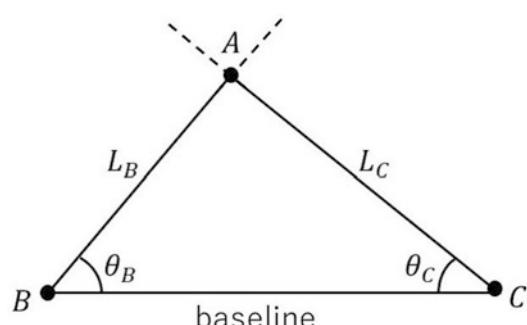

Background

The origin of triangulation dates back to the ancient Egyptian era of 3000 BC and is said to have been invented to re-measure land divisions after the frequent occurrences of the overflow of the Nile. Since then, triangulation has been used for measuring land, buildings, distances to stars, etc.

Theory

The triangulation measures unknown distances without measuring the distances directly.

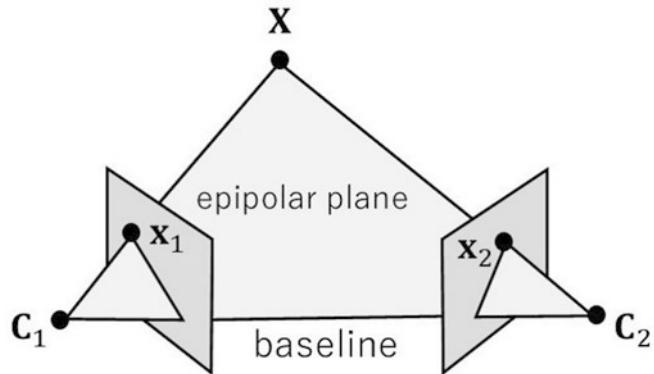

Suppose we have a triangle ABC as shown in Fig. 1, and the positions of vertex B and vertex C are known while the position of vertex A is unknown. If the interior angle θ_B at vertex B and the interior angle θ_C at vertex C are obtained, line L_B and line L_C can be drawn from vertex B and vertex C , and the position of vertex A can be determined as an intersection of these two straight lines. The line that goes through vertex B and vertex C is called a baseline, and the

Triangulation, Fig. 1 Triangulation

Triangulation, Fig. 2

Stereo camera

length between vertex B and vertex C is called a baseline length.

In computer vision, triangulation is used for recovering 3D points from stereo cameras [1–3], measuring 3D depth from a camera and projector pair [4–6], and visualizing 3D depth from multiple projectors [7]. In these methods, triangulation is considered on a specific plane called the epipolar plane, which goes through two viewpoints, C_1 and C_2 , and a 3D point \mathbf{X} to be measured, as shown in Fig. 2.

3D reconstruction from camera images based on triangulation has been considered under various situations, such as triangulation from uncalibrated cameras [8, 9], triangulation from unsynchronized cameras [10], triangulation from rolling shutter cameras [11], and triangulation from a huge amount of cameras [3].

Two representative computational methods of triangulation are the linear method, which obtains 3D points analytically by solving a system of linear equations, and the non-linear method, which provides the theoretically most accurate solution by minimizing geometric errors [1].

Triangulation from Linear Estimation

Suppose a 3D point \mathbf{X} is observed by two cameras. Assuming that the camera projection can be represented by a pinhole camera and there is no nonlinear distortion of the second order or higher, the projection from a 3D point \mathbf{X} to a pair of image points \mathbf{x}_i ($i = 1, 2$) can be described by using 3×4 matrices \mathbf{P}_i ($i = 1, 2$) of these two cameras as follows:

$$\mathbf{x}_1 = \mathbf{P}_1 \mathbf{X} \quad (1)$$

$$\mathbf{x}_2 = \mathbf{P}_2 \mathbf{X} \quad (2)$$

where \mathbf{x}_1 , \mathbf{x}_2 , and \mathbf{X} are represented in the homogeneous coordinate system. Then, we consider the triangulation and reconstruct a 3D point \mathbf{X} from a pair of image points \mathbf{x}_1 and \mathbf{x}_2 given the camera matrices \mathbf{P}_1 and \mathbf{P}_2 .

By considering the vector product of Eqs. (1) and (2) with \mathbf{x}_j ($j = 1, 2$), we have:

$$[\mathbf{x}_1]_{\times} \mathbf{P}_1 \mathbf{X} = \mathbf{0} \quad (3)$$

$$[\mathbf{x}_2]_{\times} \mathbf{P}_2 \mathbf{X} = \mathbf{0} \quad (4)$$

where $[\mathbf{x}]_{\times}$ denotes a 3×3 matrix that represents a vector product in matrix form and consists of the components of $\mathbf{x} = [x_1, x_2, x_3]^T$ as follows:

$$[\mathbf{x}]_{\times} = \begin{bmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{bmatrix} \quad (5)$$

Then, Eqs. (3) and (4) can be combined into:

$$\mathbf{M}\mathbf{X} = \mathbf{0} \quad \mathbf{M} = \begin{bmatrix} [\mathbf{x}_1]_{\times} \mathbf{P}_1 \\ [\mathbf{x}_2]_{\times} \mathbf{P}_2 \end{bmatrix} \quad (6)$$

If there is no image noise, the rank of matrix \mathbf{M} is 3, and if there is image noise, the rank is 4. The 3D point \mathbf{X} can be obtained as a solution of the linear equation, Eq. (6). It is obtained as an eigenvector that corresponds to the minimum eigenvalue of a 4×4 matrix $\mathbf{M}^T \mathbf{M}$.

Triangulation from Geometric Error Minimization

Although the linear method described above is a fast and stable method that analytically yields 3D points, it does not always provide the most accurate reconstruction results. To obtain the most accurate results, we next consider the minimization of geometric errors.

Let us consider a 3D point $\hat{\mathbf{X}}$ recovered from a pair of camera images. Then, by projecting $\hat{\mathbf{X}}$ to the images again, we obtain reprojection points, $\hat{\mathbf{x}}_1$ and $\hat{\mathbf{x}}_2$, in the pair of images as:

$$\hat{\mathbf{x}}_1 = \mathbf{P}_1 \hat{\mathbf{X}} \quad (7)$$

$$\hat{\mathbf{x}}_2 = \mathbf{P}_2 \hat{\mathbf{X}} \quad (8)$$

Then, we consider a Euclidean distance between the reprojection point $\hat{\mathbf{x}}$ and the observed point \mathbf{x} as follows:

$$d(\mathbf{x}, \hat{\mathbf{x}}) = \sqrt{(\mathbf{x} - \hat{\mathbf{x}})^\top (\mathbf{x} - \hat{\mathbf{x}})} \quad (9)$$

where the homogeneous coordinates are normalized so that their third component is equal to 1.

The distance d is called a reprojection error. By estimating the 3D point $\hat{\mathbf{X}}$ so that it minimizes the reprojection error in a pair of images, we can obtain the maximum likelihood estimate (MLE) of $\hat{\mathbf{X}}$. This is achieved by solving the following minimization problem:

$$\hat{\mathbf{X}} = \arg \min_{\mathbf{X}} d(\mathbf{x}_1, \hat{\mathbf{x}}_1)^2 + d(\mathbf{x}_2, \hat{\mathbf{x}}_2)^2 \quad (10)$$

The solution can be obtained by using numerical minimization methods such as the Levenberg-Marquardt method [12, 13].

This method provides us theoretically the most accurate results. However, the method has a risk of falling into local minima, and reconstruction tends to be unstable. Thus, it is necessary to estimate from a good initial value. As initial values, the results of the linear method are often used.

Trichromatic Theory

Michael H. Brill
Datacolor, Lawrenceville, NJ, USA

Related Concepts

- ▶ Chromaticity
- ▶ Color Constancy

Definition

Trichromatic theory is the conceptual framework by which human vision matches the color of any test light to that of an additive mixture of the spectra of three primary lights in appropriate proportions. For highly chromatic colors, such a match might require one of the primary lights to mix with the test light instead of with the other primaries; the algebra of adding the light spectra would represent this condition as subtraction.

Background

The basic correctness of trichromatic theory (acknowledged at least since Thomas Young in 1802) underlies the success of such technologies as color photography and television, both of which need only three primaries to produce acceptable color rendition. The amounts of three primary lights needed to match a test light are called the *tristimulus values* of that test light, and are used to specify color quantitatively. Two lights with different spectra and the same tristimulus values are called *metamers* (or *metameric matches*). One powerful consequence of trichromatic theory is that, if two lights are a metamer match, they can never be made to mismatch by any functional processing of the visual signal. Since illumination changes (or putting on sunglasses) may make certain objects match in color that did not match before (i.e., make the lights reflected from two objects a metamer match), that means that no visual processing is completely effective in returning the viewed world to what it would have looked like before the light changed or the sunglasses were put on. Even so, the visual system approximates this feat of restoration much of the time. The feat is called *color constancy*, and is described in another entry.

The biological basis of trichromatic theory is a set of three kinds of light sensors in the retina, called cones, each kind having a different type of light-sensitive molecule (photopigment). Whereas trichromatic theory was confirmed func-

tionally by color-matching experiments in the nineteenth century, the physiological and anatomical confirmation did not occur until the mid-twentieth century.

Theory and Application

Underlying trichromatic theory is a set of rules known as Grassmann's laws, disclosed in 1855 by Hermann Grassmann. The laws are assertions about color matches that are more or less true empirically. In the statement of these rules below, “=” denotes a color match; k denotes a scalar multiplier; \mathbf{A} , \mathbf{B} , \mathbf{C} , \mathbf{D} are the spectra of lights that participate in a match; and “+” denotes superposition (addition) of the spectral power distributions of the lights. All of color technology, including color television and color photography, depends on these rules [1]:

Symmetry: If $\mathbf{A} = \mathbf{B}$, then $\mathbf{B} = \mathbf{A}$.

Transitivity: If $\mathbf{A} = \mathbf{B}$ and $\mathbf{B} = \mathbf{C}$, then $\mathbf{A} = \mathbf{C}$.

Proportionality: If $\mathbf{A} = \mathbf{B}$, then $k\mathbf{A} = k\mathbf{B}$.

Additivity: If $\mathbf{A} = \mathbf{B}$ and $\mathbf{C} = \mathbf{D}$, then $\mathbf{A} + \mathbf{C} = \mathbf{B} + \mathbf{D}$. If $\mathbf{A} = \mathbf{B}$ and $\mathbf{A} + \mathbf{C} = \mathbf{B} + \mathbf{D}$, then $\mathbf{C} = \mathbf{D}$.

Grassmann's laws are tested by what is called a *symmetric-matching* experiment: An observer compares two lights that are presented on identical backgrounds and with a visual system adapted the same for both sides of the match.

For such technologies as color television and photography, it is important to understand how to create the same color on an image as was in an original scene. Because of trichromatic theory and Grassmann's laws, it can be found out what spectra will match each other through a set of three functions of wavelength called the *color-matching functions*. Color-matching functions are specified by the Commission Internationale de l'Eclairage (CIE) based on a set of symmetric color-matching experiments performed in 1931 by several human observers whose data were combined to produce a Standard Observer. The functions so derived are called $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$, where λ is visible wavelength (from 380

to 780 nm). Two spectral power distributions, $S_1(\lambda)$ and $S_2(\lambda)$, are said to match and produce tristimulus values X, Y, and Z when

$$\begin{aligned} X &= \int \bar{x}(\lambda) S_1(\lambda) d\lambda = \int \bar{x}(\lambda) S_2(\lambda) d\lambda \\ Y &= \int \bar{y}(\lambda) S_1(\lambda) d\lambda = \int \bar{y}(\lambda) S_2(\lambda) d\lambda \\ Z &= \int \bar{z}(\lambda) S_1(\lambda) d\lambda = \int \bar{z}(\lambda) S_2(\lambda) d\lambda. \end{aligned}$$

Of course, if two lights match according to this definition, they will match using any linearly independent linear combinations of $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$. Also, when one adds two spectral power distributions, one adds their vectors (X, Y, Z).

For illustration, Fig. 1 below shows the CIE 1931 color-matching functions $\bar{x}(\lambda)$ [in red], $\bar{y}(\lambda)$ [in green], and $\bar{z}(\lambda)$ [in blue].

Deriving the color-matching functions for a human observer requires doing a symmetric color-matching experiment. In practice there are two experimental methods.

The more common way, called the *maximum-saturation method*, arranges three narrowband primary lights and a variable-wavelength test light to form a match. The test light (assumed monochromatic) is presented with unit power, and the primary lights are adjusted in intensity so, for each wavelength of the test light, two of the primaries superposed will match the other primary superposed with the test light. The name “maximum saturation” derives from the fact that the chromaticity of the light on either side of the match is always on one of the sides of the triangle defined by the primaries. Color-matching functions derive from the maximum-saturation experiment in a straightforward way: The powers of the primaries required to make the match (including a negative sign for the primary on the same side of the match as the test light) are the color-matching functions at the test-light wavelength. Linearly transformed according to the mandates of the CIE [2], they become the \bar{x} , \bar{y} , and \bar{z} color-matching functions above. (There are effects of field size, etc. in the experiment,

but those go beyond the scope of this brief tutorial.)

The other, less common kind of color matching, the *Maxwell method*, uses a chosen white light (always the same) on one side of the match and variable powers of the test light and two out of three monochromatic primaries on the other side of the match. Color-matching functions derive from the Maxwell color match by a somewhat involved process (see [5]), and should (if Grassmann’s laws were true) be the same functions as given by the maximum-saturation experiment.

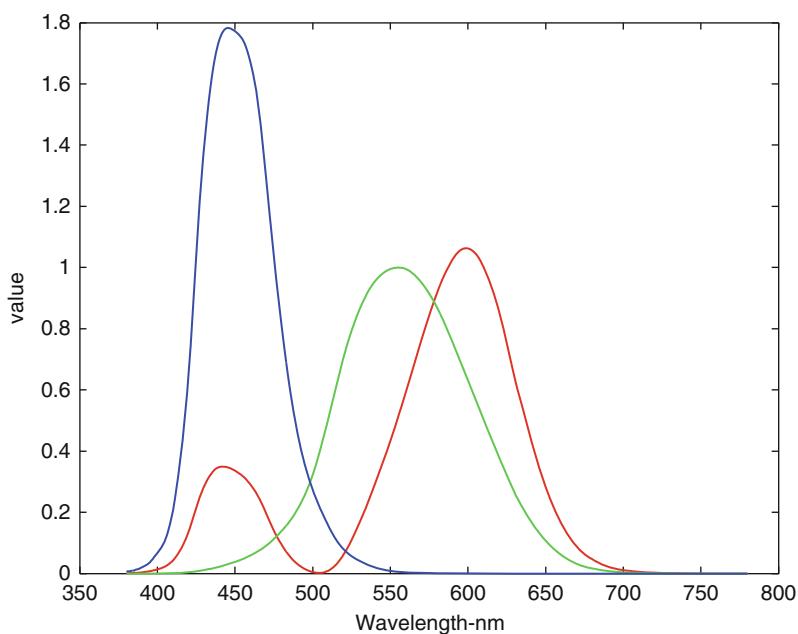

Open Problems

Grassmann’s laws are known not to be exactly true in human color matching [5, 6]. Besides the three cone types that herald the trichromacy of vision at high (photopic) light intensities, a fourth photoreceptor type (rods) contributes to vision at low (mesopic and scotopic) light intensities and away from the center of vision (fovea). At very high light intensities, unbleached photopigments deplete and, in aggregate, change their action spectrum. At still higher light intensities, a photopigment molecule can absorb multiple photons but respond as if it absorbed only one photon. These effects compromise Grassmann’s laws, but the successful application of the laws, e.g., in photography and television, is evidence that the compromises are not serious.

Nonetheless, changing the way the matching experiment is done can alter the experimental results significantly. For example, as defined above, Maxwell and maximum-saturation color matches have long been known to be inconsistent even at high luminance levels and statistically reinforced by match replication [1]. A practical consequence of the failure of additivity could be problems observed in cross-media color matching, although cross-media studies also have other well-known sources of imprecision because in that case the color matching is asymmetric.

Definition

The camera has intrinsic parameters that represent the internal characteristics of the camera and extrinsic parameters that represent the position and orientation of the camera. When all of these intrinsic and extrinsic parameters have been determined, the camera is called a calibrated camera, and when these parameters are unknown, the camera is called an uncalibrated camera.

Theory

Assuming that the projection on the camera can be represented by a pinhole camera and there is no nonlinear distortion of the second order or higher, the projection from a 3D point \mathbf{X} to a 2D image point \mathbf{x} can be described by using a 3×4 matrix \mathbf{P} :

$$\mathbf{x} = \mathbf{P}\mathbf{X} \quad (1)$$

where an image point $[x, y]^T$ is represented by homogeneous coordinates $\mathbf{x} = [x_1, x_2, x_3]^T$, which are related to the image coordinates as $[x, y, 1]^T = \lambda[x_1, x_2, x_3]^T$ with a scalar λ . Also, a 3D point is represented by homogeneous coordinates $\mathbf{X} = [X_1, X_2, X_3, X_4]^T$, which are related to the 3D point coordinates as $[X, Y, Z, 1]^T = \lambda[X_1, X_2, X_3, X_4]^T$.

\mathbf{P} is called a camera matrix and is described by a 3×3 camera intrinsic parameter matrix \mathbf{A} and extrinsic parameters, rotation \mathbf{R} and translation \mathbf{T} , as:

$$\mathbf{P} = \mathbf{A} [\mathbf{R} \; \mathbf{T}] \quad (2)$$

When all the parameters in \mathbf{P} are unknown, the camera is said to be uncalibrated, and is called an uncalibrated camera. In contrast, when all these parameters are known and the camera matrix \mathbf{P} is fixed, the camera is said to be calibrated, and is called a calibrated camera.

Also, when there are multiple cameras and their camera matrices are determined up to

a single 3D projective transformation, i.e., the ambiguity of multiple camera matrices is represented by a single projective transformation, they are said to be weakly calibrated. See the section on “► [Weak Calibration](#).”

Although we do not know any of the parameters of the cameras when they are uncalibrated, we can still use them in a variety of applications. In the following, it will be described that even such uncalibrated cameras can perform 3D reconstruction [1, 2] and viewpoint change [3].

3D Reconstruction from Uncalibrated Cameras

Suppose we have N points \mathbf{X}_i ($i = 1, \dots, N$) in the 3D space and these points are observed as N pairs of image points, $\{\mathbf{x}_i, \mathbf{x}'_i\}$ ($i = 1, \dots, N$), by a pair of cameras having different viewpoints. Then, the image observation can be described as:

$$\mathbf{x}_i = \mathbf{P}\mathbf{X}_i \quad (3)$$

$$\mathbf{x}'_i = \mathbf{P}'\mathbf{X}_i \quad (4)$$

If these cameras are uncalibrated and their intrinsic and extrinsic parameters are unknown, their camera matrices, \mathbf{P} and \mathbf{P}' , are also unknown. However, if we have enough number of corresponding points in their images, we can from the images reconstruct 3D points with some ambiguities.

Suppose we have enough number of corresponding points in a pair of images. Then, we can obtain a 3×3 fundamental matrix \mathbf{F} , which describes the geometric relationship between two cameras from these corresponding points [4–7]. This is called weak calibration. See the section on “► [Weak Calibration](#)” for the computation of the fundamental matrix.

Once the fundamental matrix \mathbf{F} is obtained, the camera matrices \mathbf{Q} and \mathbf{Q}' of these two cameras can be computed as [8]:

$$\mathbf{Q} = [\mathbf{I}, \mathbf{0}] \quad (5)$$

$$\mathbf{Q}' = [[\mathbf{e}']_{\times} \mathbf{F}, \mathbf{e}'] \quad (6)$$

where \mathbf{e}' is an epipole of the second camera and $[\mathbf{v}]_{\times}$ denotes a skew-symmetric matrix consisting of a three-vector \mathbf{v} .

The camera matrices \mathbf{Q} and \mathbf{Q}' obtained in this manner have the ambiguity of a single projective transformation with respect to the true camera matrices \mathbf{P} and \mathbf{P}' . Thus, by using the camera matrices \mathbf{Q} and \mathbf{Q}' , 3D points \mathbf{Y}_i can be reconstructed from the triangulation of two cameras whose projection equations are as follows:

$$\mathbf{x}_i = \mathbf{Q}\mathbf{Y}_i \quad (7)$$

$$\mathbf{x}'_i = \mathbf{Q}'\mathbf{Y}_i \quad (8)$$

See the section on “► [Triangulation](#)” for the 3D reconstruction. The 3D points \mathbf{Y}_i recovered from Eq. (7) and Eq. (8) have the ambiguity of a projective transformation with respect to the original 3D points \mathbf{X}_i , and this reconstruction is called a projective reconstruction [8].

3D reconstruction with uncalibrated cameras can be achieved in various ways besides the epipolar geometry-based method described above. If we have many uncalibrated views on many corresponding points, factorization is an efficient way to recover 3D geometry under affine cameras [9] and projective cameras [10, 11]. It is also possible to combine uncalibrated cameras with uncalibrated projectors [12] for 3D reconstruction.

View Transfer from Uncalibrated Cameras

We consider view transfer for generating images of different viewpoints from images observed by uncalibrated cameras at certain viewpoints.

Let us consider a set of corresponding points, \mathbf{x} , \mathbf{x}' , and \mathbf{x}'' , in images observed at three different viewpoints, C , C' and C'' . Then, these three image points have the following trilinear relationship [13]:

$$\sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 \sum_{p=1}^3 \sum_{q=1}^3 x^i x'^j x''^k \epsilon_{jpr} \epsilon_{kqs} \mathcal{T}_i^{pq} = 0_{rs} \quad (9)$$

where x^i denotes the i th component of an image point $\mathbf{x} = [x_1, x_2, x_3]^\top$ and ϵ_{jpr} denotes a rank 3 tensor, which takes 1 if the permutation from $\{j, p, r\}$ to $\{1, 2, 3\}$ is an even permutation, takes -1 if it is an odd , and takes 0 for other cases. \mathcal{T}_i^{pr} is a rank 3 tensor called trifocal tensor, which represents the geometric relationship among three viewpoints.

The trifocal tensor \mathcal{T}_i^{pr} has 27 components but only 18 DOF, since the 3 cameras are constrained by existing in a single projective space. The trifocal tensor can be computed linearly from seven sets of corresponding points and nonlinearly from six sets of corresponding point in images [14, 15]. This is called weak calibration of three cameras. See the section on “► [Weak Calibration](#)” for the computation of trifocal tensor.

Since the trifocal tensor represents the geometric relationship among three views, it enables us to transfer two views to another view. Suppose we have a trifocal tensor \mathcal{T}_i^{pr} . Then, given image points \mathbf{x} and \mathbf{x}' at two viewpoints, we can obtain nine linear equations on the image point \mathbf{x}'' at the third viewpoint from the trilinear relationship in Eq. (9). Then, the image point \mathbf{x}'' at the third viewpoint can be computed by solving the linear equations.

In this way, we can transfer views from one to another, even if the cameras are uncalibrated.

Definition

Both scattering and absorption processes are dominant effects that determine the propagation of light in water and limit the ability to see or form images. These are characterized by inherent optical properties (IOPs) of the medium, which can be related to imaging theoretical parameters such as modulation transfer function (MTF) and point spread function (PSF). Underwater vision is affected by differences in the radiance distribution, which is an apparent optical property (AOP). Specially developed sensor systems are required to extend range over which visual information can be obtained.

Background

Observation and exploration of the underwater realm has been of interest since ancient times and has forged the development of many technological advances, for example:

- Conventional imaging methods that utilize high-sensitivity, dynamic range cameras and advanced light sources
- Extended range imaging techniques that utilize time gating or angular field restriction to reduce unwanted image noise resulting from optical scatter in the transmissive medium
- Laser line scan methods using “push broom” configurations to produce 2-D or 3-D imagery
- Holographic or other techniques that exploit spatial coherency over relatively short distances for high depth-of-field particle imaging
- Optical methods using frequency conversion (fluorescence, Raman, etc.) to develop higher-dimensional image data
- Multiple-perspective methods that achieve range depth or 3-dimensional (3-D) image formation and display (including mosaics)
- Image intensity algorithms based on image processing techniques that exploit effects such as shading, filtering, or motion
- Electromagnetic (EM) methods that utilize transparent regions of the spectrum (near

infrared, ultraviolet, visible, and very low frequency (VLF))

- Acoustic imaging techniques that include 3-D reconstruction and mosaicking
- Temporally discriminant or signal-coded methods that support multidimensional image representations

Detailed descriptions of many of these preceding methods have been published elsewhere [1–3] where an emphasis is placed on extended range imaging.

Historically, advancements in underwater imaging have been slow to evolve and have taken decades to reach the present state of the art. This has been due, in part, to limitations stemming from incomplete understanding of radiative transfer in seawater, limitations in image sensor electronic and optical hardware, and computational restrictions in real-time data transfer, recording, and signal processing. Underwater vision in the optical spectrum is limited by absorption and scattering processes that are governed not only by the properties of water but also by dissolved and suspended substances. These result in limited visibility over very short distances in harbor and coastal regions. Imaging with conventional cameras beyond several optical attenuation lengths (c_z) is generally not practical due to so-called “veiling luminance” stemming from scattering centers in the medium that produce photon flux well in excess of that arriving from the scene or object plane. Therefore, the image content is not retrievable even with image stretching unless extremely high dynamic range sensors are employed. More advanced imaging systems using pulsed laser illuminators, gated detectors, narrow FOV synchronous scanners, etc. have been demonstrated, resulting in dramatic increases in the image resolution and standoff distances achievable over conventional cameras and illumination systems [1]. Hardware advances in lasers, video technology, electronic ballasting of HMI lighting, detectors, mechanical scanners, and processing algorithms have benefitted both optical and acoustic sensors systems [4]. Although these

advances are often associated with imaging hardware and methodology, credit must also be given to developments in computer vision and pattern recognition that allow extraction or interpretation of useful information from raw imagery or data. This focus has been noted in a recent publication written for the computer vision community that underscores the difficulties and challenges of underwater imaging [5].

Theory

Inherent Optical Properties (IOPs)

Basic physical processes affecting underwater light propagation are absorption [1] and both elastic [2] and inelastic [3] scattering. These processes are partially characterized in terms of the inherent optical properties [6, 7], which are dependent only on the material properties of the medium or more accurately are invariant under changes of the light field radiance distribution. The primary IOPs, absorption coefficient a , scattering coefficient b , and beam attenuation coefficient c at optical wavelength λ are related by

$$\begin{aligned} c(\lambda) &= a(\lambda) + b(\lambda) \\ a(\lambda) &= a_{\text{water}}(\lambda) + a_{\text{naph}}(\lambda) \\ &\quad + a_{\text{phy}}(\lambda) + a_{\text{CDOM}}(\lambda) \end{aligned} \quad (1)$$

The absorption coefficient may be decomposed into several additive components due to inherent absorption of water, suspended non-algal (minerogenic) particles, phytoplankton, and dissolved organic material (CDOM). The measured absorption spectrum of water from various publications is shown in Fig. 1. A transparency window is clearly observed in the blue-green spectral range.

A collimated light beam or plane wave of small cross-section A relative to c^{-1} and intensity I is therefore attenuated according to

$$I(z + \Delta z, \lambda) = I_0(z, \lambda) \exp[-c(\lambda) \Delta z] \quad (2)$$

where $c\Delta z \ll 1$. The scattering coefficient b is defined by

$$b(\lambda) = 2\pi \int_0^\pi \beta(\theta, \lambda) \sin(\theta) d\theta \quad (3)$$

where the volume scattering function is defined by

$$\beta(\theta, \lambda) \equiv |\Delta J(\theta, \lambda)| / I_0(\lambda) A \Delta z \quad (4)$$

and it is assumed that the irradiance ΔJ is scattered in direction θ . The volume scattering function β normalized to b is called the scattering phase function $p(\theta, \lambda)$. Measurements of phase functions for various ocean waters have been measured extensively [9].

Phase functions for open-ocean, coastal, and harbor waters are remarkably similar in shape, leading to the development of an average particle phase function derived by subtraction of the volume scattering function for clear water [10, 11]. Although analytic forms such as Henyey-Greenstein [12] with $g \sim 0.95$ have been used, higher accuracy forms are preferred [13, 14].

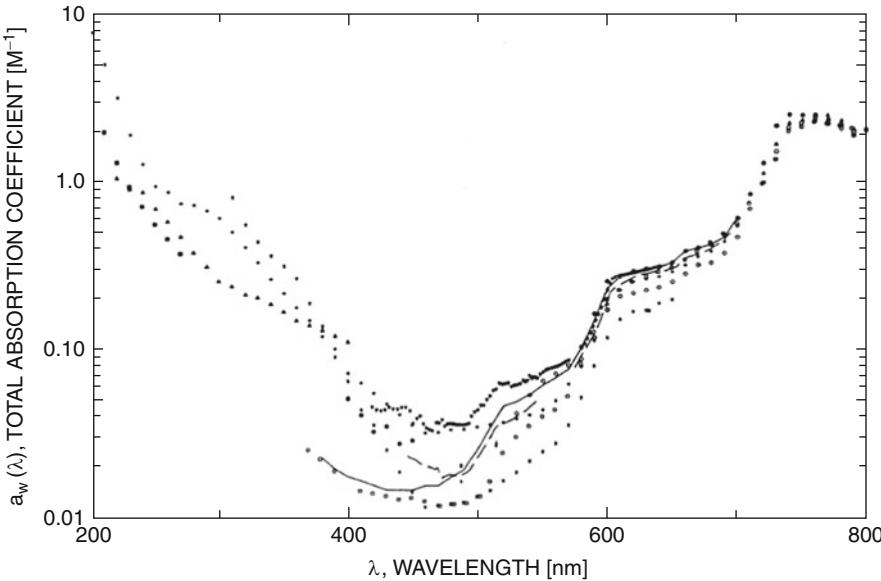

The relationship of β or p to the modulation transfer function (MTF) has been described [15], and point spread function measurements have been conducted at small angles [16–20].

The parameters a , b , and c are measured by modern optical instruments and have been synoptically characterized for many natural waters [21–23].

The MTF and PSF are related by the Hankel transform pair

$$\begin{aligned} MTF(\Psi, z, \lambda) &= 2\pi \int J_0(2\pi\theta\Psi) PSF(\theta, z, \lambda) \theta d\theta \\ PSF(\theta, z, \lambda) &= 2\pi \int J_0(2\pi\theta\Psi) MTF(\Psi, z, \lambda) \Psi d\Psi \end{aligned} \quad (5)$$

The relationship to the IOPs has been derived [24] and for a non-stratified medium is given by

Underwater Effects, Fig. 1 Measured absorption spectra of pure freshwater (various authors) [8]

$MTF(\Psi, z, \lambda)$

$$= \exp \left[- \int_0^R c(z) dz + \int_0^R b P(\Psi, \lambda) \right]$$

$$P(\Psi, \lambda) \equiv 2\pi \int J_0(2\pi\theta\Psi) p(\theta, \lambda) \theta d\theta \quad (6)$$

where $p(\theta, \lambda)$ is the single scattering phase function and no z dependence of b or c is presumed, yielding

$MTF(\Psi, R, \lambda)$

$$= \exp \left[-cR + b \int_0^R P \left(\frac{\Psi r}{R}, \lambda \right) dr \right] \quad (7)$$

Equations 5–7 link the MTF, PSF, and IOP parameters. The single scattering phase function p may be approximated analytically, and it is found that at multiple scattering lengths ($bR > 2$), the PSF is relatively insensitive to its functional form [25].

Apparent Optical Properties (AOPs)

Understanding of the radiative transfer process is paramount in designing sensors for derivation of information such as quantity, distribution,

and types of suspended materials; presence and identification of manmade objects; as well as the behavior of optical imaging and communications systems. Much of this information is obtained through the radiance distribution L , which is an apparent optical property and is described by the radiative transfer equation (RTE):

$$\left[\cos \theta \frac{d}{dz} + c(z) \right] L(z, \theta, \phi) = b(z) \int_{\Omega'} p(z; \theta; \theta', \phi') L(z, \theta', \phi') d\Omega' \quad (8)$$

Perhaps the simplest solution of the RTE is known as Gershun's law [37], and relates the absorption coefficient to the derivative of the difference of the downwelling E_d and upwelling E_u irradiance when no embedded light sources are present:

$$\frac{d}{dz} [E_d(z, \lambda) - E_u(z, \lambda)] = -a(z, \lambda) E_0(z, \lambda) \quad (9)$$

Solving the general integrodifferential equation for radiance given IOPs and boundary

conditions is difficult, but analytic solutions do exist for special cases, such as for non-scattering waters. Sophisticated numerical methods therefore must be employed to solve the RTE for realistic oceanic conditions.

This definition assumes that L is a scalar function of position z , polar angle θ , and azimuth angle ϕ and neglects polarizing properties of the medium. Inclusion of polarizing properties of the medium requires matrix formalism using a Stokes vector notation for the RTE [26]. In the presence of Raman or fluorescent inelastic scattering, wavelength dependence must also be included.

Estimation of the radiance distribution can be accomplished using a Monte Carlo approach, but the computational burden associated with most environments requires parallel processing and large memory resources for solution of practical problems. Consequently, analytical models have been advanced to predict radiance performance for different IOPs and geometric configurations [27, 35, 36] for both imaging and remote sensing applications. Recently developed time-dependent solutions of the RTE for pulsed sources [27] are practical for communications and LIDAR or other pulsed imaging systems. Pulsed imaging systems can discriminate against scattered light by gating the detector (LIDAR) or by synchronously scanning a small divergence source and narrow field-of-view detector (so-called laser line scan systems). In addition, an understanding of the impulse response of the medium and its variability is necessary in developing and optimizing any digital or analog communications system.

Remote Sensing

Inversion of the radiance distribution is the basis for remote sensing of water constituents as the IOPs are determined in part by spectral absorption characteristics of various absorbing species of phytoplankton and dissolved materials. Solid objects may also be detected. *Passive remote sensing* involves observation light emanating from the ocean surface due to solar

illumination consisting of surface-reflected light and upwelling light scattered toward the surface from particles in water column and from bottom reflection. Examples of *passive remote sensing systems* [28] are aircraft- or satellite-borne color sensors which exploit the wavelength properties of the absorption coefficient associated with various dissolved or suspended substances, such as of chlorophyll, CDOM, or mineral particles under solar illumination. The ocean also can contain light sources such as bioluminescent organisms, which may be observed at night using high-sensitivity detectors. Phytoplankton types and physiological state may be estimated as well as the bottom depth and type in very shallow waters.

Active remote sensing system using lasers, such as LIDAR, uses pulsed illumination to estimate coastal depths or discernable layers of suspended substances. Since laser light is reflected from the sea surface and subsequently from the subsurface layer, the layer depth is easily calculated if the pulse is physically much shorter than the depth to be measured. The depth is given approximately by

$$d = (c/n) \Delta t_{rt}/2 \quad (10)$$

where Δt_{rt} is the time difference between surface return and the seafloor return, c is the speed of light, and n is the index of refraction for water (approximately 1.33).

Another active remote sensing method, *laser-induced fluorosensing* uses pulsed ultraviolet or short wavelength blue laser sources to detect and estimate the concentration of layered chlorophyll containing constituents and pollutants. *Thermal sensing* vertically through the water column is also possible using comparisons of relative Raman Stokes and anti-Stokes emission spectrally adjacent to the excitation wavelength [34].

A large number of remote sensor systems have been deployed. Well known in the USA and Canada are the coastal zone color scanner launched in 1978 [29], the sea-viewing wide field-of-view sensor (SeaWiFS) launched in 1997 [30], the moderate resolution imaging

spectroradiometer (MODIS) launched 1999 and 2002 [31], and the compact airborne hyperspectral imager (CASI) [32, 33]. Geographic fidelity of remote sensor systems is typically limited by spatial resolution (meters typical for satellite and sub-meter for airborne) as well as the time required for collecting data over a large area.

Open Problems: Remote Sensing

Many remote sensing platforms exist, and great strides have been made in ocean color remote sensing. However, remote sensing problems generally require inverting the radiance distribution to obtain constituents affecting IOPs. This class of inverse problems can be based on either *explicit* or *implicit* solutions of the RTE using either active or passive illumination. Explicit solutions rely on functional dependence between the radiance distribution $L(z, \theta, \phi, \lambda)$ and the set of IOPs. Determining the absorption coefficient $a(\lambda)$ from a series of measured irradiances, as in Eq. (9), is one example of an explicit solution for an IOP given irradiance measurements. *Implicit solutions* are obtained by solving a sequence of direct or forward problems for different sets of IOPs. The set providing the best fit radiance distribution is then chosen as representing the inverse solution.

Since radiation measurements are not exact and because of overlapping spectra, time-dependent illumination during measurement, inadequate spatial, or wavelength sampling, the inversion process can be plagued with various inaccuracies. These include model sensitivity to slight changes in the radiance distribution, model uniqueness errors, radiometer calibration error, and other noise effects. Forward models may be simple based on observed radiance distributions in a geographic location, and these dependencies may not be universally unique. Inversions are usually based on an assumed model that relates known quantities to a desired output. The inversion takes place using the known quantities as inputs to the model, whose output is an estimate of the desired quantities. Due to costs and geographic scales involved in making

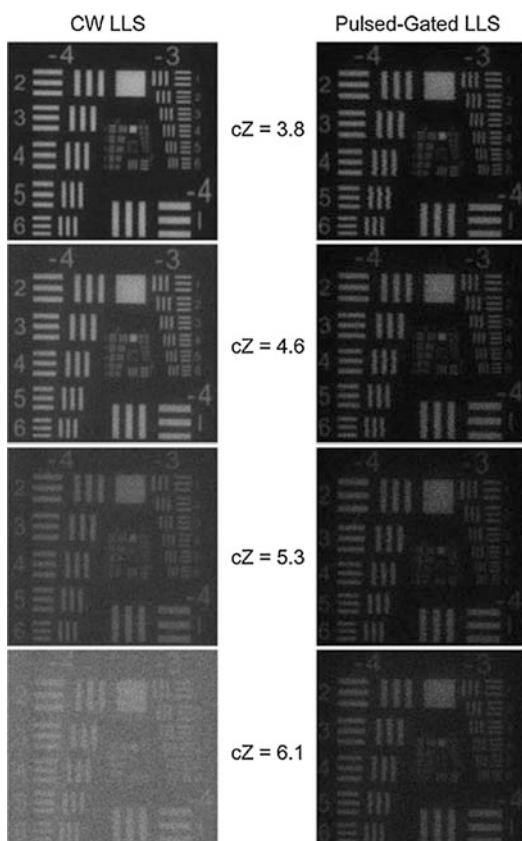

measurements to establish a model, constraints are imposed to limit the range of solutions possible from a given set of data. Constraints can be internal to the RTE or external, typically as additional required measurements (such as a measurement of the water leaving radiance or bottom depth at one point in an image). Implicit constraints may also be imposed, such as a limitation of retrieved values to the range of values found in the data set used to pre-determine certain parameters in the inverse model.

Open Problems: Polarization

New trends in underwater imaging have also involved understanding the complex behavior of polarized light fields and remote sensing of optical properties for object detection, biological monitoring, and pollution identification/tracking. The RTE as posed in Eq. (8) neglects polarization. However, scattering within the water column, refraction, reflection and transmission by the air-water surface, and reflection by submerged objects induces polarization even if the incident beam is not polarized. Objects exhibit a complex reflection distribution – the so-called bidirectional reflectance distribution or BRDF (http://en.wikipedia.org/wiki/Bidirectional_reflectance_distribution_function) rather than a single-valued parameter. Thus, accurate estimation of the underwater radiance in a particular direction will depend on polarization and BRDF from the bottom or submerged objects. Understanding the complexity of these effects on the vector radiance through the vector form of the RTE is still an open problem. Multiple scattering events, particle size distributions larger than the wavelength of light, and spatial averaging tend to negate the effects of polarization. Numerous studies have been made of individual particles of different type, shape, and refractive index with characterization of scattering and its effect on polarization. Understanding the relationship of these on the radiation distribution and the inverse problem also remains a difficult problem.

Experimental Results in Imaging

Recent experimentation in underwater imaging has been focused on obtaining images at greater optical distance (in terms of attenuation lengths cZ) with either natural [38] or artificial [39] illumination. The former uses polarization characteristics of the light field for enhancement, while the latter has relied on various methods such as pulsed illumination with restricted FOV using quasi-monostatic scanners. Continued improvements are being made in image quality as shown in Fig. 2 [40]. Image formation at over 20 receiver-to-target attenuation lengths has been demonstrated with bistatic imagers with the source-to-target distance being the

Underwater Effects, Fig. 2 Demonstrated image improvement with pulsed-gated laser line scan imager (PLLS) versus continuous-wave laser line scan systems (LLS) at multiple attenuation lengths (cZ) [40]

limiting factor due to point spread of the source illumination, and new experimental systems are being developed.

Definition

Domain adaptation refers to the class of techniques aimed to learn representations from a low-resource dataset by transferring knowledge from a related, yet shifted, resource-rich dataset. Shifts between datasets can exist in the form of changes in illumination, lighting, texture patterns, or any such biases inherent to the dataset. To transfer knowledge across domain-shifted data distributions, a domain-invariant feature representation is sought that effectively phases out biases contributing to the domain shift.

Background

Deep learning systems frequently encounter novel test distributions, a consequence of the diverse world we operate in. Unfortunately, the performance of deep learning models significantly degrades as the shift between training (also called source domain) and test (target domain) distributions increases, also called domain shift. This is illustrated in Fig. 1 – a classification model trained on source data performs well in the source distribution. However, at test time, when target distribution shifts, performance degrades. The promise of domain adaptation is to learn a domain-invariant representation to effectively transfer knowledge across domain-shifted datasets.

Depending on the availability of training data in the target domain, domain adaptation approaches can be broadly grouped into two categories: (1) unsupervised domain adaptation, where no labels exist in the target domain, and (2) semi-supervised domain adaptation, where access to few labeled target samples is assumed. In both these settings, source domain has abundant labeled training data. In the rest of

the article, we focus mainly on the unsupervised setting.

One popular approach for unsupervised domain adaptation is to enforce domain invariance in the feature space by minimizing a distance between source and target feature distributions. Using a neural network to estimate the distance, adaption is formulated as an adversarial game between a discriminator and the feature network in [1]. Measuring distance using maximum mean discrepancy and its several variants has been proposed in [2–5]. Other discriminative approaches include the use of maximum classifier discrepancy [6], virtual adversarial training [7], etc.

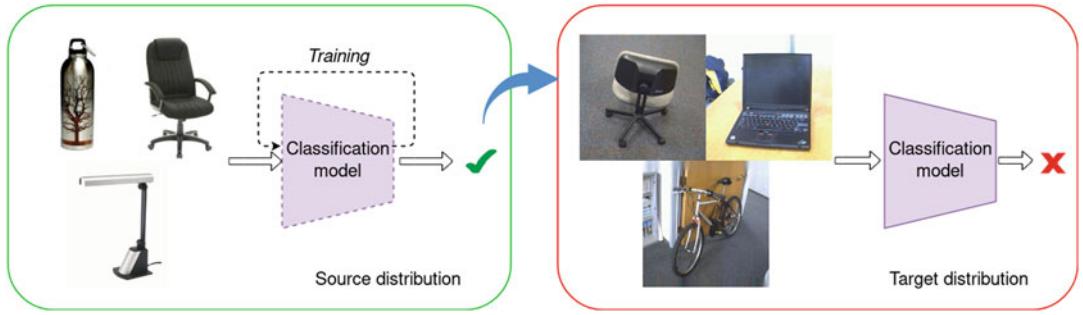

Another class of approaches that have become prominent is the use of generative models for adaptation, Generative Adversarial Networks (GANs) in particular. The last few years have witnessed tremendous success in generation abilities of GANs enabling photo-realistic synthesis of natural images [8, 9] and videos [10, 11]. The framework of GAN consists of a generator network that synthesizes samples from a distribution and a discriminator that acts as a critic on the generated samples. Training happens in a *two-player* game where the discriminator discriminates the generated distribution from the real data distribution, whereas the generator attempts to fool the discriminator.

For domain adaptation problems, a conditional GAN is often used where the generator network is conditioned either on the source data samples or on the source feature distribution. Under this framework, GAN attempts to perform cross-domain image generation to synthesize a target sample stylized as a source. The stylized target dataset is then used to train a classifier.

U

Theory

Let $D_s = \{(\mathbf{x}_i^S, y_i^S)\}$ denote the labeled source distribution and $D_t = \{(\mathbf{x}_i^T)\}$ denote the target data distribution, respectively. Here, \mathbf{x} denotes the input samples, and y refers to the label. Note that we consider unsupervised domain adaptation set-

Unsupervised Visual Domain Adaptation Using Generative Adversarial Networks, Fig. 1 Illustration of domain shift. Models trained on source distribution

ting; hence no target labels are available. We are interested in learning a transformation function $G : \mathbf{x}^S \rightarrow \mathbf{x}^T$ that transforms source samples to look like target. The transformation function needs to satisfy the following properties:

- Content preservation: Semantic content of images must be preserved under transformation i.e., the source and the transformed images should share the same semantic content.
- Style transfer: The transformed images should be stylized like samples from the target distribution.

The two properties listed above ensure that the generator networks learn to transform source images as target while preserving the semantics. Hence, a classifier trained on the transformed samples using the corresponding source labels should perform well on target domain. Next, we highlight the commonly used loss terms for realizing the above properties.

Learning the Generator Network

Content loss: A common technique for matching semantic content is to enforce source and transformed samples to produce the same task prediction. For instance, in classification tasks, if the source and transformed images produce the same prediction under a trained classifier, then both images would likely belong to the

(shown in left) generalizes poorly when tested on a domain-shifted target distribution (shown in right)

same class, thus sharing semantic content. Hence, semantic content preservation is implemented by minimizing task loss on the transformed images using source labels [12, 13]:

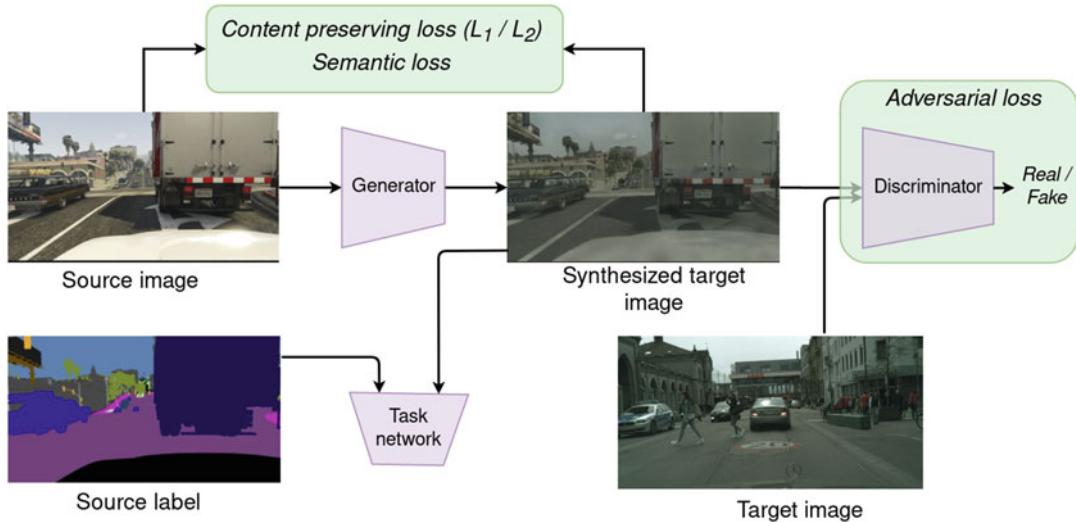

$$\min_{G,C} \mathcal{L}_{\text{cont}} := \mathcal{L}_{\text{task}}(C(G(\mathbf{x}^T)), y^S)$$

where C is the task network. While the above loss matches global semantics, it lacks pixel-wise content preservation which is crucial for tasks like semantic segmentation. To enforce this, cycle consistency loss is used in [13], where synthesized target images are transformed back to source using a second generator, and L_1 loss between the back-transformed image and the original source image is minimized, similar to [14].

Style transfer: To make the transformed samples stylized as target, an adversarial loss between the generated distribution and the real target distribution is used [12, 13, 15]:

$$\max_G \min_D L_{\text{adv}} := \mathbb{E}_{\mathbf{x}^S} \log(D(\mathbf{x}^S)) + \mathbb{E}_{\mathbf{x}^T} \log(1 - D(G(\mathbf{x}^T)))$$

Here, the discriminator discriminates real target distribution from the generated one, while the generator attempts to fool the discriminator. This adversarial game between real target distribution and the generated distribution converges when both distributions are aligned, i.e., when gener-

Unsupervised Visual Domain Adaptation Using Generative Adversarial Networks, Fig. 2 Illustration of GAN-based framework for unsupervised domain adaptation. Source images are transformed to target using a GAN model implementing an adversarial loss. To preserve

ated images look like target. As shown in Fig. 2, a well-trained GAN network successfully stylizes source samples as target.

Learning the Task Network

In the previous section, we discussed how the generative model can be used to stylize source distribution as target. The objective of domain adaptation, however, is not stylization, but rather to produce a predictive model that performs well on the target. To improve the target performance, a task network can be trained on the transformed samples using the original source labels:

$$\min_C \mathcal{L}_{\text{cont}} := \mathcal{L}_{\text{task}}(C(G(\mathbf{x}^T)), y^S)$$

Learning the task network using the above loss function utilizes GANs as a data augmentation step. Alternatively, the feature network can be updated so that target features are stylized as source as seen by a GAN [15, 16]. In this case, GANs are used for guiding domain alignment in the feature distribution. Once the features are aligned, a task network trained on source images are used for making predictions at test time.

the content of transformed images, content preserving loss and semantic losses are used. A final task network is trained on the transformed target images using the corresponding source labels

Application

The use of GANs for domain adaptation is a successful paradigm that has been used in several applications, some of which are listed below:

- Learning with limited supervision: Data collection and annotation is an expensive process, and annotating every possible variation of input data is practically infeasible. Domain adaptation comes to rescue, enabling knowledge transfer from a resource-rich domain to a poor-resource domain, thereby circumventing the need for annotating data. Strong domain transfer performance in unsupervised setting on several computer vision tasks such as object recognition [12, 15], semantic segmentation [13, 16], and object detection [17] tested under several dataset variations including changes in weather patterns [17], background [15], texture patterns [13], etc. is a testament to the success of domain adaptation.
- Learning from synthetic data: One promising solution for minimizing data annotation that has become increasingly popular recently is the utility of synthetic data for training neu-

ral nets. With the design of a realistic simulator, obtaining annotated data comes free of cost. However, domain shift between synthetic data and real data distribution results in large performance gap, motivating the need for domain adaptation. Some recent successes of this application include the use in gaze estimation [18], robotic grasping [19], semantic segmentation [16], etc.

- Medical imaging: Medical imaging is one domain where collecting data can be prohibitively expensive or in some cases impossible due to privacy constraints. The use of synthetic data and domain transfer has been utilized for problems such as depth estimation from endoscopy [20] and X-ray image segmentation [21].

Open Problems

Adaptation on other vision tasks: Over the recent years, several domain adaptation approaches have been developed for classification tasks. There is a growing interest for extending these approaches for other vision tasks including object detection, segmentation, single-view 3D reconstruction, etc.

Continual domain adaptation: Current domain adaptation approaches, including the ones discussed in this article, focus on the static setting where the source and target datasets are available beforehand. In many real-world applications, however, prior knowledge of target distribution might be unknown. Additionally, the target distributions might itself change over time. For instance, a robot trained in the United States might be deployed in unknown environments from other countries. Or the perception system of a self-driving car might witness changes in lighting conditions and weather patterns, which vary continually with time. Current adaptation algorithms cannot be used this setup as prior information about target domain is unknown. Models should rather estimate the target domain

statistics and update on the fly. Hence, to develop practical adaptation algorithms, it is very important to address distributional shifts in nonstationary continual setting.

Reinforcement learning applications Reinforcement learning (RL) applications present a natural test bed for nonstationary distributional shifts. RL algorithms are typically trained on simulated environments since either they are either sample-inefficient [22], or it is sometimes fatal to make mistakes in real environments (e.g., self-driving cars). Deploying models trained from synthetic environments to real environments might result in poor performance due to domain shift. Domain adaptation is one approach for handling such distribution mismatch. Despite the success of domain adaptation techniques for supervised tasks, they are rarely used in reinforcement learning problems. An exciting open research problem is to study the effectiveness of adaptation algorithms in RL problems involving domain shift in both stationary and nonstationary environments.

Definition

In mathematics, the term *variational analysis* usually denotes the combination and extension of

methods from *convex optimization* and the classical *calculus of variations* to a more general theory [5]. However, in computer vision literature, the term is frequently encountered as just a synonym for *calculus of variations*. This branch of mathematics deals with the minimization of functionals, which are real-valued functions on infinite-dimensional spaces, most frequently spaces of functions.

Background

In the continuous world view, images are modeled as functions on a domain $\Omega \subset \mathbb{R}^n$. Geometric entities like curves and surfaces are manifolds, which can be described as level sets of functions or by the characteristic functions of their interior region. Consequently, computer vision problems can often successfully be formulated as minimization problems on infinite-dimensional spaces, where the solution is given as the minimizer of an *energy functional* $\mathcal{V} \rightarrow \mathbb{R}$ on the space \mathcal{V} of admissible functions. The minimization of such a functional thus requires a calculus on infinite-dimensional spaces, which is provided by the classical branch of mathematics called *calculus of variations* [3, 4]. It provides necessary conditions which have to be satisfied by the minimizing function, probably most well known is the *Euler-Lagrange equation*, a partial differential equation for the unknown. However,

the methods of the calculus of variations usually provide only conditions for local minima, while it is of course desirable to formulate models where one has some guarantees about the optimality of the solution.

Recently, there has therefore been much effort to formulate computer vision in a way that the final minimization problem is a *convex functional*. The main advantage is that there are no local minima in the sense that each local minimizer is automatically a global optimum. Furthermore, for optimization, it is possible to enhance the techniques from the calculus of variations with methods from *convex optimization*, thus obtaining very efficient minimization algorithms [1, 4, 5].

The formulation of variational models as convex problems requires convex regularizers. A particularly powerful regularizer was found to be the *total variation* of a function [2]. Besides convexity, it has certain interesting geometric properties which make it possible to obtain convex formulation of segmentation and minimal surface problems. See the entry on ► “[Total Variation](#)” for more details.

Theory

Definition

The variational method is a way to solve problems given in the form of a *variational model*, i.e., as an energy minimization problem on an infinite-dimensional space which is typically a function space. It employs tools from the mathematical framework of *variational analysis*.

Background

Ikeuchi and Horn’s shape-from-shading paper and Horn and Schunck’s optical flow paper, which appeared in AIJ simultaneously, are the earliest representative works to introduce a variational method to computer vision [8]. Inspired by the extraordinary success of the idea, variational methods have been extensively studied in computer vision and become a very popular tool for a wide variety of problems. They are particularly successful in mathematical image processing, where they are used to describe fundamental low-level problems, like image segmentation [9, 11], denoising [15], and deblurring [3], but have also been employed for high-level tasks like 3D reconstruction [4, 10].

In a variational model, the solution to a problem is obtained as the minimizer of an energy defined on a typically infinite-dimensional space, for example, a function space. The underlying world view is a continuous one similar to classical physics, where images are regarded as functions on \mathbb{R}^n , while curves and surfaces,

encountered, for instance, in image segmentation and 3D reconstruction, are regarded as manifolds.

In view of this, it is not surprising that the mathematical framework of *variational analysis* used to deal with these problems was developed in close conjunction with new insights in physics in the early twentieth century [5]. It is a calculus for functionals on infinite-dimensional spaces, which together with tools from differential geometry and measure theory yields the Euler-Lagrange equations of such a functional as a necessary condition for a minimum. Commonly, solutions to the Euler-Lagrange equations are obtained either by directly solving a discretization or via a gradient descent technique.

Usually, only a local minimum is obtained this way. Recently, however, much effort has been devoted to formulate variational problems with convex energies, either directly or using relaxation techniques. In the case of a convex energy, the solution to the Euler-Lagrange equation yields a global optimum. Furthermore, the methods from variational analysis can be enhanced with methods from convex analysis and convex optimization, yielding powerful and efficient optimization methods.

Theory

There are two classical types of variational problems, which require a slightly different mathematical apparatus. The first class is concerned with the minimizer of a functional which is defined on a (usually infinite-dimensional) vector space \mathcal{V} , for example, a function space. It typically arises when the goal is to recover images, as in the problems of image denoising and deblurring.

The second type is more complex and deals with weighted minimal surfaces, i.e., minimizers of a class of functionals defined for surfaces. This type of problem arises when one tries to recover manifolds, like curves in image segmentation or surfaces in 3D reconstruction. It can be related to the first case by introducing a variation of a surface and employing methods from differential geometry.

Functionals on vector spaces The foundation for the variational method for functionals on vector spaces is the *variational principle*, which states that a minimum of a functional is a *stationary point* [2, 5]. Let $E : \mathcal{V} \rightarrow \mathbb{R}$ be a functional on the Banach space \mathcal{V} and then a point $u \in \mathcal{V}$ is called stationary if the *Gâteaux derivatives* $\delta E(u; h)$ in all directions h vanish, i.e.,

$$0 = \delta E(u; h) := \lim_{\alpha \rightarrow 0} \frac{1}{\alpha} (E(u + \alpha h) - E(u)). \quad (1)$$

Typically, the functional E is given as an integral over a domain Ω . In order to apply the variational principle in this case, one writes the Gâteaux differential in the form

$$\delta E(u; h) = \int_{\Omega} \phi_u \cdot h \, dx, \quad (2)$$

where ϕ_u is a function on Ω which depends on u .

The *du Bois-Reymond Lemma* then implies that if $\delta E(u; h) = 0$ for all h , then in fact $\phi_u = 0$ on Ω . This is a partial differential equation for the unknown u and a necessary condition which has to be satisfied by a minimizer. It is called the *Euler-Lagrange equation* of the functional E .

A frequent form for the energy E is the formulation

$$E(u) = \int_{\Omega} \mathcal{L}(u(x), \nabla u(x), x) \, dx, \quad (3)$$

with a *Lagrangian* function \mathcal{L} . In this case, an explicit formula for the Euler-Lagrange equation can be derived using the chain rule and theorem of Gauss for integration by parts. It reads

$$\frac{\partial \mathcal{L}}{\partial u} - \operatorname{div} \left(\frac{\partial \mathcal{L}}{\partial (\nabla u)} \right) = 0, \quad (4)$$

with either Neumann boundary conditions on u or Dirichlet boundary conditions on possible directions h .

Minimal surfaces. A minimal surface $\Sigma \subset \mathbb{R}^n$ is a local minimizer of the surface area integral

$$\mathcal{A}(\sum) := \int_{\Sigma} \Phi dA, \quad (5)$$

with a real-valued weight function $\Phi \geq 0$ and dA denoting the surface area element. The dimension of the surface is one less than the embedding space. Problems of this form can be handled by introducing a *variation of the surface* as a differentiable map

$$X : \sum \times (-\epsilon, \epsilon) \rightarrow \mathbb{R}^n, \quad (6)$$

where $X(\Sigma, 0) = \Sigma$ and a one-parameter family $\Sigma_\tau = X(\Sigma, \tau)$ of regular surfaces is given depending on $\tau \in \mathbb{R}$. The variational principle then implies that a minimal surface satisfies

$$\frac{d}{d\tau} \Big|_{\tau=0} \mathcal{A}(\sum_\tau) = 0 \quad (7)$$

for all possible variations. In [6], the Euler-Lagrange equation was derived in arbitrary dimension using methods from Cartan geometry [16], for the general case that Φ depends on the location s on the surface and the local normal \mathbf{n} . For a more elementary deduction for two-dimensional surfaces, see, for example, [4, 14], where [14] also deals with other classes of minimal surfaces which minimize weighted mean or Gaussian curvature.

The main result of [6] is that a minimal surface necessarily satisfies

$$(\Phi_s, \mathbf{n}) - \text{Tr}(\mathbf{S}) \Phi + \text{div}_{\sum}(\Phi \mathbf{n}) = 0, \quad (8)$$

where $\text{Tr}(\mathbf{S})$ is the trace of the shape operator of the surface, also known as the Weingarten map or second fundamental tensor. Using either explicit surface evolution methods or the *level set method* [13], a local minimum can be obtained via gradient descent as a stationary solution of a corresponding evolution equation.

In a more modern framework, the weighted surface area is replaced with the *weighted total variation* [1, 2] of the characteristic function of the surface interior. Optimization then takes place over the set of binary functions of bounded variation, which means that the difficult minimal

surface problem has been reduced to the more simple first case discussed above. Using convex relaxation techniques, this allows to solve certain classes of weighted minimal surface problems, which, for instance, arise in segmentation [12] and 3D reconstruction [10], in a globally optimal manner. The entry on ► “Total Variation” provides more details on this topic.

looking at a nearby object or fixates on a nearby object, the eyes must rotate toward each other. This is referred to as *convergence*. Similarly, when the eyes look at an object farther away, they rotate away from each other which is referred to as *divergence*.

Definition

The term *vergence* in the context of biological vision refers to a type of eye movement seen in creatures which possess binocular vision. Vergence is the simultaneous movement of both eyes in opposite directions that is required to maintain single binocular vision. When the eyes are

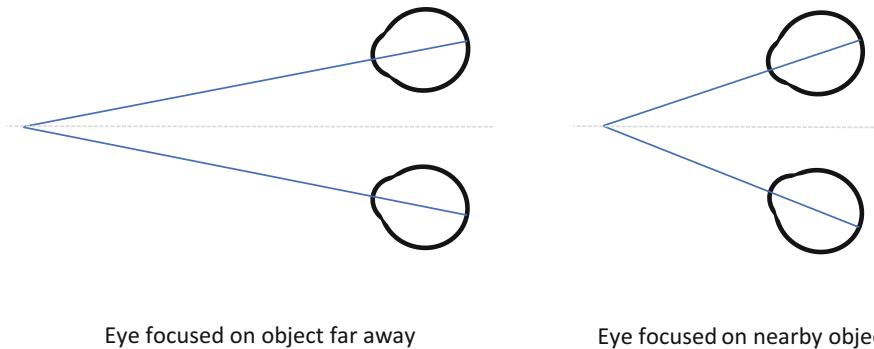

Other Properties

Vergence causes the direction or viewing angle of the two eyes to change such that the image projects to the center of the retina in both eyes. As can be seen in Fig. 1, the angle of convergence is larger when the eye is fixated on nearby objects. In humans, this convergence is caused by the contraction of the medial rectus muscles which pulls the eye toward the nose where the contraction of the lateral rectus muscles pulls the eye away from the nose. The kinesthetic sensations of the contracting and relaxing of these muscles are sensed by the visual cortex where it provides an additional binocular cue for depth perception.

Dysfunction in eye vergence can cause a subject to suffer from symptoms such as double vision, blurry vision, or other forms of visual discomfort. The ocular and neurological conditions resulting from dysfunction are discussed in more depth by Busettini et al. [1] and Ciuffreda [2]. When focusing on objects at different distances, the induced vergence change happens quite slowly (takes about a second for human eyes) unlike saccade movements which are very quick.

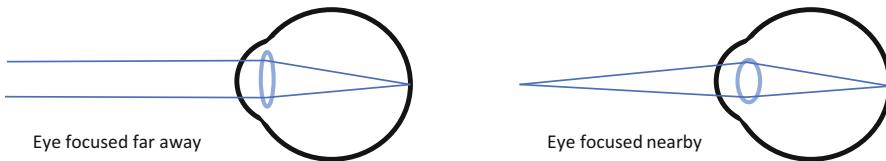

Accommodation

The term *accommodation* refers to the ability of the eye to change the optical power of the lens to enable the eye to focus on objects at different distances. When the eye focuses on a nearer object, the curvature of lens and its refractive (focusing) power increases due to the action of ciliary muscles. The kinesthetic sensations of the contracting and relaxing of these muscles are sent to the visual cortex where it provides a monocular depth perception cue.

Vergence, Fig. 1 Vergence: When the two eyes are fixated on a far away object, the vergence angle is smaller as shown on the left. However, when the object being fixated

on is nearby, the eyes rotate toward each other producing a larger angle

Vergence, Fig. 2 Accommodation: When the eye changes focus from a far away object to another object which is relatively closer, the lens undergoes deformation

which increases its curvature, and this allows the eye to focus on the nearby object

Thus, accommodation is the oculomotor response to object distance and is analogous to the focusing that occurs in a camera, and the phenomenon is essential to see the object clearly. This is illustrated in Fig. 2. Both accommodation and vergence occur simultaneously in many creatures possessing binocular vision and provide complementary depth perception cues. More details on depth perception in the human visual system are discussed by Howard et al. [3].

designed to be at a fixed distance from the user's eyes. In VR head-mounted displays (HMDs), the screen may be quite close to the eye but using special optics gives the user the sensation that the screen is a few feet away. Nevertheless the distance of this virtual screen is fixed. Due to this the eye remains focused on the screen or at a fixed distance all the time. However, the virtual objects in the scene appear at different distances at various times. Thus, the induced vergence frequently changes, and depending on the virtual object location, the vergence may be inconsistent with the induced accommodation which is always fixed. This is referred to as the vergence-accommodation conflict (VAC). It causes visual discomfort when using HMDs [5, 6]. Addressing the VAC issue and reducing eye fatigue in VR is currently an active research area [4].

Vergence and Accommodation in the Context of 3D Displays

Normally, when the eyes change focus to fixate on an object at a different distance, this is accompanied by simultaneous changes in both vergence and accommodation in both eyes. This is called the accommodation-convergence reflex. Thus accommodation and vergence are in sync. However this is not true in 3D displays and specifically in virtual reality (VR) displays. In most VR headsets, the display or screen is

Vergence and 3D Eye Rotations

The study of how the eye rotates in 3D has been a topic of intense investigation for centuries among

physiologists and useful for eye tracking and 3D gaze estimation. When eyes undergo 3D rotations and its axes of rotation, their behavior is said to satisfy Listing's law. This law states that for a fixed head position and a specific orientation of the eye referred to as the initial position, the eye can only rotate to a specific set of orientations that can be reached by a 3D rotation about an axis that lies in a plane orthogonal to the line of sight with the eye in the initial position. This plane is called Listing's plane. However, Listing's law is only true when the eye is looking at distant objects, i.e., focused at infinity. In that position, the eye has zero vergence. When the eyes converge on a near object, the eyes undergo torsion which is a rotation about each eye's line of sight. Under these circumstances, the eye movement can be explained using the binocular extension of Listing's law or L2. For a fixed vergence angle, the second law states that there is one and only one torsion angle that the eyes adopt for a specific gaze direction. When the gaze direction or vergence changes, the torsion must also change. Readers can find more details on the topic in [7].

Video Anomaly Detection for Smart Surveillance

Sijie Zhu¹, Chen Chen¹, and Waqas Sultani²

¹University of North Carolina at Charlotte, Charlotte, NC, USA

²Information Technology University, Lahore, Pakistan

Definition

Anomalies in videos are broadly defined as events or activities that are unusual and signify irregular behavior. The goal of anomaly detection is to temporally or spatially localize the anomaly events in video sequences. Temporal localization (i.e., indicating the start and end frames of the anomaly event in a video) is referred to as frame-level detection. Spatial localization, which is more challenging, means to identify the pixels within each anomaly frame that correspond to the anomaly event. This setting is usually referred to as pixel-level detection.

Background

In modern intelligent video surveillance systems, automatic anomaly detection through computer vision analytics plays a pivotal role which not only significantly increases monitoring efficiency but also reduces the burden on live monitoring. Video anomaly detection has been studied for a long time, while this problem is far from being solved (as witnessed by the low accuracy on UCF-Crime [1] dataset) due to the difficulty of modeling anomaly events and the scarcity of anomaly data. Identifying anomaly

events requires understanding of complex visual patterns, and some patterns can only be detected when long-term temporal relationship and causal reasoning are learned in the model, e.g., arson, burglary, shoplifting, etc.

Early works mainly follow the setting of general anomaly detection which may be better referred to as novelty detection, where all novel events are considered as anomaly [2]. This problem is typically formulated as unsupervised learning, where the models are trained with only normal video frames and validated with both normal and anomaly frames. A popular idea is to find a set of basis to represent normal frames and identify frames with high reconstruction loss or error as anomaly for inference, e.g., sparse coding [3, 4] and autoencoder [5]. However, due to the limitation of data and computation, these approaches [2–4, 6, 7] are conducted on small-scale datasets with relatively simple scenarios, which are not satisfactory for real-world surveillance applications.

While it is theoretically pleasing to consider all the novel events as anomaly, this setting has drawbacks for practical surveillance applications. Taking the campus scenario [2, 8] as an example, riding a bike is novel (i.e., considered as an anomaly) since the model only sees people walking [2]. However, it should not be considered as an anomaly in general for security purpose. As some anomaly activities in real world applications may have clear definitions, e.g., different criminal events which follow specific patterns, recent works [1, 9] start to leverage supervision for real-world anomaly detection. UCF-Crime [1] is currently the largest anomaly detection dataset with realistic anomalies, which contains thousands of anomaly and normal videos. The training set contains both anomaly and normal videos with video-level annotation as a weak supervision, and the frame-level annotation is provided for validation set. The detection performance has been significantly improved with weakly supervised methods [1, 9].

There is also a line of research focuses on specific anomaly detection tasks where only one type of anomaly is considered, e.g., traffic

accident on highway. Since the camera poses, foreground patterns, and backgrounds are highly similar and stable, the geometric prior knowledge and physics principles can be employed for manually designed detection pipelines. Several representative works [10, 11] rely on object detection to identify anomaly events.

Representative Approaches

Based on the experimental setting on the training data, video anomaly detection methods can be generally classified into three categories, i.e., unsupervised, weakly supervised, and supervised. We provide a brief overview of recent approaches for each category.

Unsupervised Methods

Since real-world anomaly events happen with low probability, it is hard to capture all types of anomaly. However, normal videos are easy to access from social media and public surveillance, unsupervised methods are thus motivated to detect anomaly events with *only normal videos in the training set*. Although the unsupervised methods are not able to achieve satisfactory performance on complex real-world scenarios, they are believed to have better generalization ability on unseen anomaly patterns.

Classic Machine Learning Early unsupervised methods mainly adopt classic machine learning techniques with hand-crafted features as well as probability models. Kim et al. [6] propose to first extract optical flow features and find typical patterns with a mixture of probabilistic PCA (Principal Component Analysis). A space-time MRF (Markov Random Field) is then constructed to model the relationship between spatio-temporal local regions of a video for Bayesian inference. Inspired by studies of crowd behavior like social force model, Mehran et al. [12] estimate the interaction forces in crowd to better model the normal crowd behavior. Then normal and anomaly frames are classified with BoW (Bag of Words) and LDA (Latent Dirichlet

Allocation). Li et al. [2] introduce a mixture of DT-based (Dynamic Textures) model for temporal normalcy. And a discriminant saliency detection is utilized for measurement of spatial normalcy. Ullah et al. [7] first extract the corner features and refine them with interaction flow. A random forest is then trained to classify normal and anomaly frames. Cong et al. introduce sparse coding for anomaly detection, and Lu et al. [4] further propose an efficient sparse combination learning framework to achieve a speed of 150 frames per second (fps).

Deep Learning Thanks to deep learning techniques, recent works are able to take advantage of large-scale dataset and powerful computation resource. Following the setting of unsupervised anomaly detection, a number of works [5, 13–15] are proposed based on deep AE (autoencoder). Hasan et al. [5] propose to learn both motion feature and discriminative regular patterns with a FCN (Fully Convolutional Network) based AE. The regularity score is computed based on the reconstruction error of AE model. To better model the temporal relationship within a video, [13] combines FCN and LSTM (long short term memory) as a ConvLSTM-AE, which further improve the performance of AE framework. [14] explores the combination of sparse coding and RNN (Recurrent Neural Network). A temporally coherent sparse coding framework is proposed to introduce temporal information of video in the background of sparse coding. [15] proposes a memory-augmented AE to memorize prototypical normal patterns for anomaly detection. An attention-based sparse addressing is then designed to access the memory and reconstruct future frames. For all mentioned AE-based methods, the anomaly events are determined based on the reconstruction error. On the other hand, [16] proposes to formulate the problem as a multi-class classification by applying k-means clustering and one-versus-all SVM (Support Vector Machine).

Instead of directly computing the reconstruction error of future frames with a set of basis or AE, another popular direction is to predict

the future frames based on the past frames, and assign high anomaly score when the real future frame is highly different from the predicted one. To achieve future prediction, the idea of GANs (Generative Adversarial Networks) [25] is introduced, where a generator and a discriminator are trained alternatively to achieve opposite goals. The generator is trying to produce frames that are similar to real frames, while the discriminator is trained to distinguish the generated fake frames from the real frames. With abundant training data and proper training techniques, the generator would be able to produce highly realistic fake frames which are indistinguishable from the real ones for the discriminator. Recent works [8, 17] usually employ a FCN based framework as the generator to predict future frames. Liu et al. [8] propose to add constraint on intensity, gradient and motion for future frame generation. The intensity constraint provides the consistency between generated frames and real ones on RGB space, and the gradient constraint can sharpen the generated images. The motion constraint aims to generate predicted frames with similar motions to the real ones by minimizing their optical flow difference. Ye et al. [17] further introduce a predictive coding module and an error refinement module based on the GAN-based framework.

Weakly Supervised Methods

With the increasing video data on social media platforms such as YouTube, (<https://www.youtube.com/>) it is possible to access and annotate a large amount of anomaly videos [1]. For certain application scenarios where the anomaly activities are well defined, the performance can be significantly improved by introducing supervision information. Recent works [1, 9] follow the weakly supervised setting where only video-level annotation is available for training. That is the training videos are labeled with normal or anomalous; however, the temporal location of the anomaly event in each anomaly video is unknown (i.e., weak supervision).

Sultani et al. [1] and He et al. [18] formulate the weakly supervised problem as MIL (multiple instance learning). Every frame of a

normal video should be normal, and there is at least one anomaly frame in an anomalous video. [18] proposes a graph-based MIL framework with anchor dictionary learning, and all experiments are conducted on UCSD [2] dataset with a weakly supervised setting. [1] proposes a deep learning based method along with a large-scale dataset with realistic crime-related anomalies and surveillance videos, namely, UCF-Crime [1]. A C3D framework is used to extract spatio-temporal features and generate anomaly score. To distinguish normal and anomaly frames with this weak supervision, the loss function forces the highest score of a negative video to be higher than the highest score of a normal video. With the parameters of C3D model frozen, [1] outperforms previous works by a large margin on the UCF-Crime dataset.

Instead of improving the MIL technique, Zhong et al. [9] consider the weakly supervised learning as a noisy label learning problem, where the annotation of some frames in anomaly videos are wrong. They train a GCN (Graph Convolutional Network)-based cleaner to refine the noisy labels so that the classification network can be trained end-to-end with frame-level labels.

Supervised Methods

For certain scenarios where the backgrounds and objects are well defined, e.g., the roads and cars for highway traffic accidents detection, recent works [11, 19] are usually based on the frame-level annotated training videos (i.e., the temporal

annotations of the anomalies in the training videos are available – supervised setting). A popular solution is to leverage the geometric prior knowledge and object detection with additional supervision from other public datasets.

Shah et al. [10] first applies Faster-RCNN to detect vehicles, and then an attention-based LSTM module is applied to learn the accident score. For recent works [11, 19] on AI city challenge, (<https://www.aicitychallenge.org/>) the frame-level annotation of accident is given on training set. Apart from applying object detection, [11] models the background and space using semantic segmentation, and the geometric prior is leveraged by perspective detection. The vehicle dynamics are then represented by a spatial-temporal matrix. The anomaly events are identified based on the IOU (Intersection Over Union) of different objects while applying the NMS (Non-Maximum Suppression) procedure. [19] utilizes YOLOv3 (You Only Look Once) as the object detector and specifically improves the framework for small object scenarios. Then a multi-object tracking is introduced to generate the trajectories of anomaly vehicles. The accident starting time is estimated based on a curve fitting algorithm.

Datasets

In this section, we briefly review the popular datasets for video anomaly detection. An

Video Anomaly Detection for Smart Surveillance, Table 1 An overview of datasets for video anomaly detection

| Dataset | # of videos | Average frames | Example anomalies |
|----------------------|-------------|----------------|-------------------------------------|
| UCSD Ped1 [2] | 70 | 201 | Bikers, small carts |
| UCSD Ped2 [2] | 28 | 163 | Bikers, small carts |
| Subway Entrance [20] | 1 | 121,749 | Wrong direction, no payment |
| Subway Exit [20] | 1 | 64,901 | Wrong direction, no payment |
| Avenue [4] | 37 | 839 | Run, throw, new object |
| UMN [21] | 5 | 1,290 | Run |
| DAD [22] | 1,730 | 100 | Traffic accidents |
| CADP [10] | 1,416 | 366 | Traffic accidents |
| Iowa DOT [23] | 200 | 27,000 | Traffic accidents |
| ShanghaiTech [8] | 437 | 726 | Bikers, cars |
| UCF Crime [1] | 1,900 | 7,247 | Arson, accident, burglary, fighting |
| Street Scene [24] | 81 | 2509 | Jaywalking, car illegally parked |

overview of all listed datasets is provided in Table 1.

UCSD The UCSD dataset contains two subsets, denoted as Ped1 and Ped2. They are captured with different camera poses at two spots in UCSD campus where most pedestrians walk. The training set (34 clips for Ped1 and 16 clips for Ped2) only contains normal frames, and the test set (36 clips for Ped1 and 12 clips for Ped2) consists of both normal and anomaly frames. Frame-level annotation is provided for all test clips, and ten of them have pixel-level ground-truth. UCSD dataset considers pedestrians walking as the normal pattern, so non-pedestrian entities like bikers and skaters are defined as anomaly instances. Dataset link: <http://www.svcl.ucsd.edu/projects/anomaly/dataset.html>

Subway Subway [20] dataset contains two subsets, i.e., Subway Entrance and Subway Exit. They contain only one long surveillance video each in subway station. They are first proposed specifically for real-time detection of unusual events detection in crowded subway scenes, e.g., moving in the wrong direction, or no payment. Dataset link: <http://vision.eecs.yorku.ca/research/anomalous-behaviour-data/>

Avenue The Avenue [4] dataset contains 15 videos, and each video is about 2 min long. The total frame number is 35,240. 8,478 frames from 4 videos are used as training set. Typical unusual events include running and throwing objects. Dataset link: <http://www.cse.cuhk.edu.hk/leojia/projects/detectabnormal/dataset.html>

UMN The UMN [21] (University of Minnesota) dataset consists of five videos captured from different angles. The normal pattern is defined as walking and the main anomaly activity is running. Dataset link: <http://mha.cs.umn.edu/>

DAD DAD [22] (Dashcam Accident Dataset) is proposed specifically for accident detection. The normal pattern is vehicles moving around, and anomaly events include different traffic accidents, e.g., car hits car, or motorbike hits motorbike.

DAD dataset consists of 678 videos from 6 cities. 58 videos are used for training. For the rest 620 videos, 620 clips with accidents are sampled as positive clips, and 1130 normal clips are sampled as negative clips. They are then randomly split into two subsets, i.e., 455 positive and 829 negative clips for training and 165 positive and 301 negative clips for testing. Dataset link: <https://aliensunmin.github.io/project/dashcam/>

CADP CADP [10] (Car Accident Detection and Prediction) focuses on car accident on CCTV (Closed-Circuit Television) cameras. All the 1416 videos of CADP contain traffic accidents, and 205 of them have temporal as well as spatial annotations. CADP contains videos captured under various camera types, qualities, weather conditions, and the anomaly events are realistic for real-world applications. Dataset link: https://ankitshah009.github.io/accident_forecast_in_traffic_camera

Iowa DOT Traffic Iowa DOT (Department of Transportation) Traffic dataset [23] consists of 200 videos, each approximately 15 min in length, recorded at 30 fps and 800×410 resolution. Training and testing set each contains 100 videos. As the official dataset for the 2018 AI City challenge [23] Track 3, it does not provide annotation for the testing set. Main anomaly patterns are car crashes and stalled vehicles. Dataset link: <https://www.aicitychallenge.org/2018-ai-city-challenge/>

ShanghaiTech ShanghaiTech [8] dataset is collected in ShanghaiTech University under 13 scenes with complex light conditions and camera viewpoints. It consists of 437 videos with 726 average frames each. The training set consists of 330 normal videos and testing set contains 107 videos with 130 anomalies. Anomaly events include unusual patterns in campus such as bikers or cars. Dataset link: https://svip-lab.github.io/dataset/campus_dataset.html

UCF Crime UCF Crime [1] consists of 1900 untrimmed videos covering 13 real-world anomaly events, including Abuse, Arrest, Arson,

Video Anomaly Detection for Smart Surveillance, Table 2

Assault, Road Accident, Burglary, Explosion, Fighting, Robbery, Shooting, Stealing, Shoplifting, and Vandalism. 950 of them are normal videos and the rest videos contain at least one anomaly event for each. The training set contains 800 normal and 810 anomalous videos. The remaining 150 normal and 140 anomalous videos are temporally annotated for validation. Both training and testing sets cover all the 13 anomaly events. Some of the videos may contain multiple anomaly categories, e.g., robbery along with fighting, burglary with vandalism, and arrest with shooting. All the videos are realistic for real-world surveillance applications. Furthermore, UCF Crime covers different light conditions, image resolutions, and camera poses in complex scenarios, thus is very challenging. Dataset link: <https://www.crcv.ucf.edu/projects/real-world/>

Street Scene Street Scene [24] dataset is focused on single scene anomaly detection. It consists of 46 training videos and 35 testing videos taken from a static USB camera looking down on a scene of a two-lane street with bike lanes and pedestrian sidewalks. There are a total of 203,257 color video frames (56,847 for training and 146,410 for testing) with 1280×720 resolution. The frames were extracted from the original videos at 15 frames per second. 17 types of anomaly events/activities are presented in the dataset such as jaywalking, loitering, car illegally parked, etc. Dataset link: <https://www.merl.com/demos/video-anomaly-detection>

Benchmarks

In this section, we introduce popular evaluation metrics and show existing results on five popular benchmark datasets, i.e. UCSD Ped2 [2], Avenue [4], UMN [21], Shanghai Tech [8], UCF [1], and Iowa DOT Traffic [23].

The frame-level evaluation criterion uses the frame-level ground truth annotations to determine which detected frames are true positives (i.e., true anomaly frames) and which are false positives, yielding frame-level true-positive and false-positive rates. In pixel-level evaluation, it requires the algorithm to take into account the spatial locations of anomaly objects in frames. A detection is considered to be correct if it covers at least 40% of anomaly pixels in the ground-truth [2]. The pixel-level evaluation can be conducted only if the pixel-level annotations are available for the testing videos.

As shown in Tables 2 and 3, the frame-level AUC (Area Under the Curve) of ROC (Receiver Operating Characteristic) curve is widely used as the evaluation metric for temporal localization of anomaly events. Since the anomaly detection can be considered as a binary classification for each frame, the ROC curve is generated by applying different thresholds for the anomaly score of each frame and calculating the TPR (True-Positive Rate) and FPR (False-Positive Rate).

For traffic accident detection with supervised setting, the F1 score, RMSE (Root Mean Square Error) of anomaly start time, and S3 score are

| Method | F1 score | RMSE | S3 score |
|--------------------|----------|--------|----------|
| UWIPPL [19] | 0.9577 | 6.7461 | 0.9362 |
| Traffic Brain [11] | 0.9706 | 5.3058 | 0.9534 |

used as evaluation metrics. The F1 score is defined as:

$$F1 = \frac{2TP}{2TP + FP + FN}, \quad (1)$$

where TP, FP, and FN denote true-positive, false-positive, and false-negative numbers. The S3 score is computed as:

$$S3 = F1(1 - NRMSE), \quad (2)$$

where the NRMSE denotes the normalized root mean square error [23]. We show the performance of two state-of-the-art methods on Iowa DOT Traffic dataset in Table 4.

Video Anomaly Detection Conference Workshop

The NVIDIA AI City Challenge (<https://www.aicitychallenge.org/>) was launched in 2017 and has been held as a full-day workshop of IEEE/CVF Conference on Computer Vision and Pattern Recognition (CVPR) since 2018. Traffic anomaly detection in surveillance videos is one track of the challenge.

Open Problems

Although there has been significant progress toward building efficient video anomaly detection algorithms in recent years, in particular the deep learning-based approaches, we highlight a few possible open problems that are worth exploring in the future.

- Although different learning frameworks have been adopted, the learned representations are still not satisfactory for distinguishing complex anomaly activities. Possible better representations include better 3D feature extractor, attention mechanism, and causal reasoning (identifying the cause of an anomaly event, e.g., too fast → accidents).
- Early works mainly focus on the unsupervised setting, and recent works have shown potential on improving performance by leveraging some supervision information for certain scenarios. It would be promising to explore better setting for practical applications, e.g., better trade-off between the generalization ability (unsupervised setting) and performance (weakly supervised setting).
- It may be acceptable for anomaly detection systems operating in public spaces where there is no expectation of privacy. However, what if the technology needs to be applied to non-public spaces where there is a stronger expectation of privacy? It is worth exploring effective ways to de-identify the training videos and train anomaly models with de-identified data.
- The current anomaly detection approaches or systems act as an alerting mechanism. How do we explain the AI decisions and convey these effectively to stakeholders, e.g., law enforcement, attorneys, media, local residents, and broader community. We expect techniques to close the gap between performance and interpretable AI models.

Acknowledgments This work was supported by UNCC Faculty Research Grant 111206, and in part by NSF CNS-1910844.

Definition

Image mosaicing is the process of generating a composite image (mosaic) from a video sequence, or in general from a set of overlapping images of a scene or an object, usually resulting in a mosaic image with a larger field of view, a higher dynamic range, or a better image resolution than any of the original images.

Background

When collecting video of a scene or object, each individual image in the video may be limited compared to the desired final product, including limitations in the field of view, dynamic range, or image resolution. This is the case not only with personal video capture [1–3] but also with image-based rendering [4–6], aerial videography [7–11], and document digitization [12]. Generating mosaics with larger fields of view [2, 3, 5, 10, 12, 13], higher dynamic ranges [14], and/or higher image resolutions [15] facilitates video viewing, video understanding, video transmission, and archiving. When the major objective of video mosaicing is to generate a complete (e.g., 360°) view of an object (or a scene) by aligning

and blending a set of overlapping images, the resulting image is also called a video panorama [2, 5, 6].

Theory and Application

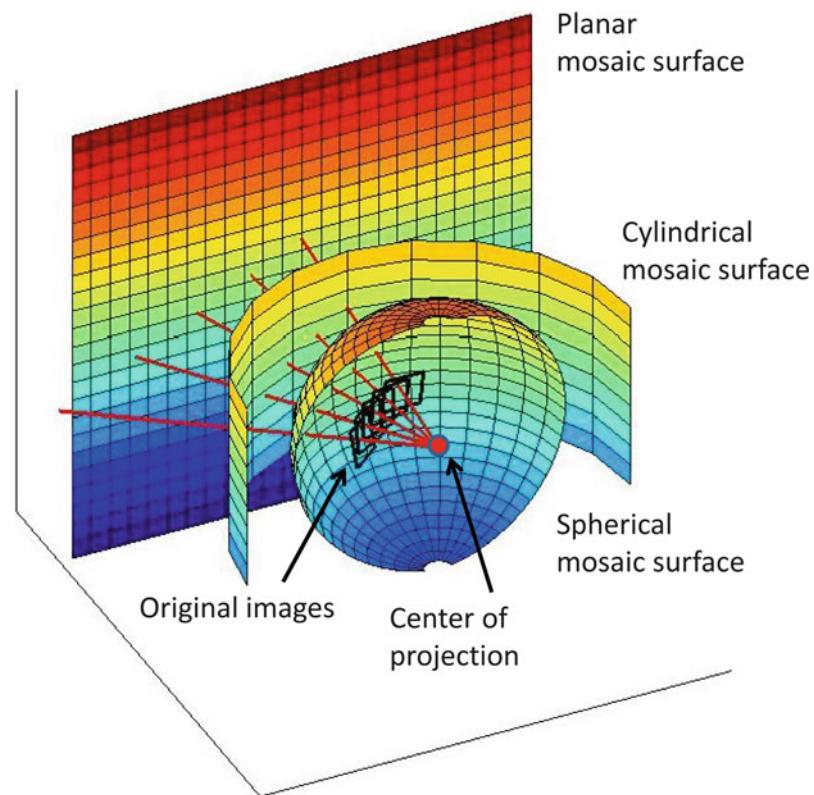

Video mosaicing takes in a video sequence and generates one or more mosaiced images with either a larger field of view, a higher dynamic range, a higher image resolution, or a combination of them. This entry will mainly discuss the principles in generating large field of view mosaics (panoramas), but the general principles can also be applied to mosaics for other objectives (high dynamic range imaging and super-resolution imaging). Here, *video* mosaicing implies that the images in the sequence are taken by a video camera, usually at 30 frames per second, but images taken by a digital camera such that there is a certain amount of spatial overlap between two consecutive frames can also be viewed as a video sequence.

There are three key components in a typical video mosaicing algorithm: motion modeling, image alignment, and image composition. Depending on the type of camera motion and the structure of the objects or scenes, the *motion model* can be a 2D rigid motion model (with rotation, translation, scaling), an affine model, a perspective model (i.e., homography), or a full 3D motion model.

Many popular video mosaicing methods [16], for example, in [6, 14], assume a pure rotation model of the camera in which the camera rotates around its center of projection (i.e., the optical center, sometimes called nodal point). In this case, the motion between two consecutive frames can be modeled by a homography, which is a 3×3 matrix. Then, depending on the fields of view (FOVs) of the mosaic, the projection model of the mosaic can be a perspective projection (when FOV is less than 180°), a cylindrical projection (when FOV is 360° in one direction), or a spherical projection (when the FOV is full 360° in both directions). Figure 1 illustrates the relations between the original images, and the three types

Video Mosaicing, Fig. 1

Mapping a set of overlapping images into a mosaic: planar, cylindrical, or spherical

of mapping surfaces each image can be projected onto planar, cylindrical, and spherical.

However, the applications of video mosaics from a pure rotation camera are limited to mostly consumer applications such as personal photography, entertainment, and online maps. For more specialized applications such as surveillance, remote sensing, robot navigation, and land planning, to name a few, the motion of the camera cannot be limited to a pure rotation. Translational motion usually cannot be avoided, causing the *motion parallax* problem to arise. In computer vision, motion parallax refers to the different changes in positions of images of objects at different distances caused by the translational movement of the viewer (i.e., the camera). There are three kinds of treatments for the motion parallax problem. First, when the translational components are relatively small, the motion models can be approximated by a pure rotation. In this case, the generated mosaics lack geometric accuracy, but with some

treatments for the small motion parallax and moving targets, such as de-ghosting [6], the mosaics generally look very good. Second, if the scene can be regarded as planar, for example, because the distance between the camera and the scene is much larger than the depth range of the scene, the perspective motion model (homography) or, in some applications, a 2D rigid motion model or an affine model can be used [8, 11, 13]. In these cases, the problems are much simpler due to the 2D scene assumption. Finally, a 3D camera motion model is applied when the translational components of the camera motion are large and the scene is truly 3D. In this case, motion parallax cannot be ignored or eliminated. Examples include a camera mounted on an airplane or a ground vehicle translating a large distance [3, 4, 7, 10], or a camera's optical center moving on a circular path [2, 5]. Here, multi-perspective projection models are used to generate the mosaics, enabling stereo mosaics or stereo panoramas to be created that preserve

the 3D information in the scene, allowing the structure to be reconstructed and viewed in 3D. In this case, the accuracy of geometric modeling and image alignment is crucial for achieving the accuracy of 3D reconstruction and viewing.

Image alignment (or *image registration*) is the process of finding the alignment parameters (e.g., the homography in the rotational case) between two consecutive images. Image alignment is a critical step in mosaic generation, for both seamless mosaicing and for accurate geometric representation. There are two approaches to image registration: direct methods and feature-based methods. In a direct method, a correlation approach is used to find the motion parameters. Here, the images are divided into small blocks, and each block in the first image is searched for over a predefined spatial range in the second image. The best match is determined by finding the maximal correlation value. Other approaches such as using optical flow or using an iterative optimization framework also belong to the direct methods, in which no explicit feature points are extracted. But direct methods, especially those based on optical flow, can only be used when the inter-frame motion is relatively small. In a feature-based method, a feature detection operator such as the Harris corner or SIFT (scale invariant feature transform) detector is used first, and then the detected features are matched over the two frames to build up matches [16]. Either way, a parameter model is fitted using all the matches, usually using a robust parameter estimation method to eliminate erroneous feature matches. For more accurate or consistent results, a global optimization can be applied among more than two frames. For example, global alignment may be applied to all the frames in a full 360° circle in order to avoid gaps between the first and the last frame [6].

Image composition is the step of combining aligned images together to form the viewable mosaic. There are three important issues in this step: compositing surface determination, coordinate transformation and image sampling, and pixel selection and blending. Mosaicing with the rotational camera model is a good starting point to discuss these issues (Fig. 1); mosaic composit-

ing under other motion models are discussed afterward.

If the video sequence only has a few images, then one of the images can be selected as the reference image, and all the other images are warped and aligned with this reference image. In this case, the reference image with a perspective projection is the compositing surface, and therefore the final mosaic is a larger perspective image, which is an extension of the field of view of the reference image. However, this approach only works when the view angles of the images span less than 90°. If the camera rotates more than 90°, a cylindrical or a spherical surface should be selected as the compositing surface. A cylindrical surface is a good representation when a full 360° panoramic mosaic is to be generated, in one direction. And a spherical surface is suitable if 360° × 360° mosaics are to be created.

After a compositing surface is selected, the next issue is coordinate transformation and sampling. This is also called image warping. Given the motion parameters obtained in the image registration step, the mapping between each frame to the final compositing surface can be calculated: For any pixel in an original image frame, its pixel location in the compositing surface can be calculated. For generating dense pixels, an interpolation schema is needed, such as nearest neighbor, bilinear, or cubic interpolation methods. Usually a backward mapping relation is utilized such that in the mapping area on the compositing surface, each pixel obtains a value from an original image frame (or a blending of multiple values from multiple original frames, see below), line by line, and column by column. Therefore, for each integer pixel location in the mosaic, a decimal pixel location can be found in the original image; then an interpolation method is used in the original image to generate the value of the pixel in the mosaic.

The third important issue in image composition is pixel selection and blending. Naturally in generating mosaics, there are overlaps among consecutive frames, resulting in two key questions: First, *where do we place the seam (i.e., the stitching line)* (the pixel selection problem)? Second, *how do we select the values of pix-*

els in the overlapping areas (the pixel blending problem)? For the second problem, the simplest methods are to average all the pixels in the same location in the overlapping area, or to use their median value. The former might create a so-called ghost effect due to moving objects, small motion parallax, or illumination changes, while the latter approach may generate a slightly better view effect. More sophisticated blending methods include Laplacian pyramid blending [17] and gradient domain blending [1]. The pixel selection problem is important when moving objects or motion parallax exists in the scene. In these cases, to avoid a person being cut in half or appearing twice in the mosaic, or to avoid cutting a 3D object that exhibits obvious motion parallax and hence could produce obvious misalignment in the mosaic, an optimal seam line can be selected at pixel locations where there are minimum misalignments between two frames [14].

Other benefits having multiple values from multiple images for each mosaiced pixel include high dynamic range imaging [14] and improved image resolution mosaicing [15]. For the former, a composite mosaic represents larger dynamic ranges than individual frames using varying shutter speeds and exposures, while the latter uses the camera motion to generate higher spatial resolution in the mosaiced image than that of the original images.

So far the discussions on image composition have focused primarily on 2D mosaics, assuming either the camera motion is (almost) a pure rotation or the scene is flat or very far from the camera, in order to avoid or reduce the motion parallax problem. When motion parallax cannot be avoided, 3D mosaics have to be considered. Methods have been proposed to generate mosaics, for example, for curved documents based on 3D reconstruction [12], when the camera motion has translational components. Needless to say, with 3D reconstruction, a composite image with a new perspective view, or a new projection representation (such as orthogonal projection), can be synthesized from the original images. However, the drawback of this approach is a full 3D reconstruction is needed, which is both computationally expensive and

prone to noise. A more practical yet still fundamental approach without 3D reconstruction is to generate multi-perspective mosaics from a video sequence, under various names, such as mosaics on an adaptive manifold [8], creating stitched images of scenes with parallax [7] and creating multiple-center-of-projection images [4]. When the dominant motion of the camera is translation, the projection model of the mosaic can be a parallel-perspective projection, in that the projection in the direction of the motion is parallel, whereas the projection perpendicular to the motion remains perspective. This kind of mosaic is also called push broom mosaic [18] since the projection model of the mosaic in principle is the same as push broom imaging in remote sensing. A more interesting case is that by selecting different parts of individual frames, a pair of stereo mosaics can be generated that exhibit motion parallax, while each of them represent a particular viewing angle of parallel projection [10]. To generate stereo mosaics, the motion model is 3D, and therefore, a bundle adjustment for 3D camera orientation is needed. The projection model is parallel perspective, and therefore, the composting surface is a plane that holds the parallel-perspective image. To generate a true parallel-perspective view in each mosaic for accurate 3D reconstruction, pixel selection is carried out for that particular viewing angle, and a coordinate transformation is performed based on matches between at least two original images for each pixel. A similar principle can be applied to concentric mosaics with circular projection [2,5].

In some applications such as surveillance and mapping, geo-referencing mosaicing is also an important topic. This is usually done when geo-location metadata is available, for example, from GPS and IMU measurements [9, 11] taken with the video/images. Geo-referenced mosaics assign a geo-location to each pixel either by directly using the metadata from the video frames used to generate the mosaic or, when metadata is not available, by aligning the video frames to a geo-referenced reference image such as a satellite image.

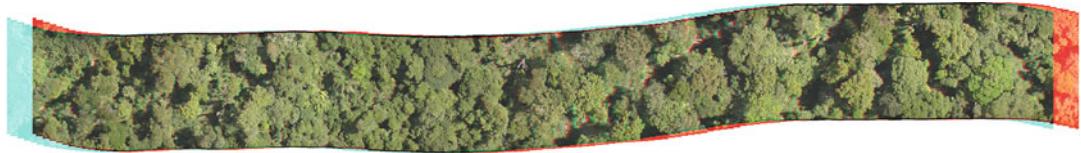

Video mosaicing techniques are also used for dynamic scenes, such as to generate

Video Mosaicing, Fig. 2 A 360° panoramic mosaic generated on a cylindrical surface

Video Mosaicing, Fig. 3 A pair of concentric mosaics of the City College of New York campus

Video Mosaicing, Fig. 4 A pair of push broom mosaics of the Amazon rain forest

dynamic push broom mosaics for moving target detection [18] and to create animated panoramic video textures in which different portions of a panoramic scene are animated with independently moving video loops [19, 20].

handheld video camera that undertakes an off-center rotation with 360 degrees of field of view coverage. Figure 4 is a pair of push broom stereo mosaics created from a video sequence taken by a camera looking down from an airplane flying over the Amazon rain forest.

Open Problems

Some open problems can be found in a good survey paper on image alignment and stitching [16]. These include robust alignments for stereo mosaics (or mosaics with motion parallax), mosaics for high dynamic range imaging and for super-resolution imaging, and dynamic mosaics.

Experimental Results

Figure 2 shows a 360° panoramic mosaic represented on a cylindrical surface, which is generated from a video sequence taken by a video camera that roughly rotates around its optical center. Figures 3 and 4 show two stereo mosaics that can be viewed with a pair of 3D glasses, red for the right eye and the cyan for the left eye. High-resolution mosaics can be viewed by clicking the images in the figures in the online edition. The concentric stereo mosaic in Fig. 3 is generated from a video sequence taken by a

Definition

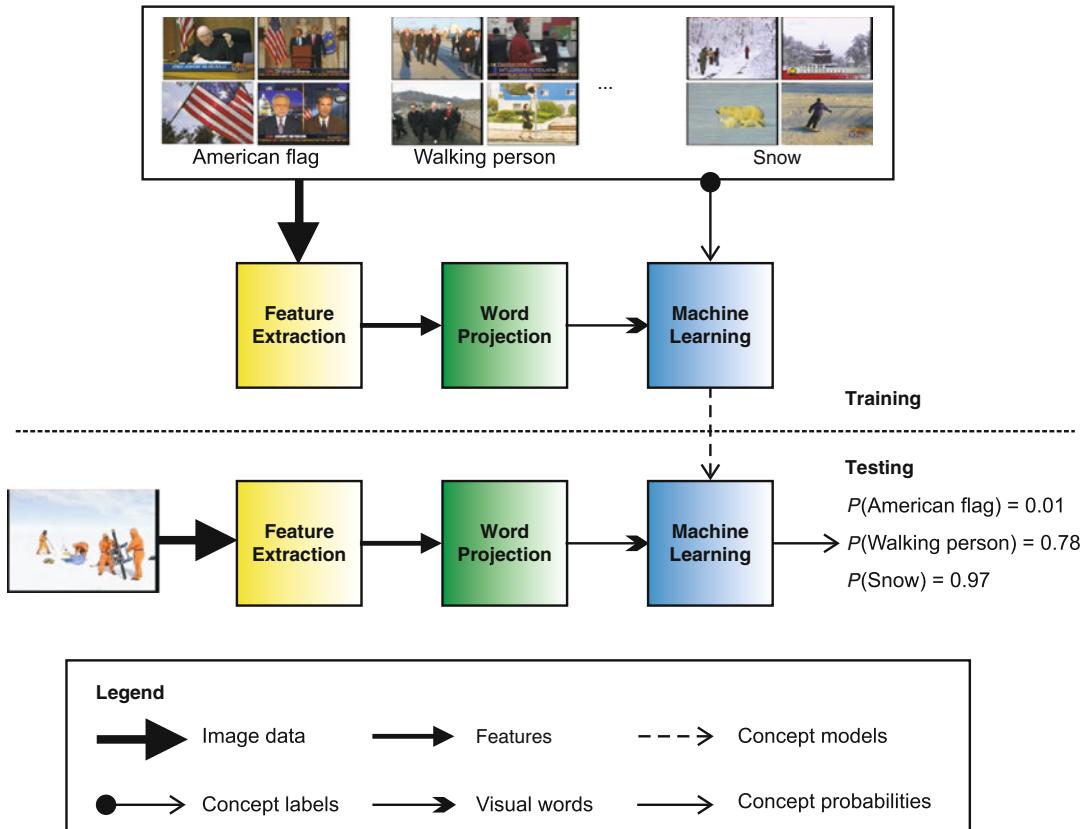

Video retrieval is the process of searching in video based on an analysis of its visual content.

Background

The cause for the general video retrieval problem is the semantic gap: the lack of correspondence between the low-level features that machines extract from the visual signal and the high-level conceptual interpretations a human gives [1]. In order to bridge the gap, many retrieval solutions have been proposed in the past, e.g., by using text, speech, tags, or example images [2, 3]. But the most authentic and cognitive hardest is to type a concept from visual information and to retrieve the images carrying that concept [4].

Theory

The video retrieval method of choice in the field is rendered in Fig. 1. The first step is to extract from an image locally measured features, lots of them, ranging from 40 to 100,000. The fea-

Video Retrieval, Fig. 1 General scheme for detecting visual concepts in images, with three typical concepts highlighted. First, researchers project extracted image features into visual words. Then they train concept

models from both the visual words and the concept labels using machine learning. Finally, during testing, researchers assign concept probabilities to previously unlabeled images

tures are invariant descriptors which cancel out accidental circumstances of the recording caused by differences in lighting, viewpoint, or scale. In order to capture the complexity of the world, many texture, shape, and color descriptors need to be extracted.

The second step is to project the descriptors per pixel onto one of 4,000 words. They are not real words but rather summarizations of one local patch of the image describing one detail: a corner, a texture, or a point. Researchers initially only summarized the image at the most salient points, but it now appears that full-density descriptions are superior.

In the third step, a machine-learning algorithm converts the visual words into one of the semantic concepts. In fact, it assigns a probability to all

of the concepts simultaneously, which are used for ranking images in terms of concept presence. Researchers train the algorithm with the help of manually labeled examples. Because there are far more negative examples than positive ones, they intensively compute the optimal machine-learning parameters using grids and GPUs.

Detecting an object such as the American flag is relatively simple if one has an answer to the variance in sensory conditions like illumination and shading, as the flag always shows the same colors and color transitions. Note that a geometrical model of a flag would fail almost always as it rarely appears like a straight square. To detect a walking person from one image requires a richness of poses learned from a labeled set, and snow is even harder to detect as it is white, is

texture-free, and may assume all sorts of shapes. Remarkably, although none of the features in current detection methods is specific to any of the concepts, the technique can still detect any of them with sufficient success.

Application

Crucial drivers for progress in video retrieval are international search engine benchmarks such as ImageCLEF (Cross-Language Evaluation Forum), Pascal VOC (Visual Object Classes), PETS (Performance Evaluation of Tracking and Surveillance), and VACE (Video Analysis and Content Extraction). However, thus far the National Institute of Standards and Technology TRECVID (TREC Video Retrieval) benchmark [5] has played the most significant role.

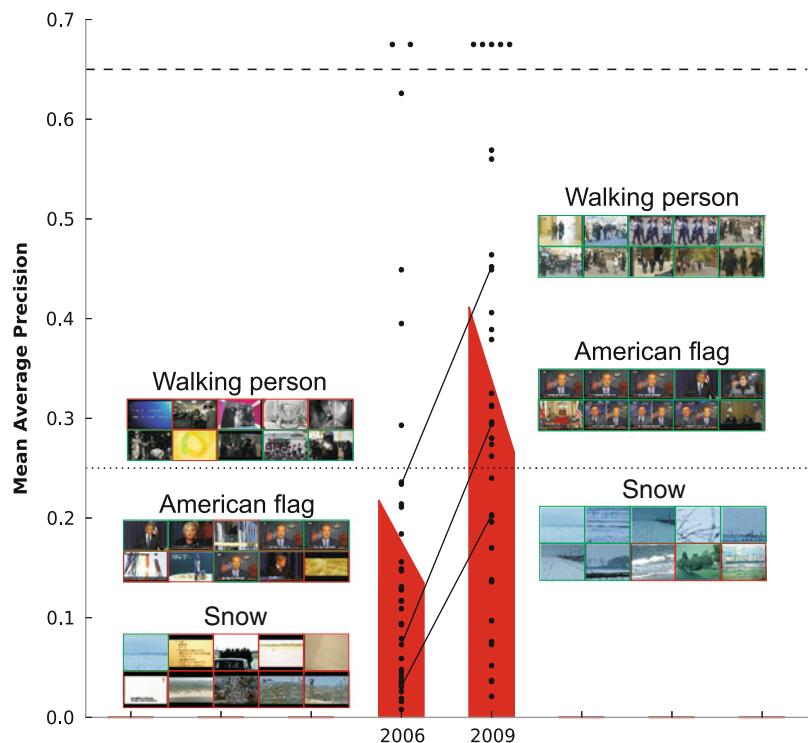

The aim of the TRECVID benchmark is to promote progress in video retrieval by providing a large video collection, uniform evaluation pro-

cedures, and a forum for researchers interested in comparing their results. NIST performs an independent examination of results using standard information retrieval evaluation measures, like average precision. With participation from more than 100 teams, including University of Oxford, Tsinghua University, and Columbia University, TRECVID has become the de facto standard for evaluating video retrieval research.

TRECVID has been an important driver for the community in sharing resources for validity of video retrieval experiments, most notably the manual annotations provided by the Large Scale Concept Ontology for Multimedia [6]. Due to the open character of benchmarks, effective concept detection approaches are quickly handed over from one group to another implementing fast convergence on successful methods. It was shown recently that in just 3 years, performance has doubled [7]. For learned concepts, detection rates degenerate when applied to data of a different origin. However, in this setting also, performance has doubled in just 3 years; see Fig. 2.

Video Retrieval, Fig. 2

Video retrieval progress as evaluated on 36 concept detectors (\bullet) derived from broadcast video data using state-of-the-art search engines from 2006 and 2009. The figure highlights performance for three typical concepts. The *top* of the skewed bar indicates the maximum average performance by training on similar examples, and the *bottom* indicates the minimum performance when training on a data set of completely different origin [7]. Progress in video retrieval is substantial and quickly maturing in robustness for real-world usage of any concept

Open Problems

Despite good progress many problems in video retrieval remain to be solved. Apart from the need to further improve the robustness and efficiency of concept detectors, there is also a need to expand the number of detectors and to facilitate retrieval mechanisms that cater for on-the-fly search [8]. For both scenarios, the widely available socially tagged image examples on the web seem suited. Another open problem considers complex search requests by the combination of detectors at query time into events or short stories. Even though individual detectors may be reasonable, their combination often yields nothing but noise. Finally, the problem of explaining to a user what visual information in the video was the characteristic evidence in making a meaningful retrieval decision is unsolved.

Definition

Video-based face recognition is a type of face recognition where the test data are videos rather than still images. Similar to traditional face recognition, approaches for video-based face recognition attempt to identify a person in a video (identification) or decide whether two subjects in two different videos have same identity (verification).

Background

In computer vision and biometrics, video-based face recognition has received significant amount of attention in recent years. It has a wide range of applications including visual surveillance, access control, video content analysis, etc. Large amounts of video data are becoming available everyday since millions of cameras have been installed in buildings, streets, and airports around the world and people are using billions of handheld devices that are capable of capturing videos.

Video-Based Face Recognition, Fig. 1 An example of video-based face identification problem consisting of a pre-enrolled gallery of three subjects and two frames from the test video

An example of video-based face identification from the IARPA Janus Surveillance Video Benchmark (IJB-S) dataset [1] is shown in Fig. 1. In this example, gallery consists of pre-enrolled still images, and a test video is captured from a surveillance camera. Every face in the video should be detected and matched to a subject in the gallery or to an unseen class for the open-set scenario. Notice that the low-quality faces in the video frames make this problem very challenging.

A video-based face recognition pipeline usually consists of components including face detection, face alignment, feature extraction, face association, and set/sequence-based face matching. The first three frame-wise components are almost identical to still image-based face recognition. Their differences are mainly in the last two components: (1) Since a video contains lots of frames with much more information than a single image, faces are usually associated before matching, where faces with the same identity across different video frames are associated into sets/sequences. (2) Face matching is also performed in set/sequence, instead of using just a single image.

The overall algorithm includes the following steps:

1. Given a video, faces are first detected from video frames and aligned using the estimated fiducial points.
2. Face features are extracted from the detected faces using feature extractors for face recognition.
3. Face sets/sequences with unique identities (ideally) are constructed by face tracking/association approaches.
4. Face sets/sequences are matched under a certain similarity metric based on the face features in sets/sequences.

Figure 2 illustrates an example of video-based face recognition system proposed in [2]. It exactly consists of four steps: (1) face detection from input videos and alignment by a face detector, (2) face feature extraction by a face classifier, (3) face association across video frames by single/multiple-shot association techniques, and (4) feature sets modeling and matching by subspace learning and subspace-based similarity metrics.

Theory

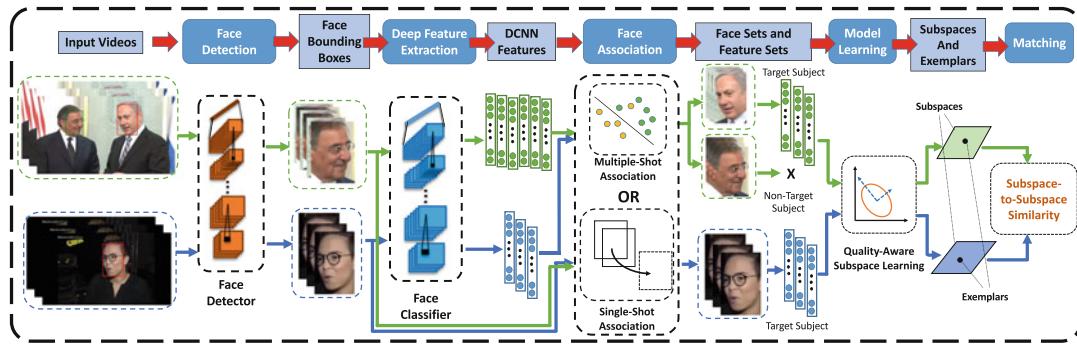

In this section, we introduce the details of each component in a video-based face recognition system.

Face Detection and Alignment

The first step of a face recognition system is to detect the faces. Face detection is a special type of object detection and usually follows similar designs, including single-stage and two-stage architectures, as general object detection.

Najibi et al. [3] proposed a very fast single-stage fully convolutional network. Chen et al. [4] proposed a multi-task face detector based on the single-stage SSD detector with extra branches. The multi-scale face detector, Deep Pyramid Single Shot Face Detector (DPSSD), is proposed in [5]. It is fast and capable of detecting tiny faces, which is very suitable for face detection in videos.

To reduce the pose variation of faces captured under unconstrained conditions, the detected faces are further aligned using their facial

Video-Based Face Recognition, Fig. 2 A video-based face recognition system [2]

landmarks (fiducials) which are estimated by a specific fiducial estimator.

HyperFace [6] is the first multi-task network that can simultaneously detect faces, extract fiducials, estimate pose, and recognize gender. In [7], Ranjan et al. built on [6] and used multi-task learning to simultaneously obtain face-related information like face bounding boxes, fiducials, facial pose, gender, and identity. Kumar et al. [8] proposed a Pose Conditioned Dendritic Convolutional Neural Network for fiducial estimation.

After fiducial estimation, face alignment is usually performed by a similarity transform estimated from five/seven fiducial points on the face.

Feature Extraction

After aligned faces are prepared, feature extraction is the next step that generates discriminative descriptors for each face. It is the most important step for both still and video-based face recognition system. Many Deep Convolutional Neural Network (DCNN)-based approaches have been proposed for still image-based face recognition, which can be directly used as feature extractors for video-based face recognition.

Taigman et al. [9] learned a DCNN model on the frontalized faces generated from 3D shape models built from face dataset. Sun et al. [10,11] achieved results surpassing human performance for face verification on the LFW dataset [12]. Schroff et al. [13] adopted the GoogLeNet for face recognition. Parkhi et al. [14] achieved impressive results using VGGNet for face veri-

fication. Chen et al. [15, 16] reported very good performance on IJB-A [17], JANUS CS2, LFW, and YouTubeFaces [18] datasets. Ranjan et al. [5] proposed the crystal loss to train the network on very-large-scale training data and achieved good performance on IJB-C[19]. Deng et al. [20] presented a recent face recognizer with state-of-the-art performance.

Face Association

For video-based face recognition, subjects are expected to appear in multiple frames in a video. To improve face recognition performance, faces from the same identity in a video are collected together using the face association step before matching. The association is usually based on the appearance and spatiotemporal locations of faces.

For single-shot videos, in which the bounding boxes of a certain identity are probably contiguous, face tracking methods are more reliable. Zhou et al. [21] incorporated appearance-based models in a particle filter to realize robust visual tracking. Roth et al. [22] proposed a multi-pose face tracking approach in two stages using multiple cues. Comaschi et al. [23] proposed an online multi-face tracker using detector confidence and a structured SVM. An efficient tracker, SORT [24], achieves comparable results to other state-of-the-art methods with 20 times faster speed.

For multi-shot videos, it is challenging to continue tracking across different scenes. Face association based on the appearance is more robust to scene changes in these videos. Du et al. [25] proposed a conditional random field (CRF)

framework for face association. Chen et al. [26] introduced a face association approach based on one-shot SVMs.

Set/Sequence-Based Face Matching

Given a set/sequence of faces from the same subject, the final step is to model it into a unified representation, match it with other faces, and generate similarity scores. Several methods have been introduced to represent set/sequences including (weighted) average pooling, subspace/manifold-based modeling, sparse representation, and recurrent neural networks.

For set-based face matching, Wang et al. [27, 28] proposed a Manifold-to-Manifold Distance (MMD) that models sets of faces as manifolds or subspaces. Wang et al. [29] modeled the image set with its second-order statistic for image set classification. Zheng et al. [2] proposed a quality-aware principal angle-based subspace-to-subspace similarity, where subspaces are learned using quality-aware principal component analysis. Chen et al. [30, 31] proposed a set-based algorithm using sparse representation and dictionary learning. Some adaptive pooling methods [32–34] are also proposed, which flatten face sets by performing adaptive weighted average pooling on face features. Based on [2], Zheng et al. further introduced a graphical model-based approach which leverages the contextual information in the videos by identity information propagation to improve face recognition performance.

For sequence-based face matching, Gong et al. [35] proposed a recurrent network for sequence feature aggregation. Zheng et al. [36] proposed a hybrid dictionary learning approach which models the temporal correlation in the sequences of video faces by dynamical dictionaries.

Open Problems

Compared to still image-based face recognition, unconstrained video-based face recognition is

still an unsolved problem. It is much more challenging due to the following reasons:

- Large scale: For video-based face recognition, test data are videos where each video contains tens of thousands of frames and each frame may have several faces. This makes the scalability of video-based face recognition a challenging problem. To design an efficient face recognition system, each component of the system should be fast, especially face detection, which is often the bottleneck in the face recognition pipeline.
- Large variation: Since faces are mostly from unconstrained videos, they have more significant variations in pose, expression, illumination, blur, occlusion, and video quality than still faces. The representations for video faces should be robust to these large variations.
- Lack of labeled data: Most off-the-shelf feature extractors for face recognition are trained on still images which have less variations than unconstrained videos. To fill the performance gap between face recognition in still images and unconstrained videos, we need to train a video-specific model with large amount of labeled training data.
- Noisy association: Frequent occlusions, pose variations, and scene changes make face association in unconstrained videos very difficult. Face recognition performance will suffer if the associated face sets contain more than one identity.
- Varying size: Each video contains different number of faces for each identity. After face association, each face set/sequence will also vary in size. During face matching, it is challenging to efficiently encode a varying-length set/sequence of samples into a fixed-size unified representation.
- Temporal information: In the era of deep learning, there are just a few methods that consider the temporal correlation in face sequences for video-based face recognition. Recognition performance can be improved by leveraging the temporal information.

Definition

View- and rate-invariant human action recognition is the recognition of actions independent of the camera viewpoint, action speed, and frame rate of capture of the video.

Background

At its essence, human action is the movement of the body through a sequence of poses. The visual appearance of a given action in a video sequence depends upon several classes of variables: (1) the geometry of the person performing the action, (2) the style of the action being performed, (3) the clothing worn by the person, (4) the camera viewpoint, and (5) the time taken, not only for the entire action but also for each individual pose

transition to complete. A generally applicable human action recognition system needs the ability to classify an action from its visual appearance regardless of the values of the above classes of variables. In other words, the system needs to be *subject invariant, style invariant, clothing invariant, view invariant, and rate invariant*. Subject invariance, style invariance, and clothing invariance have seen relatively little progress so far. While progress has been made on view invariance and rate invariance, the collective body of work has not yet matured. Therefore, this entry summarizes the main approaches that have been proposed so far, highlighting their motivations, theoretical foundations, and limitations.

Theory

Human action recognition is dependent upon modules isolating different humans in the scene. Therefore, in the following, it is assumed that human detection has been performed and image regions corresponding to a single human performing an action have been identified and are provided as an input to the view- and rate-invariant human action recognition system.

View Invariance

The objective of view invariance arises mainly in the case of monocular video. Multiple cameras allow the possibility of acquiring the depths of image points, which makes the view invariance problem much easier. Therefore, this section focuses only on monocular video.

Detecting an action requires a model, either explicit or implicit. An explicit model for human action can be based on the temporal sequences of body joint angles. Recovery of joint angles from image sequences is difficult due to joints being physically hidden behind the skin and clothing and due to the unknown viewpoint. Although it may be possible to theoretically establish viewpoint invariance using explicit models, such approaches are limited by the difficulties involved in recovering joint angles.

Alternatively, actions can be modeled implicitly, based on quantities derived directly from the observed images. However, such models maintain at best a tenuous link to the hidden joint angles, making it difficult to theoretically establish view invariance. From early days of research into view-invariant human action recognition, 3D motion capture and its 2D projections to images remains a very useful source for creating the substrates of human action and their composition to form human actions.

Given difficulties with both types of approaches, it is not surprising to note that no theoretically sound and practically applicable algorithm has been designed so far that can recognize human actions invariant to viewpoint changes. Nevertheless, two classes of approach have emerged based on explicit and implicit models for human action that are described in more detail below.

Geometry-Inspired Approaches

Geometry-inspired approaches draw upon results from geometric invariance and apply them to points on the body as it moves. Geometry-driven approaches depend upon body parts having been detected, tracked, and labeled across frames. Extremities of the body such as the head, hands, and feet have a better chance of being detected, whereas internal joints such as the shoulders, elbows, and knees are harder to detect and need to be inferred. Methods to infer the full 2D body pose from silhouettes have been proposed [1–3], but a system integrating such methods with a full body-based view-invariant action recognition method has not been demonstrated yet. An example of an extremity-based approach is [4]. Examples of full-body approaches are [5, 6] and [7].

Image-Based Approaches

An implicit model of an action can be based upon a manifold of appearances arising from the same action as seen from different viewpoints. Given an unknown action from an unknown viewpoint,

appearance descriptors are extracted and matched with learned appearance descriptors. Recent approaches use deep neural networks to map different views of the same action to a canonical view [8]. Matching error is calculated based either on pixel-wise dissimilarity of the silhouettes [9, 10] or in a derived space such as Hu moment space, Fourier shape space [11], or spaces over dense motion trajectories [8, 12].

An implicit model for an action can also be based upon exploiting self-similarity. The observation used in such a method is that although a given pose may appear different from different views, repeating instances of the same pose across time will be self-similar in a given view, provided that the viewing angle between the subject and the camera for the pose is the same. Constructing a pair-wise self-similarity matrix across time will produce structures that appear similar. Such an approach assumes the existence of repeated poses in the action and works best when there are many repeating instances within one action cycle. Examples of such approaches include [13] and [14].

Rate Invariance

A robust action recognition system has to be invariant to the rate at which the action is performed. This will enable the results of the action recognition system to be invariant to the frame rate of the camera and the rate at which the actor is performing these actions. While a linear rate invariance is sufficient to handle frame-rate variations, it is necessary to model and be able to handle nonlinear rate variations in order to handle the rate changes that are due to actors, speed of performance. This is because the actors may perform different sub-actions at varying relative rates, thereby leading to a nonlinear rate change across the entire action.

Motivation

Consider the INRIA iXmas activity recognition dataset [15]. Shown in Fig. 1(L) is the distribu-

tion of the number of frames in different executions of the same activity for four distinct activities. Figure 1(L) clearly shows that for the same activity, the rate of execution and consequently the number of frames during the execution vary significantly. Moreover, in most realistic scenarios, this temporal warping might also be inherently nonlinear making simple resampling methods ineffective. This implies that for uncontrolled scenarios, the variations due to temporal warpings could be even more significant. Ignoring this temporal warping might lead to structural inconsistencies apart from providing poor recognition performance. The sequence of images shown in the first two rows of Fig. 1(R) corresponds to two different instances of the same individual performing the same activity. There is an obvious temporal warping between the two sequences. If this temporal warping is ignored, the distance between these two sequences will be large, leading to incorrect matching. Moreover, if some statistical description of the activity, like an average sequence, is required, then ignoring the temporal warping could lead to structural inconsistencies like the presence of four arms and two heads in the average sequence, shown in the third row of Fig. 1(R). If temporal warping is accounted for, then such inconsistencies are avoided and the distance between the two sequences is rightly small. The fourth row shows a typical average sequence obtained after accounting for time warping.

Rate Invariance in Gait Recognition

Results on gait-based person identification shown in [17] indicate that it is very important to take into account the temporal variations in the person's gait. In [18], preliminary work indicating that accounting for execution rate enhances recognition performance for action recognition was presented. Typical approaches for accounting for variations in execution rate are directly based on either the dynamic time-warping (DTW) algorithm [19] or some variation of this algorithm [18]. A method for computing an average shape for a set of dynamic shapes in spite of the exis-

tence of varying rates of execution is provided in [20]. A method to learn the best class of time-warping transformations for a given classification problem is proposed in [21].

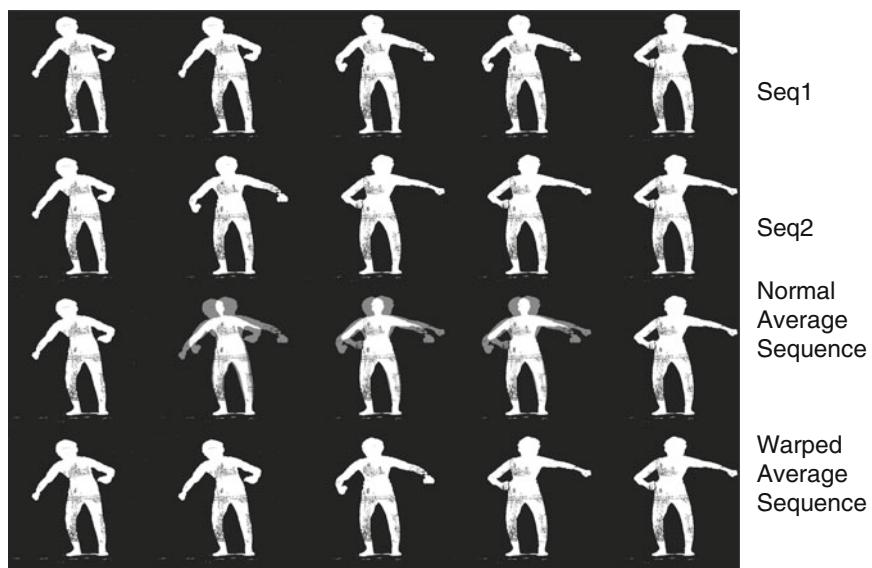

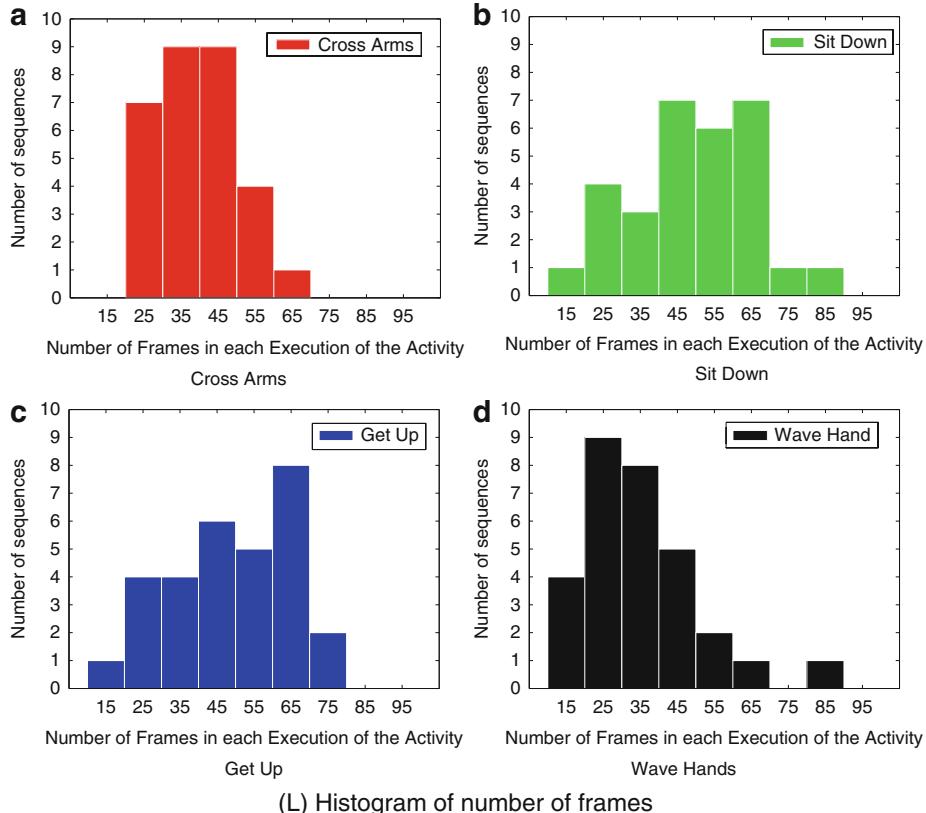

Decoupling Feature Variability from Rate Variability

The most common way to handle rate variations in the execution of an action is to decouple the variations in features from the variations in dynamics due to rate changes. This is done by modeling an action sequence as a composition of these two sources of variability – variability on the feature space and variability due to execution rate. Keeping the model on the feature space completely independent of the model on the space of execution rates allows for the ability to exploit any of the abovementioned viewpoint-invariant features. Therefore, as more sophisticated features become available, such models will be able to exploit the characteristics of those features while retaining the ability to deal with variations in execution rate. If the chosen features are viewpoint and anthropometry invariant, then the resulting algorithm becomes invariant to all the three significant modes of variations – viewpoint, anthropometry, and execution rate.

Dynamic Time Warping

Dynamic time warping (DTW) [19] is the most common algorithm that is used for accounting for the nonlinear execution rate variations. The DTW algorithm which is based on dynamic programming computes the best nonlinear time normalization of the test sequence in order to match the template sequence by searching over the space of all time warpings. The advantage of using DTW is that by cleverly using dynamic programming, the complexity of the search space is considerably reduced. The usual temporal consistency constraints used in order to reduce the space of time warpings are as follows:

End-point constraints: the start and the end of the activity trajectories must match exactly.

View- and Rate-Invariant Human Action Recognition, Fig. 1 Figure courtesy [16] (L). Histogram of the number of frames in different executions of the same action in the INRIA iXmas dataset. The histograms for four different activities are shown. (a) Cross arms. (b) Sit

down. (c) Get up. (d) Wave hands. (R) Row 1, Row 2: two instances of the same activity. Row 3: a simple average sequence. Row 4: average sequence after accounting for time warps

Monotonicity: the warping function should be monotonically increasing, i.e., the sequence of action units must be unchanged.

Continuity: the warping function must be continuous.

The DTW algorithm thus computes the best time warping between a test sequence and a template sequence. Once the best time warping is computed, then the test sequence is then unwarped according to the computed warp. The unwarped action sequences are now time-synchronized since all temporal rate variations have been accounted for. From each frame of the unwarped sequence, features (typically view-invariant features) are extracted and then matched in order to result in an algorithm that is both view and rate invariant.

Open Problems

Approaches that are theoretically view invariant are based on inherent parameters of an action such as joint angles or positions. Unless these methods are coupled with methods that infer the inherent joint parameters, they will be of little practical value. On the other hand, image-based approaches are more practical but not generally and probably view invariant. An open problem in view-invariant action recognition is to find a method that is theoretically sound and yet practical.

Definition

Recognizing human actions from previously seen viewpoints is relatively easy when compared with unseen viewpoints. View-invariant action recognition aims at recognizing human actions from unseen viewpoints.

Background

Human action recognition is an important problem in computer vision. It has a wide range of applications in surveillance, human-computer interaction, augmented reality, video indexing, and retrieval. The varying pattern of spatiotemporal appearance generated by human action is key for identifying the performed action. We have seen a lot of research exploring this dynamics of spatiotemporal appearance for learning a visual representation of human actions. However, most of the research in action recognition is focused on some common viewpoints [1], and these approaches do not perform well when there is a change in viewpoint. Human actions are performed in a three-dimensional environment and are projected to a two-dimensional space when captured as a video from a given viewpoint. Therefore, an action will have a different spatiotemporal appearance from different viewpoints. As shown in Fig. 1, observation o1 is different from observation o2 and so on. The research in view-invariant action recognition addresses this problem and focuses on recognizing human actions from unseen viewpoints.

There are different data modalities which can be used for view-invariant representation learning and perform action recognition. These include RGB videos, skeleton sequences,

View-Invariant Action Recognition, Fig. 1 An action captured from different viewpoints (v1, v2, and v3) providing different observations (o1, o2, and o3) [2]

depth information, and optical flow. The skeleton sequences and depth information require additional sensors and are comparatively more difficult to capture when compared with RGB videos. Similarly, the optical flow is computationally expensive and requires extra processing on RGB videos. These modalities can be used independently as well as in combination to solve the problem of view-invariant action recognition. Figure 2 shows a sample instances activities performed by an actor which is captured from three different viewpoints in three different modalities.

Human action recognition from video sequences involves the extraction of visual features and encoding the performed action in some meaningful representation which can be used for interpretation. The view-invariant encoding of actions involves a lot of challenges, and there are different ways to address them. One possible solution is to track the motion as it evolves with the performed action. The track in itself will be invariant to any change in the viewpoint and can be used to extract a view-invariant representation of actions. Another approach is to analyze the spatiotemporal volume, which is covered by a human while performing any action. It is interesting to observe that such spatiotemporal volumes will have some similarities for same actions, and they can be useful to address change in viewpoints. The tracking of a human body can be useful to some extent, but human joints can move independently while performing most of the activities. Therefore, tracking of skeleton joints independently is very important for understanding human actions. The availability of large-scale training data has also enabled us to learn view-invariant representations using deep learning. We will cover the details of these approaches in the following sections.

View-Invariance in Human Actions

The dynamics of body parts and the change in appearance play an important role in understanding human actions. These two properties can be effectively used to determine human actions in a

video stream if there is no change in viewpoint. However, it becomes challenging when there is a change in the viewpoint, as the dynamics, as well as the appearance, will change with it significantly. Therefore, it is important to represent human actions in such a way that the representation is invariant to any change in viewpoint. The idea is to encode the human action with a representation which does not change with change in viewpoint. We can observe in Fig. 2 how the appearance of the activity changes when seen from different viewpoints. It does not matter how the action is captured; this variation is present in all the modalities, including RGB, skeleton, and depth.

Motion Trajectories

An action sequence performed by any person will have a motion trajectory, which will be different for different actions. These motion trajectories can be useful in extracting rich view-invariant representation for action classification. The actions are performed in a 3D environment, and therefore, the corresponding motion trajectories are in 3D space. The change in speed and direction of the trajectory plays an important role in inferring the performed action. The continuities and discontinuities in position, velocity, and acceleration in a 3D trajectory are preserved in 2D trajectories under a continuous projection [4]. Therefore, we can use the 2D spatiotemporal curvature of these 3D motion trajectories to represent actions which will capture the change in speed as well as direction.

A spatiotemporal curvature can be represented using instants which segment the motion trajectory into intervals. Instances indicate a significant change in the speed and direction in the motion trajectory and define motion boundaries [4]. A special class of motion boundary, which is independent of starts and stops, is the dynamic instant that happens while performing an action. A dynamic instant represents a significant change in the motion characteristics and occurs only for one frame. It provides motion boundaries, called intervals, which represent the time period between two dynamic instants when the motion characteristics are not changing. In Fig. 3a, we

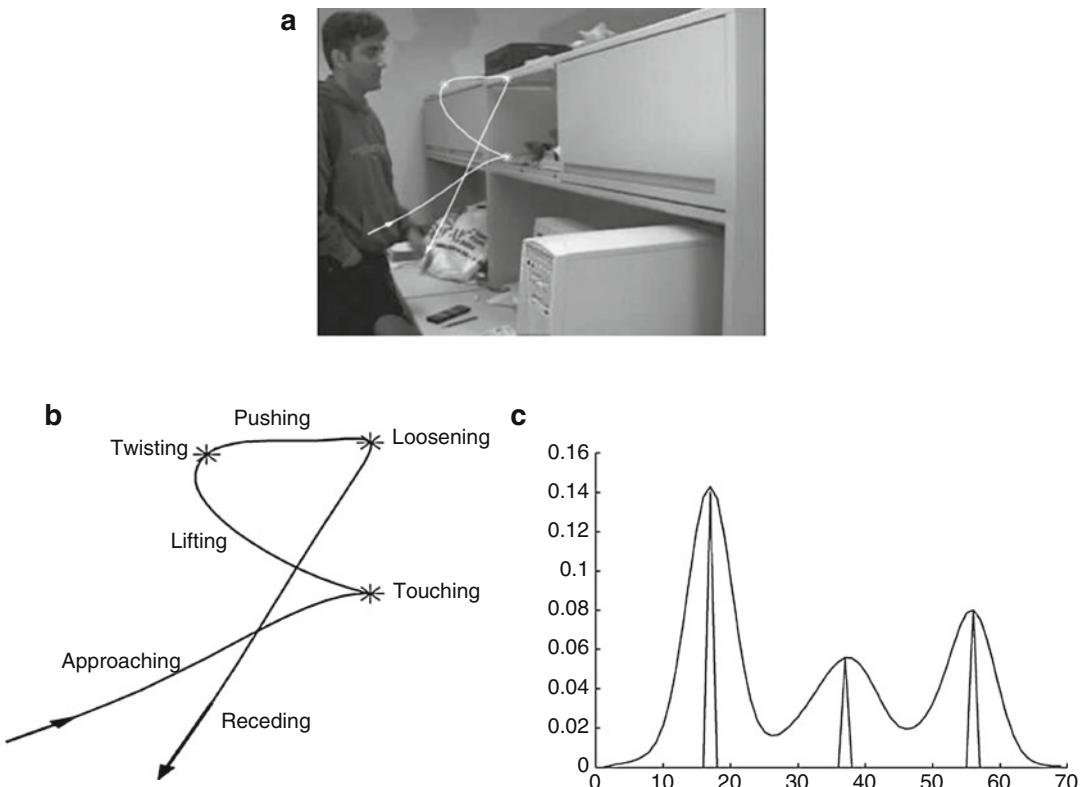

View-Invariant Action Recognition, Fig. 2 Video frames showing action in different modalities as seen from three different viewpoints [3], Row-1: RGB, Row-2: skeleton, and Row-3: depth

can observe a sample video frame for activity “opening a cabinet.” If we track the hand motion of the person while performing this action, we will get a spatiotemporal curvature shown in Fig. 3b. It shows the instants as well as corresponding intervals in the motion trajectory. Figure 3c shows the spatiotemporal curvature values along with the detected dynamic instants in the motion trajectory.

View-Invariance The discontinuities in 3D motion trajectory, which we perceive as instants, are always projected as discontinuities when projected in 2D curvatures [4]. These instants which are maxima in spatiotemporal curvature will be view-invariant for most scenarios. Therefore, the number of instants in a spatiotemporal curvature is an important characteristic which will be view-invariant. The only exception will be the cases when there is a perfect alignment of the viewing direction with the plane where the action is being performed. In these cases, the position of the trajectory in consecutive frames will be projected to the same location in the frame resulting in a 2D

trajectory, which is essentially a single point. Another important characteristic of instants in spatiotemporal curvature is the change in direction. This is known as sign characteristic, and it defines the direction of turns in action. It is very useful in distinguishing different actions captured from varying viewpoints. A clockwise turn is represented by a “+” sign and counter clockwise turn by “−” sign.

These two characteristics of instants, number of instants and sign of instants, in a spatiotemporal curvature provide a view-invariant representation of actions. This representation can be used to determine whether two spatiotemporal curvatures belong to the same action class. The first requisite is a match between the number of instants and the sign sequence. Thereafter, we can compute a view-invariant similarity measure between the two trajectories. This can be performed using affine epipolar geometry, which will ensure viewpoint invariance in the similarity measure [4]. However, there are some limitations with this approach. It requires an exact match between corresponding instants in the spatiotemporal curvature, which can be difficult as there

View-Invariant Action Recognition, Fig. 3 (a) A sample video frame showing “opening a cabinet” action. A hand trajectory in white is superimposed on the image, (b)

a representation of the trajectory in terms of instants and intervals, and (c) corresponding spatiotemporal curvature values and detected maximums (dynamic instants) [4]

can be false or missed instant detection. Also, this approach does not take into account the temporal information between the instants. These issues can be addressed using a view-invariant dynamic time warping to measure the similarity between two spatiotemporal curvatures [5]. The view-invariant time-warping not only suppress the instant outliers, it also compensates for the variation in the execution-style [6]. It can shrink the slow-motion trajectories, which are longer in temporal axis, and expand the fast motion trajectories which are relatively shorter.

Limitations The idea of spatiotemporal curvature is simple yet effective in extracting view-invariant representation for actions. However, there are certain limitations in this approach. The assumption that an action can be represented by a trajectory of single point in a video frame will not

hold true for actions where full-body is involved. The skeleton joints in a human body will have a different motion for the same performed action. Therefore, this approach is limited to actions where the action can be approximated to a trajectory of single point at any time frame during the motion.

Tracking Joints

A single point-based motion tracking of human actions cannot be generalized for actions where multiple body joints are involved. It only carries motion information ignoring any shape or relative spatial information. Therefore, it is important to consider multiple human joints involved in the action while tracking the motion. The movement of different joints while performing an action is not independent of each other. The human body has certain anthropometric proportion, and there

exist some geometric constraints between multiple anatomical landmarks such as body joints. This allows us to analyze human actions performed by different people using the semantic correspondence between human bodies.

The pose \hat{X} of an actor while performing an action can be represented as a set of points in any given frame of a video. Here the pose is defined as $\hat{X} = \{X_1, X_2 \dots X_n\}$, where $X_i = (x_i, y_i, z_i, \Lambda)^T$ are homogenous coordinates and there are n such landmarks. Each point represents the spatial coordinate of an anatomical landmark on the human body, as shown in Fig. 4. The body size and proportion vary greatly between different people and age groups. However, even though the human dimensional variability is substantial, it is not arbitrary [7]. Therefore, geometric constraints can be used between the pose of two different actors performing the same action. The proportion between two sets of points describing the pose of two different actors can be captured by a projective transformation. Suppose we have a set of points \hat{X} and \hat{Y} describing actors A_1 and A_2 . Then the relationship between these two sets can be described by a matrix M such that $X_i = MY_i$, where $i = 1, 2 \dots n$ and M is a 4×4 non-singular matrix. The transformation simultaneously captures the different pose of each actor as well as the difference in size/proportions of the two actors. There are two types of constraints which are useful for action recognition, postural constraints and action constraint [7]. The postures of two actors performing the same action at any time instant should be the same. This constraint allows us to recognize the action at each time instant by measuring the similarity between the postures. Along with this frame-wise constraint, another global constraint can be used on the point sets describing two actors if they are performing the same action.

The anthropometric constraints in a human body allow the transformation of pose between two actors. Moreover, utilizing the postural and action constraints can help in recognizing action by measuring the similarity between two sets of points. The transformation and geometric constraints will address the issue of view-invariance in actions. However, this approach assumes the

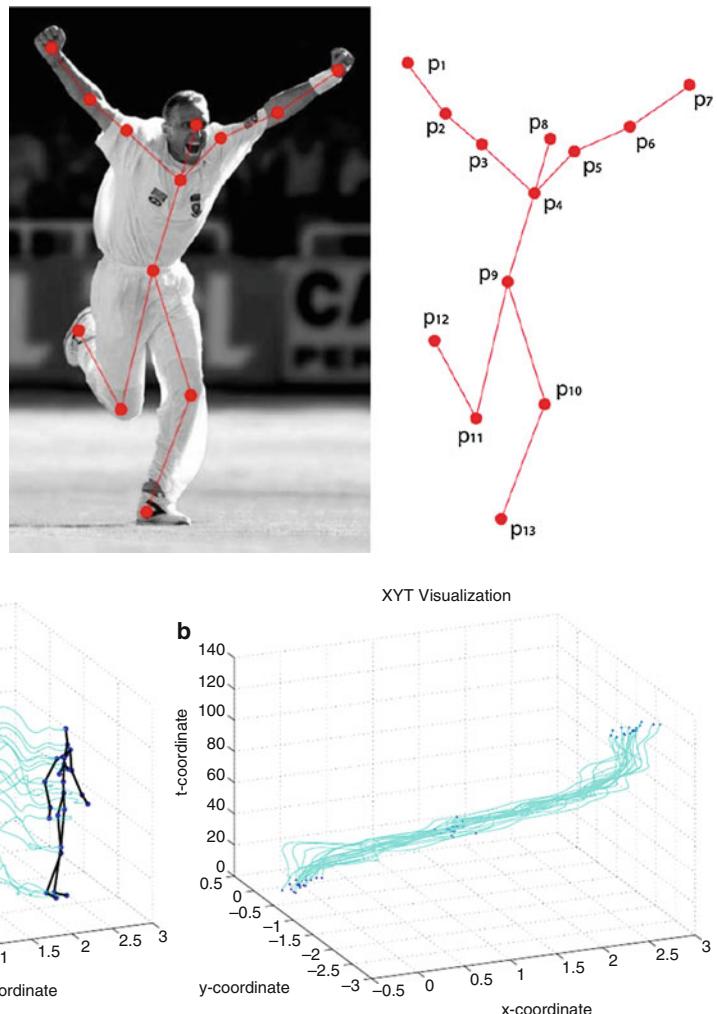

temporal alignment of poses for each frame in the video. This can be problematic as different actors will have a unique style of executing an action. Therefore, a temporal alignment is also required, which is invariant to temporal transformations. This can be done using dynamic time warping, which is particularly suited to action recognition as it is expected that different actors may perform portions of actions at a varying rate [7].

The frame-wise representation of action decouples pose from its motion along the temporal domain. This approach can be effective to some level, but it ignores the temporal information focusing only on the order of poses, which limits its potential. We can model an action as a spatiotemporal construct since it is a function of time as well. It can be represented as a set of points, $\hat{A} = \{X_1, X_2 \dots X_p\}$, where $X_i = (x_i, y_i, z_i, t_i)^T$ are spatiotemporal coordinates, $p = mn$, where we have m landmarks and there are n recorded postures for that action [8]. A sample action “walking” is shown in Fig. 5 in both xyz and xyt space at different time steps.

The variability associated with the execution of an action can be closely approximated by a linear combination of action basis in joint spatiotemporal space. An instance of an action can be defined as a linear combination of a set of action basis $A_1, A_2 \dots A_k$. Therefore, any instance of an action can be expressed as $A' = \sum_{i=1}^k a_i A_i$, where $a_i \in \mathbb{R}$ is the coefficient associated with the action basis $A_i \in \mathbb{R}^{4xp}$. The space of an action, A is the span of all its action basis. The variance captured by action basis can include different execution rates of the same action, different individual styles of performances, as well as the anthropometric transformations of different actions. These action basis can be used to project a 4D pose point to its image (xyt) using a space-time projection matrix [8]. These projections are useful in forming an action representation which can further be used for recognition of new instances.

All the joints in the pose and all the time steps in a trajectory may not be required to identify the action category. We can select the joints dynamically based on the action and also choose fewer poses along the temporal domain

View-Invariant Action Recognition, Fig. 4 A sample video frame showing a pose and corresponding point-based pose representation [7]

View-Invariant Action Recognition, Fig. 5 Representation of an action in xyzt 4D space. (a) Action in xyz space, (b) action in xyt space [8]

known as canonical poses [9]. These empirically selected joints and canonical poses provide view-invariant trajectories which we call invariance space trajectories (IST). These trajectories are also invariant representations of human actions and useful for action recognition.

Spatiotemporal Volume

The tracking of joints in the motion trajectories can be effective for action representation. However, as we discussed earlier, not all joints may be useful in recognizing the performed action. Another alternative to joints is the contour of the actor, which also captures the complete

shape information. Tracking of actor contours will consider both shape and motion of the actor performing the action. When an actor performs some action in a 3D environment, the points on the outer boundary of the actor are projected as 2D (x,y) contour in the image plane. A sequence of 2D contours from frames with respect to time generates a spatiotemporal volume (STV) in (x, y, t), which is a 3D object in the (x, y, t) space [10]. The object contours in two consecutive frames can be tracked by finding a point correspondence between them. This can be done using a graph-theoretical approach by maximizing the match of a weighted bipartite

graph. In Fig. 6, we can observe some samples of generated spatiotemporal volumes for various actions.

An STV can be considered as a manifold, and it will be nearly flat for small scales defined by a small neighborhood around a point. Therefore, it can be represented as a continuous action volume \mathbf{B} by computing plane equations in the neighborhood around a point. We define it using a 2D parametric representation by considering the arc length of the contour (s), which encodes the object shape, and time (t) which encodes the motion. The action volume is defined as $\mathbf{B} = f(s, t) = [x(s, t), y(s, t), t]$. The parameters s and t can be used to generate trajectories and contours for any point in the object boundary. This representation is important for computing action descriptors corresponding to changes in direction, speed, and shape of parts of contours [10]. This can be done by analyzing the surface type of a point in STV using Gaussian curvature and mean curvature. These surface types are important action descriptors, and for any given action, they are called *action sketch*. In Fig. 6, several of these action descriptors are superimposed on the STVs for various actions. The underlying curves of the contour and point trajectory for each action descriptor in the action sketch will have a maxima or a minima. It can be proved that the maxima/minima of the contour and the trajectory will not change by changing the viewpoint of the camera. Therefore, this representation is also invariant to any change in viewpoint.

The 3D volume of STV, along with the action descriptor derived from this volume, can be used for action recognition. The relation between two STVs is defined as $x\mathcal{F}x' = 0$, where x and x' are points on two different action sketches and \mathcal{F} is a 3×3 fundamental matrix defining this relation. This relation estimates whether two different action sketches belong to the same action class and is a useful property for action recognition. This 3D volume can further be utilized to build a 4D action feature model(4D-AFM) [11]. This model elegantly encodes the shape and motion of actors observed from multiple views. A sample example for this model is shown in Fig. 7. This model enhances the view-invariant robustness of

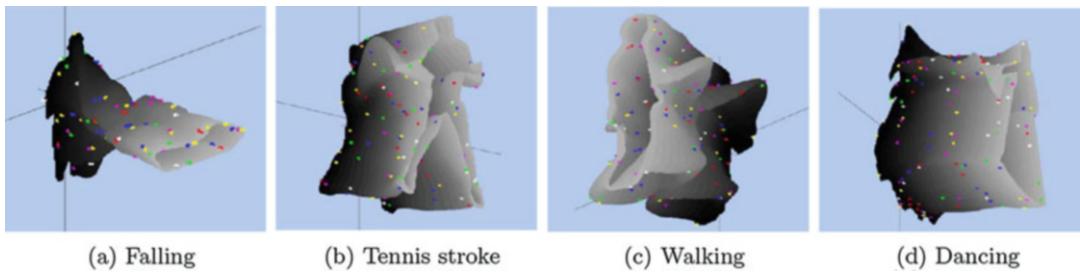

this approach, as features from multiple views are mapped to a unified model. Action recognition can be performed with this model based on the scores of matching action features from the action videos to the model points by exploiting pairwise interactions of features.

Learning-Based Methods

The classical approaches focused on finding good features and utilize simple matching-based techniques for action recognition. In learning-based methods, both feature extraction and action recognition are performed jointly. The availability of multi-view activity datasets, such as IXMAS [12], UWA3D Multiview Activity II [13], Northwestern-UCLA [14], and NTU-RGBD [3], has enabled the development of learning-based robust methods for view-invariant feature learning. These features can be learned from different types of modalities, such as RGB [2, 15], skeleton [3, 16], depth [2, 17], and optical flow [17].

We have seen earlier how motion trajectory is effective for extracting view-invariant descriptions. Apart from point-based and joint based trajectories, we can also extract dense trajectories from any action sequence. These trajectories provide dense points from each frame and track them using displacement information from a dense optical flow field. Given a dense trajectory of length L , a sequence S is formed to represent the displacement vectors $\Delta P_t = (P_{t+1} - P_t) = (x_{t+1} - x_t, y_{t+1} - y_t)$. The sequence is defined as a series of displacement vectors $(\Delta P_t, \dots, \Delta P_{t+L-1})$ which is normalized by $\sum_{i=t}^{t+L-1} \|\Delta P_i\|$. Any action sequence can be represented using this dense motion trajectory description.

These representations can be used to learn action basis if we have a limited amount of samples. We discussed earlier how these action bases can be useful for view-invariant action recognition. However, if we have a large amount of samples, computing action basis will be computationally expensive. An alternative is to perform clustering of these action descriptions and use the cluster centers as action representatives [16]. These cluster centers can further be used

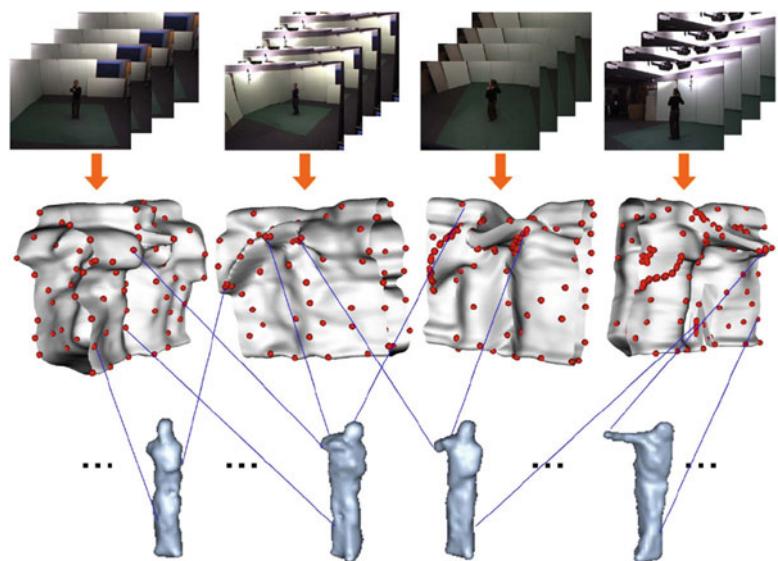

View-Invariant Action Recognition, Fig. 6 Generated spatiotemporal volumes (STVs) for some sample actions. The color-coded action descriptors are also shown corre-

sponding to ridges (yellow), saddle ridges (white), peak (red), valley (pink), and saddle valleys (green) [10]. (a) Falling (b) Tennis stroke (c) Walking (d) Dancing

Illustration of constructing 4D-AFM. The first row shows videos from four different views. The second row shows the STVs extracted from the videos and the locations of the spatiotemporal action features on the surface of STVs. These action features are mapped to the 4D action shape as shown in the third row [11]

for describing new action trajectories using bag-of-word approach. If we have a sufficient number of samples from multiple views to compute these cluster centers, then we can train a fully connected neural network to perform nonlinear transformation and learn view-invariant feature representation. These learned view-invariant features can then be used to perform robust action classification on novel and unseen views.

Multitask learning The dense trajectories can be very effective for learning view-invariant representations for action recognition. However, they require an additional computation time, which is not suitable for systems with low latency. Convolutional neural network provides an efficient way to learn meaningful represen-

tations directly using the input video. These networks can be very effective in performing action classification on videos with previously seen views. However, they fail to generalize well for unseen views which are not present in the training data. This is caused due to the absence of view-invariance in the learned representation. This can be addressed by a multitasking approach where the representation is also utilized for some other task which enforces the network to learn a view-invariant representation. This task could be a prediction of optical flow from unseen view [17] or cross-view video synthesis [2]. Both these approaches enable the network to learn view-invariant feature representations and perform well on action recognition for unseen views.

Datasets and Experimental Results

The availability of public datasets for multi-view action recognition enables the research community to benchmark the research progress. There are four main public datasets which are widely used and provide action sequences captured from multiple viewpoints.

IXMAS The Inria Xmas Motion Acquisition Sequences (IXMAS) dataset [12] have videos for 11 action classes with actions performed 3 times by 10 actors. All actions have been captured using five camera views.

UWA3D Multiview Activity II This dataset [13] contains RGB videos of 30 human activities performed by 10 subjects with different scales. Each subject performed all the actions 4 times. Depth and Skeleton data captured using Kinect is also available with this dataset.

Northwestern-UCLA Northwestern-UCLA Multiview 3D event dataset [14] contains RGB, depth, and human skeleton data captured simultaneously by three Kinect cameras. This dataset has ten action categories, and each action is performed by ten actors. There are a total of 1493 action sequences. There are two main data splits: cross-subject (CS) and cross-view (CV) as suggested by [14]. View-invariant action recognition is examined with CV split where videos from the first two views are used for training, and the third view is for testing.

NTU RGB-D This is the largest dataset for view-invariant human action recognition [3]. Along with RGB videos, depth and skeleton data is also available. It contains more than 56K videos and 4 million frames with 60 different action classes. There are a total of 40 different actors, who perform actions captured from 80 different viewpoints.

Northwestern-UCLA and NTU RGB-D datasets provide multiple modalities, such as RGB, depth, and skeleton, along with multiple views to perform view-invariant action recognition. The performance of a method is

evaluated by computing an accuracy score based on whether it predicts the correct action class or not. In Tables 1 and 2, we can observe the performance of different methods using different modalities on Northwestern-UCLA and NTU RGB-D datasets. The cross-subject (CS) evaluation measures the performance on unseen subjects, and the cross-view (CV) evaluation measures the performance on unseen views. The cross-subject performance is better than cross-view performance for most of the methods. This is mainly due to high variation in actions when seen from different viewpoints as compared with an unseen person where the appearance will have more variation. Therefore, the methods which focus on the motion will perform better than those which focus more on the appearance of the actor.

Conclusion and Open Problems

Action recognition for unknown and unseen views is a challenging problem. The tracking of motion trajectories have found to be successful so far, but they are computationally expensive to extract and therefore not scalable for large-scale scenarios. The availability of large-scale multi-view datasets has enabled us to develop networks which are effective in recognition performance and can be trained end-to-end. However, their performance is limited by the variation of viewpoints in the available datasets. These datasets are lab curated, and actions are performed in a controlled environment. Apart from this, they are also limited in terms of variation in the number of available viewpoints. Therefore, it will be challenging to generalize the methods trained on these datasets to real-world scenarios.

Definition

Vignetting is a reduction of an image's brightness at the periphery compared to the center of the image. It describes the effective falloff in irradiance for off-axis points for imaging systems.

Background

In real imaging systems, the image brightness is often reduced at the periphery compared to the center of the image. This effect is known as vignetting and is undesirable for computer vision algorithms that rely on measured pixel intensities. Vignetting can be caused by several mechanisms. The image irradiance varies across the field of view according to the fourth power of the cosine of the field angle. This off-axis illumination falloff is one of the prominent reasons for vignetting and is also referred to as cosine-fourth falloff [1].

Vignetting can also be caused by optical and mechanical effects. Light rays arriving at oblique angles to the optical axis may be obstructed by the aperture stop, lens rim, or improper lens hood. This could lead to spatially varying attenuation over the entire image. A large aperture causes more vignetting, and using a small aperture (increasing the F-number) can reduce it. Real lenses often have multiple lens elements to correct for spherical and chromatic aberrations. Rear

lens elements may be partially occluded by front lens elements, reducing off-axis illumination.

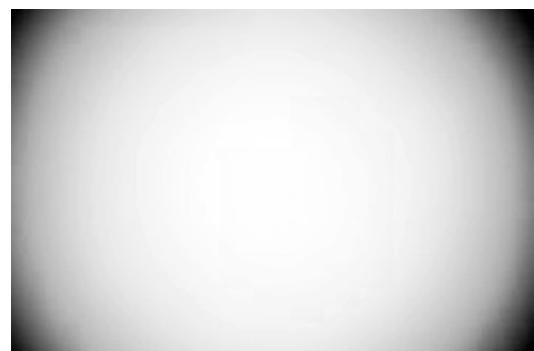

For digital cameras, pixel vignetting is another vignetting effect caused by the variation in angular sensitivity of digital sensors to the incoming light. A micro-lens array on top of the sensor helps to collect off-axis light and can reduce pixel vignetting.

Pupil aberration [2] is another cause of irradiance falloff at the periphery. This is attributed to nonlinear refraction of rays resulting in a nonuniform light distribution across the aperture.

Theory

It is important to remove vignetting effects for computer vision applications. A simple way to remove vignetting is to capture a reference photo of a uniformly illuminated white background. This reference photo can be used to cancel the vignetting effect on subsequent images captured by the camera. However, such a reference photo is valid only for the images captured under the same camera settings (zoom, aperture) and the same illumination conditions. This approach cannot be used on photos captured under settings other than those used for the reference photo or on photos captured by unknown cameras. Techniques that model the vignetting effects to recover a vignetting-free image [3–8] are useful in such scenarios (Fig. 1).

Let $\mathbf{x} = [u, v]$ denote a pixel \mathbf{x} with coordinates u and v . The observed image intensities $I(\mathbf{x})$

V

Vignetting, Fig. 1 An example of vignetting

can be modeled as

$$I(\mathbf{x}) = \text{CRF}(kL(\mathbf{x})V(\mathbf{x})), \quad (1)$$

where $L(\mathbf{x})$ is the true irradiance, $V(\mathbf{x})$ denotes the attenuation due to vignetting, k is the exposure value, and $\text{CRF}(\cdot)$ is the camera response function. Several models for the vignetting function $V(\mathbf{x})$ exist [3, 5, 6]. The polynomial vignetting model is given by

$$V(\mathbf{x}) = 1 + \sum_{n=1}^D \beta_n r(\mathbf{x})^{2n}, \quad (2)$$

where $r(\mathbf{x})$ is the distance of pixel \mathbf{x} from the image center. Similar model based on hyperbolic cosine functions is described in [7].

In [9], Kang and Weiss proposed a model to correct for vignetting effects using a single photo of a flat, textureless surface. Their model describes the overall image attenuation in terms of an off-axis illumination factor $A(\mathbf{x})$, a camera tilt factor $T(\mathbf{x})$, and a geometric factor $G(\mathbf{x})$:

$$V(\mathbf{x}) = A(\mathbf{x})G(\mathbf{x})T(\mathbf{x}), \quad (3)$$

where

$$A(\mathbf{x}) = \frac{1}{(1 + r^2(\mathbf{x})/f^2)^2}, \quad (4)$$

$$G(\mathbf{x}) = 1 - \alpha r(\mathbf{x}), \quad (5)$$

$$T(\mathbf{x}) = \cos \tau \left(1 + \frac{\tan \tau}{f} (u \sin \psi - v \cos \psi) \right)^3, \quad (6)$$

f denotes the effective focal length and α is a constant describing the geometric factor $G(\mathbf{x})$. The camera tilt factor $T(\mathbf{x})$ is described using a tilt axis in a plane parallel to the image plane at an angle ψ with respect to the x -axis, and the tilt angle is denoted by τ . $T(\mathbf{x})$ is used to account for the foreshortening of the imaged surface with respect

to the camera. An extended version of Kang-Weiss model is described in [3]. These models can be used to correct the vignetting effects.

Application

Vignetting is usually an undesirable effect caused by real imaging systems. Due to vignetting, the observed image intensities deviate from those predicted by standard models of image formation. Thus, computer vision algorithms may not perform well in presence of vignetting. On the other hand, photographers sometimes introduce intentional vignetting for artistic effects, such as to draw attention to the center of the frame. Vignetting can also be used for camera calibration under certain conditions [9, 10].

Vignetting models can be used to recover a vignetting-free image. Examples of vignetting removal are presented in [3–5]. Vignetting correction is also used in stitching multiple photos to compensate for the varying intensity of scene points across different images [5, 6].

Viscosity Solution

Fabio Camilli¹ and Emmanuel Prados²

¹Dipartimento SBAI, “Sapienza”, Università di Roma, Rome, Italy

²INRIA Rhône-Alpes, Montbonnot, France

Definition

Viscosity solution is a notion of weak solution for a class of partial differential equations of Hamilton-Jacobi type.

Background

A first-order partial differential equation of the type

$$H(x, u(x), Du(x)) = 0 \quad (1)$$

is called a Hamilton-Jacobi equation. A function u is said to be a classical solution of (Eq. 1) over a domain if u is continuous and differentiable over the entire domain and x , $u(x)$, and $Du(x)$ (the gradient of u at x) satisfy the above equation at every point of the domain. Consider the boundary value problem

$$|u'(x)| - 1 = 0 \text{ for } x \in (-1, 1), u(\pm 1) = 0. \quad (2)$$

By Rolle’s theorem, it is easily seen that classical solutions of the previous problem do not exist, whereas there exist infinite many weak solutions, that is, continuous functions which satisfy the equation at almost every point (the saw-tooth solutions, see Fig. 1a).

At first, this situation can seem rather atypical, but in fact, it is nothing of the sort. For example, it concerns the distance functions which are widely used in computer vision. In particular, it is easy to see that the distance function of a closed curve in a plan, which typically has strong edges (see Fig. 1), is almost everywhere a solution of the Eikonal equation

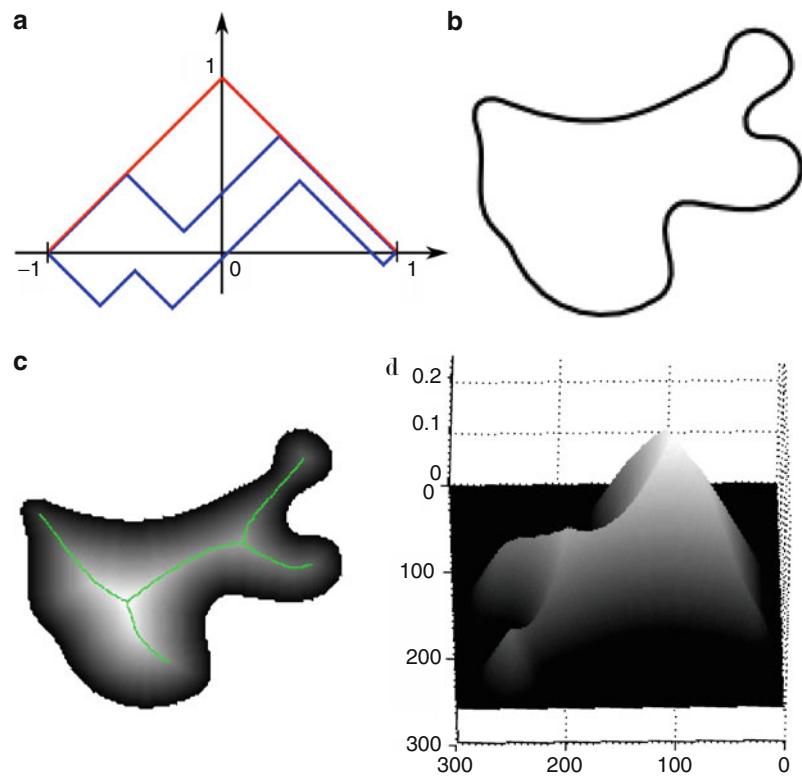

$$|Du(x)| - F(x) = 0 \quad (3)$$

with $F(x) = 1$ and $u(x) = 0$ on the curve. Also, in general, as in the case of (Eq. 2), this last equation has no classical solution. Another typical example concerns the shape-from-shading problem which naturally yields a Hamilton-Jacobi equations having the same behavior. In particular, by modeling the problem with an orthographic camera, a directional front lighting, and a Lambertian surface, the problem consists then in solving an Eikonal equation in which the function F depends on the considered image.

It is therefore very important to have a theory which allows merely continuous functions to be solutions of Hamilton-Jacobi equations and to provide at the same time a way to select the relevant solution among the weak solutions of the problem.

Viscosity Solution, Fig. 1

Distance functions in 1D and 2D: (a) three examples of weak solutions of (Eq. 2). The red curve corresponds to the viscosity solution. (b) Example of a closed curve in the plan. (c) Distance function (represented as a color map) to the curve displayed in (b). To improve the visibility, the distance function is only displayed inside the curve. As usually, one can distinguish strong edges we have partly highlighted by green curves. This gives the skeleton of the shape. (d) 3D representation of the function distance (c). The distance function is the viscosity solution of the Eikonal Equation (Eq. 3), with $F(x) = 1$ and $u(x) = 0$ on the curve

**Theory**

The notion of viscosity solution was introduced at the beginning of the 1980s by M. G. Crandall and P. L. Lions [1], and it is related to Kruzkov's theory of entropy solutions for scalar conservation laws.

The basic idea is to replace the differential $Du(x)$ at a point x where it does not exist (e.g., because of a kink in u) with the differential $D\phi(x)$ of a smooth function ϕ touching the graph of u , from above for the subsolution condition and from below for the supersolution one, at the point x .

Definition 1

(i) A continuous function u is said to be a viscosity subsolution of (Eq. 1) if for any x and for any smooth function ϕ such that $u - \phi$ has a maximum point at x , then

$$H(x, u(x), D\phi(x)) \leq 0.$$

(ii) A continuous function u is said to be a viscosity supersolution of (Eq. 1) if for any x and for any smooth function ϕ such that $u - \phi$ has a minimum point at x , then

$$H(x, u(x), D\phi(x)) \geq 0.$$

(iii) A continuous function u is said to be a viscosity solution of the Hamilton-Jacobi equation if it is a viscosity subsolution and supersolution.

There is also an equivalent definition for viscosity solution which involves the notion of sub- and super-differentials (see [2]).

It is straightforward to observe that solutions in the classical sense are viscosity solutions. Inversely, if a viscosity solution u is differentiable at x , then it solves the equation at this point in the classical sense. Hence, the notion of viscosity solution includes the one of classical solution.

By looking closely at the definition, one can understand rather intuitively how it allows a specific weak solution to be selected among the other

ones and which of them is selected. In fact, this definition eliminates a certain type of edges. In particular for Hamilton-Jacobi (Eq. 2), the definition allows upward edges, but not downward edges. Thus, in Fig. 1, all the weak solutions of (Eq. 2) which have downward edges are then excluded. Also, only the maximal weak solution (represented in red) is a viscosity solution.

In addition, the definition of viscosity solutions selects among the almost everywhere solutions the one which is consistent with the regularized problem. In fact, the name “viscosity” is motivated by the consistency of the notion with the method of “vanishing viscosity”: the viscosity solution of (Eq. 2) can be obtained as the limit for $\epsilon \rightarrow 0$ of the classical solutions of

$$\begin{aligned} -\epsilon u''(x) + |u'(x)| - 1 &= 0 \text{ for } x \in (-1, 1), \\ u(\pm 1) &= 0 \end{aligned} \quad (4)$$

(the term ϵ has the physical meaning of a viscosity coefficient).

The main characteristics of the notion of viscosity solution are:

- (i) A very efficient and flexible way to prove uniqueness theorems and comparison principles
- (ii) General existence results obtained via the adaptation of the classical Perron's method, by approximation arguments (such as the vanishing viscosity method in (Eq. 3)), by means of representation formulas (via dynamic programming methods in optimal control theory), etc.
- (iii) The stability of the notion of viscosity solution with respect to the uniform convergence, and its generalizations, which allows to prove, for example, the convergence of numerical schemes
- (iv) The correct formulation of various boundary conditions, including the classical Dirichlet, Neumann, and oblique derivative conditions

For good accounts of the viscosity solution theory, we refer to [2–5]. Finally, let us note

that the notion and the theory of viscosity solutions have been extended to a large class of partial differential equations. In particular, a number of results allow us to deal with second-order equations [6], degenerate equations [7], and integro-differential equations [8, 9]. The application to convergence of numerical schemes is also very important; see, for example, [10] and the appendix by Falcone in [2].

Application

The range of applications of the notion of viscosity solution is enormous, including common class of partial differential equations such as evolutive problems and problems with boundary conditions, equations arising in optimal control theory (the Hamilton-Jacobi-Bellman equation), differential games (the Isaacs' equation), second-order equations arising in stochastic optimal control and stochastic differential games, and geometric equations (mean curvature and Monge-Ampere equations).

In computer vision, it has various applications. In particular, the distance functions and the Eikonal equations are widely used. Nowadays, thanks to the links between the viscosity solutions and the optimal control theory [2], one can easily prove that the distance functions correspond to the viscosity solutions of the Eikonal equations, which, moreover, provide various convenient tools for computing them. Also, all these notions have played an important role in shape representation [11, 12], in morphology [13, 14], in tractography [15–17], and in general, in image processing [17–19]. Furthermore, they are intensively used in the level set framework where the curves and the surfaces are represented by their signed distance functions [19, 20]. The latter framework is used extensively, for example, in segmentation and 3D reconstruction.

Another main application of the notion of viscosity solution is to shape-from-shading problems, which give rise to first-order differential and integro-differential equations of Hamilton-Jacobi type; see [21, 22], and the entry *Shape from Shading*. A natural question in this context

is why the viscosity solutions provide suitable solutions to this specific problem. In other words, why would the viscosity solutions have more sense than any other weak solution? In fact, here, the values of the viscosity solutions mainly come from its amazing stability combined with its consistency with the classical solution. To be more clear, let us consider the shape-from-shading problem with a continuous image I of a real scene. In such a case, to be physically plausible, the real surface u^* behind this image must be smooth (C^1); otherwise, any infinitesimal displacement of the light direction would break this continuity property. Let I^* be the virtual image generated by the considered image formation model with surface u^* . I^* is necessary close to I , if not this would mean that the considered model is not appropriate. Then, thanks to the stability properties, the unique (To be well posed the problem in the viscosity sense, we can assume that we have adequate boundary constraints, for example, only Soner constraints on the boundary of the image if we consider the model of [23].) viscosity solution u to the shape-from-shading Hamilton-Jacobi equation associated with the real image I is close to u^* , because u^* is the viscosity solution to the same equation in which we replace I by I^* (since it is also a solution in the classical sense). In other words, among all the weak solutions of the considered shape-from-shading equation (which has no solution in the classical sense with the real image I because of the modeling errors and the noise), the viscosity solution is necessarily close to the real surface which has been photographed.

Definition

Visual cognition is the branch of psychology that is concerned with combining visual data with prior knowledge to construct high-level representations and make unconscious decisions about scene content [1].

Background

Although the terms visual cognition and cognitive vision are strikingly similar, they are not equivalent. Cognitive vision refers to goal-oriented computer vision systems that exhibit adaptive and anticipatory behavior. In contrast, visual cognition is concerned with how the human visual system makes inferences about the large-scale composition of a visual scene using partial information [1–3].

Theory

Visual cognition, often associated with high-level vision and top-down visual processing, constructs visual entities by collecting perceived parts into coherent wholes, determining which parts belong together. Since the sensory data on which the processes of visual cognition operate are typically incomplete and insufficient to specify the percept of which we are aware, there are many possible solutions or interpretations. Consequently, additional extraretinal information, often referred to as object information, is used by visual cognition to infer what the percept is.

The entities that are constructed by visual cognition include both static structures, such as perceived surfaces and objects, and dynamic entities that emerge over time, such as patterns of biological motion. The dynamics of these visual entities can be used to infer a causal relationship between events or to attribute some sense of

intentionality to the entity. Thus, the unconscious inferences of visual cognition also impact on the construction of a theory of mind for other cognitive agents, i.e., the inference of the goals of other agents [4].

A key role of the representations of visual cognition is their use to communicate with other centers of the brain. Thus, visual cognition provides a bridge to general high-level cognitive function while still making its own independent cognitive inferences. In essence, visual cognition constructs a representation of the visual world which is constantly updated on the basis of new visual data and which encapsulates knowledge about the world in a high-level descriptive manner that can be exchanged with the rest of the brain.

Visual cognition addresses several distinct areas such as visual attention (including spatial attention, selective attention, visual search, change detection, and the control of eye movements) [5–8], short-term and long-term visual memory [9], and object, face, and scene recognition [10, 11].

The processes of visual cognition are held to be principally unconscious, operating rapidly on the flux of visual data sensed by the retina in order to choose the conscious percept of which we become aware. Consequently, visual cognition embraces both the selectivity of visual attention and unconscious inferential decision-making.

Although the primary concern of visual cognition is human visual perception and not computer vision, the two fields share some common ground. For example, many of the theories of visual cognition have their roots in cognitivist psychology which asserts that cognition is intrinsically computational [12, 13]. This has led to several computational models of visual cognition, combining relevant aspects of computer and human vision.

Open Problems

There is some debate in the psychology community as to where one should draw the line between

vision and cognition and how sharply one should draw it; for comprehensive discussion, see the paper by Pylyshyn [14], the many commentaries on it (e.g., [15]), and his response [16]. The issue revolves around the cognitive impenetrability of visual perception: whether or not any cognitive functionality such as inference or rationality is involved in visual perception, especially early vision. Cavanagh's recent review [1] suggests that the visual system does have its own independent cognitive processes, quite apart from the more general cognition that occurs in other parts of the brain and with which the processes of visual cognition interact.

Visual Cortex Models for Object Recognition

Tomaso Poggio and Shimon Ullman

Department of Brain and Cognitive Sciences,
McGovern Institute, Massachusetts Institute of
Technology, Cambridge, MA, USA

Definition

Visual cortex model-based methods aim to develop algorithms for object detection, representation and recognition that attempt to mimic human visual systems.

Background

Object recognition is difficult Like other natural tasks that our brain performs effortlessly, visual recognition has turned out to be difficult to reproduce in artificial systems. In its general form, it is a highly challenging computational problem which is likely to play a significant role in eventually making intelligent machines. Not surprisingly, it is also an open and key problem for neuroscience.

Within object recognition, it is common to distinguish two main tasks: identification, for instance, recognizing a specific face among other faces, and categorization, for example, recognizing a car among other object classes. We will

discuss both of these tasks below, and use “recognition” to include both.

Models of the visual cortex Over the last two decades, some of the best performing recognition systems have come from research at the intersection of computational neuroscience and computer vision. Recent models of visual cortex based directly on known functional anatomy [20, 21] and building on earlier attempts (e.g., [1, 6, 15, 19, 22–24]) were able to account for and predict a number of physiological data from areas of the ventral stream from V1 and V2 to V4 and IT. This family of models was able to mimic human performance in rapid categorization tasks [20]. Surprisingly, some of these models of visual cortex were among the best computer vision systems at the time [16–18, 21].

Computer Vision and the Visual Cortex: Fundamental Differences

The recent past has shown convergence of computational schemes and brain modeling. There still are, however, major differences between models and the cortex, as well as large differences in performance between models and the brain. We will discuss below two examples of prominent features of cortical structure which have only a minor role in current computational models.

Why Hierarchies

The organization of visual cortex is hierarchical, with features of increasing complexity represented at successive layers. Models of the visual cortex have naturally adopted hierarchical structures. In contrast, in computer vision, the large majority of current schemes are nonhierarchical, with no clear difference in performance between hierarchical and nonhierarchical models. Some computational schemes, however, may be implicitly hierarchical and possibly derive some of their power from their hierarchical organization. For instance, SIFT [13] can be regarded as a three-layer network with the output roughly corresponding to intermediate units in a hierarchical

cortical model [19]. What is the possible advantage of hierarchical visual representations, and can artificial systems benefit from adopting such representations?

Scale and position invariance One possible role of feature hierarchies is the need to achieve a useful trade-off between selectivity to complex patterns and sufficient tolerance for changes in position and scale, as seen in the response of IT neurons [10–12]. While scale and position invariance can be achieved quite readily in computer vision systems by sequentially scanning the image at different positions and scales, such a strategy appears unlikely to be realized in neural hardware. When properly measured, scale and position tolerance for new objects is less than originally claimed [2], but still substantial [8, 12]: for at least some of the cells in AIT, position tolerance is on the order of 2–4 degrees in the fovea and scale invariance is on the order of a factor of 2–4, which is remarkable large. It is still not entirely clear how such generalization can be achieved without training for different positions and sizes for each object. It appears possible that hierarchical representations make it possible to transfer invariant recognition from previously trained objects to novel objects by the reuse of shared parts at multiple levels.

A second possible advantage of hierarchical representations has to do with efficiency – computational speed and use of computational resources. For instance, hierarchy may increase the efficiency of dealing with multiple classes in parallel, by allowing the use of shared features at multiple levels. An increase in efficiency may also be related to the issue of *sample complexity*. Hierarchical architectures in which each layer is adapted through learning to properties of the visual world may reduce the complexity of the learning task and thus the overall number of labeled examples required for training. Finally, hierarchies also offer an advantage in not only obtaining recognition of the object as a whole but also recognizing and localizing parts and subparts at multiple levels, such as a face together with the eyes, nose, mouth, eyebrow, nostril, upper lip, and the like (see [5]).

Feed Forward vs. Back Projections

A feed-forward architecture from V1 to prefrontal cortex, in the spirit of the Hubel and Wiesel simple-complex hierarchy, seems to account for several properties of visual cells. In particular, recent “readout” experiments measuring information that could be read out from populations of IT cells [8] confirm previous estimates that, after about \sim 100 ms from onset of the stimulus, performance of the classifier was essentially at its asymptotic performance during passive viewing.

In addition, feed-forward models also appear to account for recognition performance of human subjects for images flashed briefly and followed by a mask [20–22].

The evidence suggests, therefore, that a feed-forward process is sufficient for a fast initial recognition phase, during which primates can already complete difficult recognition tasks involving “what” is in the image. What, then, is the role of the extensive anatomical back projections in the primate visual system?

Their role may be restricted to learning, but we believe it is broader. Even when the feed-forward projections by themselves may be capable of answering the “what” question of vision, the back projections may play a role in answering the detailed question of “what is where” [14]. This proposal is similar to previous ideas suggesting that visual cortex follows a hypothesis-and-verification strategy [3, 7] or a Bayesian inference procedure in which top-down priors are used to compute a set of mutually consistent conditional probabilities at various stages of the visual pathway [9]. A recent model [5] along these lines demonstrated the use of initial classification using a bottom-up sweep, followed by precise localization of the object and its parts and subparts by a top-down pass.

Top-down pathways in the visual cortex also include the dorsal stream and connections between the dorsal and the ventral stream that are likely to be involved in attentional effects. A Bayesian model [4], which takes into account these bottom-up and top-down signals, performs well in recognition tasks and predicts some of the main psychophysical and

physiological properties of attention. For natural images, the top-down signal improves object recognition performance and predicts human eye fixations well. The top-down flow of information combined with a hierarchical representation allows the system to answer not only the *what* question, that is, to perform object identification and categorization, but also the *what is where* question, that is, identification and localization at multiple levels. This is a useful addition, but at the same time we do not believe that the process of vision can be fully characterized in terms of answering “what is where” [14]. For example, humans can recognize subtle aspects of actions, goals, and social interactions at a level which is far beyond the capabilities of our present algorithms. They also can answer essentially any reasonable question, beyond what and where, on any given image – in a kind of Turing test for vision. The top-down pathway is likely to play an important role for this broader range of visual tasks.

Discussion: Future

We briefly consider two problem domains for future studies. The first focuses on how to close the gap between computer and human vision in the tasks considered above – object categorization and identification. The second part considers broader aspects of vision and its roots in evolution.

Closing the Performance Gap

One general question regarding possible improvements in visual recognition is whether recognition is obtained by multiple specialized mechanisms or by a uniform scheme applied to different recognition tasks. For example, suggestions have been made that general categorization and individual recognition may be subserved by different mechanisms or that face recognition may depend on special mechanisms, not used for other object categories. It appears to us that the underlying computational problems

in different recognition tasks are similar and can therefore be approached by the same general scheme, applied to different training sets (and possibly implemented by more than a single neuronal mechanism). It is also possible that certain cortical regions could specialize in specific categories (such as faces or locations) not because they implement different recognition strategies, but to facilitate selective readout by other cortical regions. The basic recognition scheme could be augmented, however, by specialized mechanisms, dealing with special cases and exceptions. The full system could then be a combination of a scheme that may be characterized as rule based, which can capture the main properties of a category and generalize broadly to novel examples, and a memory-based recognition scheme, which can deal with atypical cases and exceptions to the rule-based scheme.

We next consider future directions which we think could play a useful role in bringing the performance of artificial recognition models closer to the performance level of human vision. These are not the only possible routes for closing the performance gap, but they provide examples of promising general directions motivated by human perception that could usefully be incorporated into artificial systems.

Continuous learning of rich models In current computational schemes, a model for the object or category of interest is constructed during a learning stage and then used for recognition. In contrast, the primate visual system shows continuous plasticity and can continue to learn when confronted with new examples. The disadvantage of a fixed limited training stage is that the resulting object model may remain too simple. A visual category often contains a core of typical examples but also a large number of possible variations, atypical members, and counterexamples. An object can be recognized by its overall shape, but also by small distinguishing parts, and both aspects need to be included in its representation. To achieve human-level performance, it appears therefore that it will be necessary to construct rich object models, learned continuously from a large number of examples.

Such use of continuous learning raises interesting computational challenges: new methods will be required to learn from errors, and to continuously modify an existing representation based on new incoming information, possibly combining rule-based and memory-based mechanisms mentioned above.

Integrating segmentation and recognition

Recognition and segmentation are related tasks in the perception of objects: we can usually recognize the object and at the same time identify in the image the precise region containing the object of interest. Historically, segmentation and recognition were treated in computer vision as sequential processes: figure-ground segmentation first identifies in the image a region likely to correspond to a single object; recognition processes are subsequently applied to the selected region to identify the segmented object. More recently, computational models started to treat the two tasks together, performing object segmentation not only in a bottom-up manner based on image properties, but also in a top-down manner based on object representations stored in memory. This led to substantial progress in object segmentation; however, most current recognition systems do not include segmentation as an integral part of the recognition process. It seems to us that recognition and segmentation are closely linked tasks, and their solutions constrain each other. This integration appears to be supported by considerable physiological and psychophysical evidence [25, 26]. A closer integration of recognition and segmentation at both the object and part levels is likely therefore to improve the recognition of objects and their parts.

A Greater Challenge: Vision and Evolution

The brain uses vision, together with other senses, to obtain knowledge about the world and act upon it. This knowledge goes beyond object recognition and categorization: vision is also used, for example, to recognize actions performed by

agents in the surrounding environment as well as their goals and social interactions.

It seems to us that these broader aspects of visual recognition cannot be efficiently handled by simple extension of existing recognition methods. It is likely that in addition to the general learning mechanisms currently used in object recognition models, the brain also uses specialized mechanisms, which have evolved to focus on and extract information required for making judgments about actions, goals, social interactions, and the like. Innate structures and circuits in the brain by themselves do not incorporate full solutions to these challenging problems, but are more likely to provide useful constraints and initial biases which later lead, guided by learning from the environment, to powerful specific mechanisms.

A general broad question for future studies is therefore the nature of the innate machinery used by the visual system, its genetic encoding, and how the combination of innate machinery and learning from the environment leads to our understanding of the visual world.

Visual Hull

David C. Schneider

Image Processing Department, Fraunhofer Heinrich Hertz Institute, Berlin, Germany

Synonyms

Shape from Silhouette

Definition

The visual hull of a three-dimensional object is a bounding volume of the object which is computed from the object's silhouettes in the images of multiple calibrated cameras by intersecting the object's viewing cones.

Background

The concept of visual hull is based on two intuitions: Firstly, the shape of a three-dimensional object is bounded by the silhouette of its projection in an image. Secondly, if several projections from multiple viewpoints are available,

these constraints can be combined to obtain an approximation of the object’s shape. The practical relevance of visual hull algorithms lies in the fact that they can compute an approximate 3D shape using only silhouettes and calibration data. These are often easier and faster to obtain than image-to-image correspondences, especially for camera configurations with few cameras and/or wide baselines. Visual hull computation is the prototypical example of a shape-from-silhouette method.

The term “visual hull” was coined by Laurentini [1, 2] who studied the properties of hulls obtained from an infinite number of cameras. However, the underlying concepts – the intersection of viewing cones – can be traced back to the early 1970s (e.g., [3]). Sometimes, the term “visual hull” is restricted to the theoretical case of infinite camera count; hulls computed from a finite number of cameras are then regarded as approximations.

Theory

Definition

The visual hull of an object can be defined either as a surface or as a volume. The following definition is volumetric. Assume that the object can be represented as a surface S in three-dimensional space. Further assume that there are n cameras viewing the object. The *viewing cone* C_i of S with respect to camera $i \in 1 \dots n$ is a generalized cone defined as the union of all rays that originate from the camera’s optical center \mathbf{c}_i and pass through any point \mathbf{p} on S (Fig. 1, right):

$$C_i = \bigcup_{\mathbf{p} \in S, \lambda \geq 0} \lambda \mathbf{p} + (1 - \lambda) \mathbf{c}_i$$

The *visual hull* \mathcal{H} of S is the intersection of all viewing cones (Fig. 1, left):

$$\mathcal{H} = \bigcap_{i=1 \dots n} C_i$$

Seen as a surface, the visual hull is the boundary of this volume.

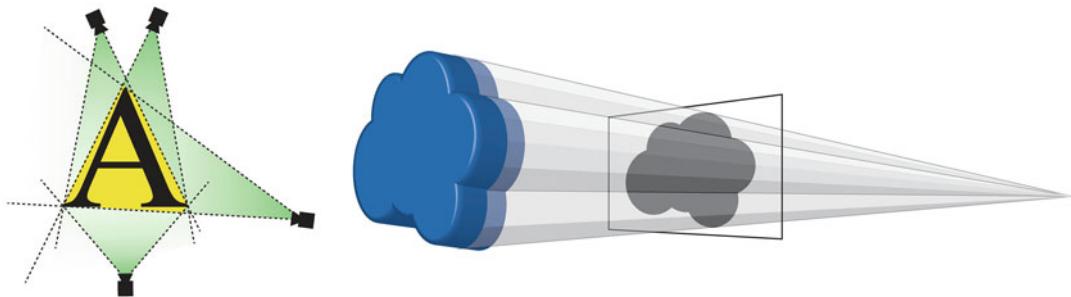

Properties

The visual hull bounds the shape it is constructed from, that is, the volumetric intersection of the hull and the original shape is the shape itself. How closely an object’s true 3D shape can be approximated by its visual hull depends on two factors:

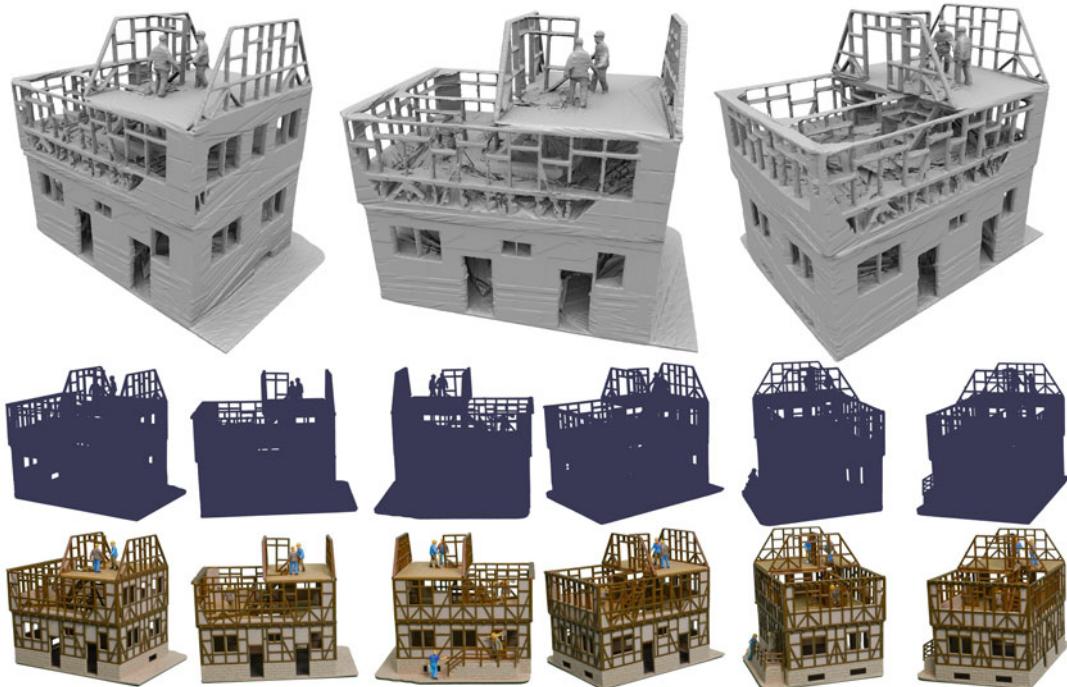

- (1) *The geometry of the object.* The visual hull can represent some but not all concavities of an object. Intuitively, a concavity can be represented if (and as far as) there exists a line through the concavity which does not intersect the object. Or, equivalently, it can be represented if and as far as there exists a location and orientation for a camera such that the concavity in the object is represented as a concavity in the silhouette of the object in the camera image. A straightforward example of a representable concavity is the handle of a tea cup. The inside of the cup, on the other hand, is not representable (unless a camera is placed inside the cup).
- (2) *The number and placement of the cameras used for computing the hull.* A high count and a regular distribution of cameras are beneficial. With a finite number of cameras, the visual hull typically has a “piecewise extruded” look Fig. 2 shows an example of representable on non-representable geometry in a visual hull reconstruction.

Algorithms

The above definition of the viewing cone only refers to *whether* a ray intersects the surface and not *where*. Therefore, the viewing cones can be computed without knowledge of the shape S as long as the set of intersecting rays can be computed. Whether a ray of a specific view intersects the surface can be determined from the view’s camera matrix and a foreground-background mask, or silhouette, which classifies each pixel as showing a part of S or the background. Therefore, the visual hull is a shape approximation which can be computed solely from calibrated cameras and a foreground-background segmentation.

Visual Hull, Fig. 1 *Left:* The visual hull (yellow) of the object (A) is the intersection of the four viewing cones (green). *Right:* The viewing cone of a 3D object and its relation to the object’s silhouette (mask) in an image

Visual Hull, Fig. 2 Renderings of the visual hull of a toy house (top row). The hull was computed from the masks (middle row) of 216 turntable images of the object (bottom row). Note that fine structures, like the beams, are well

represented in the hull as long as they are individuated in the masks. Surface details, on the other hand, cannot be reproduced by the hull

In contrast to the above definition, it is easier to project voxels from the volume into the images than to shoot rays into the volume. The most simple visual hull algorithm is the following: First, all voxels of the volume are marked as “occupied.” Then the voxels are traversed and the center of each voxel is projected into all available segmentation masks. A voxel is marked as “unoccupied” if its center projects to a background pixel in *any* of the masks.

For high volume resolutions, traversing all voxels is inefficient with respect to memory usage and computation time. Therefore, many algorithms represent the volume using a hierachic spatial data structure such as an octree, for example, [4, 5]. When octree cells are projected into the segmentation masks, their spatial extent must be accounted for: An octree cell must be subdivided if any of its projections spans foreground as well as background pixels.

While the volumetric approach makes hull computation relatively simple, it may complicate the further use of the visual hull itself. For many applications, such as rendering on graphics hardware or CAD, a polyhedral surface representation is required. Computing a surface from volume data is a nontrivial task which is often approached with the marching cubes algorithm. The resulting surfaces, however, may require further processing to reduce their high polygon count. This has led to the development of algorithms which directly compute a polyhedral representation of the visual hull, for example [6, 7].

Application

The visual hull is often used as an initialization and/or as a constraint for 3D reconstruction algorithms. Since the visual hull bounds the true shape, the true shape can be found by removing voxels from the hull. Hull computation, on the other hand, ignores consistency of appearance between multiple views (“photoconsistency”). Therefore, volumetric 3D reconstruction algorithms often aim at minimizing a photoconsistency-based error by removing voxels from the hull. Early examples are space carving [8] or the multi-hypothesis algorithm of [9]. Visual hulls are also used to initialize non-volumetric algorithms such as patch-based stereo [10].

The visual hull is sometimes used directly as shape approximation (“proxy”) for image-based rendering and visualization. This approach is particularly successfull for objects where the hull is a good approximation of the actual shape, for example the human body. Hull-based free-viewpoint rendering systems for scenes with humans are described, for example, by [12]. For this type of application, real-time capable hull algorithms have been developed. In [11], for example, new viewpoints are rendered without explicitly representing the geometry of the visual hull.

Obtaining a good segmentation is often a challenge when using visual hull in practice. However, the hull is more sensitive to some types of errors in the masks than others: A voxel is only falsely marked as occupied if the corresponding pixel is falsely classified as foreground in all masks. Conversely, a voxel is falsely marked as unoccupied if a pixel is falsely marked as background in a single mask.

Visual Servoing

François Chaumette
Inria, Univ Rennes, CNRS, IRISA, Rennes,

Synonyms

Vision-based control; Visual feedback

Definition

Visual servoing refers to the use of visual data as input of real-time closed-loop control schemes for controlling the motion of a dynamic system, a robot typically. It can be defined as sensor-based control from a vision sensor and relies on techniques from image processing, computer vision, and control theory.

Background

Basically, visual servoing consists in using the data provided by one or several cameras so that a dynamic system achieves a task specified by a set of visual constraints [3, 12]. Such systems are usually robot arms or mobile robots, but can also be virtual robots, or even a virtual camera. A large variety of positioning tasks, or target tracking tasks, can be considered by controlling from one to all the degrees of freedom (DoF) of the system. Whatever the sensor configuration, which can vary from one on-board camera located on the robot end-effector to several free-standing cameras, a set of visual features has to be selected at best from the available image measurements, allowing to control the desired DoF. A control law has then to be designed so that these visual features reach a desired value, defining a correct achievement of the task. A desired planned trajectory can also be tracked. The control principle is to regulate the error between the current and desired values of the visual features to zero, or, in other terms, to minimize an objective function from which Lyapunov-based stability analysis can be performed. With a vision sensor providing 2D measurements, potential visual features are numerous, since 2D data (coordinates of particular points in the image, parameters related to geometrical shapes, intensity levels of set of pixels, etc.) as well as 3D data provided by a localization algorithm exploiting the extracted 2D measurements can be considered.

Typically, an iteration of the control scheme consists of the following successive steps:

- acquire an image;
- extract some useful image measurements;

- compute the current value of the visual features used as inputs of the control scheme;
- compute the error between the current and the desired values of the visual features;
- update the control outputs, which are usually the robot velocity, to regulate that error to zero, i.e., to minimize its norm.

For instance, for the first example depicted on Fig. 1, the image processing part consists in extracting and tracking the center of gravity of the moving people, the visual features are composed of the two Cartesian coordinates of this center of gravity, and the control scheme computes the camera pan and tilt velocities so that the center of gravity is as near as possible of the image center despite the unknown motion of the people. In the second example where a camera is mounted on a six DoF robot arm, the image measurements are the four segments that form the contour of a rectangular object. These segments are tracked in the image sequence acquired during the robot motion. The visual features are selected from the corresponding straight lines (depicted in red). The control scheme now computes the six components of the robot velocity so that these four straight lines reach particular positions (depicted in green).

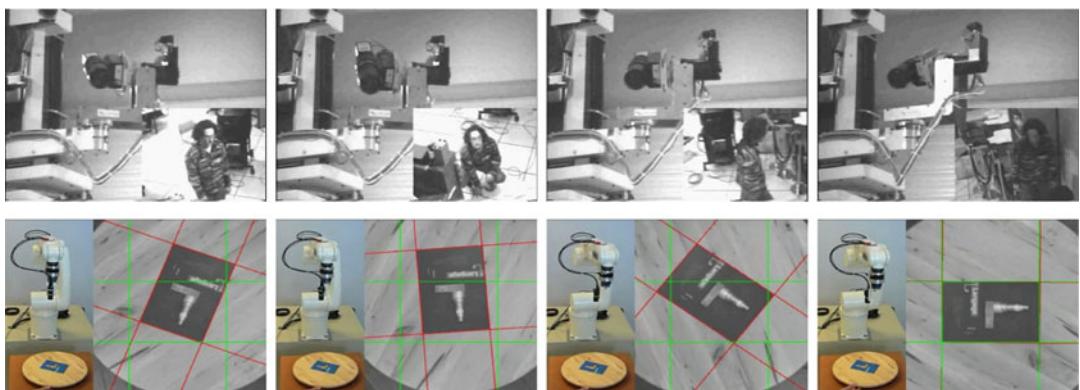

Theory

Most if not all visual servoing tasks can be expressed as the regulation to zero of an error $\mathbf{e}(t)$ defined by

$$\mathbf{e}(t) = \mathbf{s}(\mathbf{m}(\mathbf{r}(t)), \mathbf{a}) - \mathbf{s}^*(t). \quad (1)$$

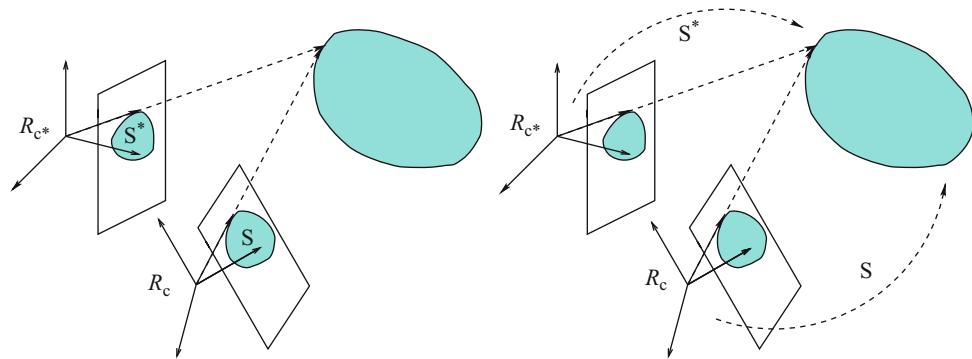

The parameters in (1) are defined as follows [3]: the vector $\mathbf{m}(\mathbf{r}(t))$ is a set of image measurements (e.g., the image coordinates of points, or the area, the center of gravity and other geometric characteristics of an object, etc.). These image measurements depend on the pose $\mathbf{r}(t)$ between the camera and the environment, this pose varying with time t . They are used to compute a vector $\mathbf{s}(\mathbf{m}(\mathbf{r}(t)), \mathbf{a})$ of visual features, in which \mathbf{a} is a set of parameters that represent potential additional knowledge about the system (e.g., coarse camera intrinsic parameters or 3D model of objects). The vector $\mathbf{s}^*(t)$ contains the desired value of the features, which can be either constant in the case of a fixed goal or varying if the task consists in following a specified trajectory.

Visual servoing schemes mainly differ in the way that the visual features are designed. As represented in Fig. 2, the two most classical approaches are named image-based visual servoing (IBVS), in which \mathbf{s} consists of a set

Visual Servoing, Fig. 1 Two examples of visual servoing tasks: on the top, pedestrian tracking using a pan-tilt camera; on the bottom, controlling the 6 degrees

of freedom of an eye-in-hand system so that an object appears at a particular position in the image

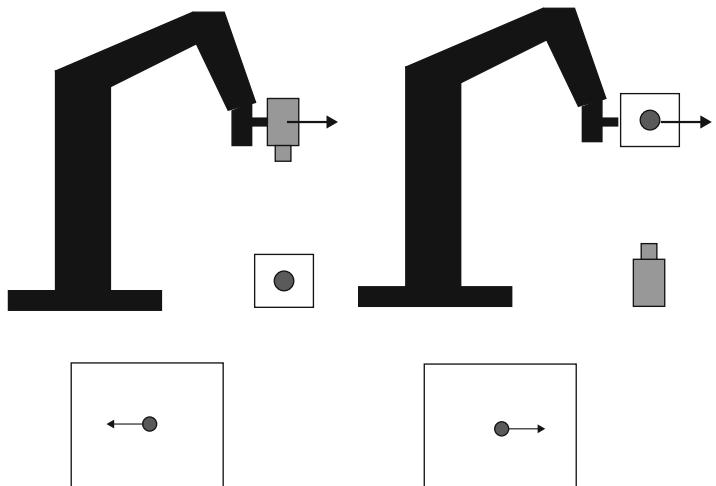

Visual Servoing, Fig. 2 If the goal is to move the camera from frame R_c to the desired frame R_{c^*} , two main approaches are possible: IBVS on the left, where the

features s and s^* are expressed in the image, and PBVS on the right, where the features s and s^* are related to the pose between the camera and the observed object

Visual Servoing, Fig. 3

In visual servoing, the vision sensor can be either mounted near the robot end-effector (eye-in-hand configuration) or outside and observing the end-effector (eye-to-hand configuration). For the same robot motion, the motion produced in the image will be opposite from one configuration to the other

of 2D parameters that are directly expressed in the image [10, 19], and pose-based visual servoing (PBVS), in which \mathbf{s} consists of a set of 3D parameters related to the pose between the camera and the target [19, 20]. In that case, the 3D parameters have to be estimated from the image measurements either through a pose estimation process using the knowledge of the 3D target model or through a triangulation process if a stereovision system is considered. Inside IBVS and PBVS approaches, many possibilities exist depending on the choice of the features. Each choice will induce a particular behavior of the system. There also exist hybrid approaches, named 2-1/2D visual servoing, which combine 2D and 3D parameters in \mathbf{s} in order to benefit from the advantages of

IBVS and PBVS while avoiding their respective drawbacks [13].

The Features Jacobian

The design of the control scheme is based on the link between the time variation $\dot{\mathbf{s}}$ of the features and the robot control inputs, which are usually the velocity $\dot{\mathbf{q}}$ of the robot joints. This relation is given by

$$\dot{\mathbf{s}} = \mathbf{J}_s \dot{\mathbf{q}} + \frac{\partial \mathbf{s}}{\partial t} \quad (2)$$

where \mathbf{J}_s is the features Jacobian matrix, defined from the equation above similarly as the classical robot Jacobian. For an eye-in-hand system (see the left part of Fig. 3), the term $\frac{\partial \mathbf{s}}{\partial t}$ represents the time variation of \mathbf{s} due to a potential object motion, while for an eye-to-hand system (see

the right part of Fig. 3), it represents the time variation of \mathbf{s} due to a potential sensor motion.

As for the features Jacobian, in the eye-in-hand configuration, it can be decomposed as [3]

$$\mathbf{J}_s = \mathbf{L}_s {}^c\mathbf{V}_e \mathbf{J}(\mathbf{q}) \quad (3)$$

where

- \mathbf{L}_s is the interaction matrix of \mathbf{s} defined such that

$$\dot{\mathbf{s}} = \mathbf{L}_s \mathbf{v} \quad (4)$$

where $\mathbf{v} \in se_3$ is the relative velocity between the camera and the environment expressed in the camera frame. More details on how to determine this matrix are given below.

- ${}^c\mathbf{V}_e$ is the spatial motion transform matrix from the vision sensor to the end-effector. It is given by

$${}^c\mathbf{V}_e = \begin{bmatrix} {}^c\mathbf{R}_e & [{}^c\mathbf{t}_e]_{\times} {}^c\mathbf{R}_e \\ \mathbf{0} & {}^c\mathbf{R}_e \end{bmatrix} \quad (5)$$

where ${}^c\mathbf{R}_e$ and ${}^c\mathbf{t}_e$ are, respectively, the rotation matrix and the translation vector between the sensor frame and the end-effector frame and where $[{}^c\mathbf{t}_e]_{\times}$ is the skew symmetric matrix associated with ${}^c\mathbf{t}_e$. Matrix ${}^c\mathbf{V}_e$ is constant when the vision sensor is rigidly attached to the end-effector, which is usually the case. Thanks to the robustness of closed-loop control schemes with respect to calibration errors, a coarse approximation of ${}^c\mathbf{R}_e$ and ${}^c\mathbf{t}_e$ is generally sufficient in practice to serve as a satisfactory estimation of ${}^c\mathbf{V}_e$ to be injected in the control law. If needed, an accurate estimation is possible through classical hand-eye calibration methods.

- $\mathbf{J}(\mathbf{q})$ is the robot Jacobian such that $\mathbf{v}_e = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}$ where \mathbf{v}_e is the robot end-effector velocity.

In the eye-to-hand configuration, the features Jacobian \mathbf{J}_s is composed of [3]

$$\mathbf{J}_s = -\mathbf{L}_s {}^c\mathbf{V}_f {}^f\mathbf{V}_e \mathbf{J}(\mathbf{q}) \quad (6)$$

where

- ${}^f\mathbf{V}_e$ is the spatial motion transform matrix from the robot reference frame to the end-effector frame. It is known from the robot kinematics model.
- ${}^c\mathbf{V}_f$ is the spatial motion transform matrix from the camera frame to the reference frame. It is constant as long as the camera does not move. In that case, similarly as for the eye-in-hand configuration, a coarse approximation of ${}^c\mathbf{R}_f$ and ${}^c\mathbf{t}_f$ is usually sufficient.

The Interaction Matrix

A lot of works have concerned the modeling of various visual features \mathbf{s} and the determination of the analytical form of their interaction matrix \mathbf{L}_s . To give just an example, in the case of an image point with normalized Cartesian coordinates $\mathbf{x} = (x, y)$ and whose 3D corresponding point has depth Z in the camera frame, the interaction matrix \mathbf{L}_x of \mathbf{x} is given by [10]

$$\mathbf{L}_x = \begin{bmatrix} -1/Z & 0 & x/Z & xy & -(1+x^2) & y \\ 0 & -1/Z & y/Z & 1+y^2 & -xy & -x \end{bmatrix} \quad (7)$$

where the three first columns contain the elements related to the three components of the translational velocity and where the three last columns contain the elements related to the three components of the rotational velocity.

By just changing the parameters representing the same image point, that is, by using the cylindrical coordinates defined by $\mathbf{y} = (\rho, \theta)$ with $\rho = \sqrt{x^2 + y^2}$ and $\theta = \text{Arctan}(y/x)$, the interaction matrix of these parameters has a completely different form [3]:

$$\mathbf{L}_y = \begin{bmatrix} -\cos\theta/Z & -\sin\theta/Z & \rho/Z & (1+\rho^2)\sin\theta & -(1+\rho^2)\cos\theta & 0 \\ \sin\theta/(\rho Z) & -\cos\theta/(\rho Z) & 0 & \cos\theta/\rho & \sin\theta/\rho & -1 \end{bmatrix} \quad (8)$$

This implies that using the Cartesian coordinates or the cylindrical coordinates as visual features will induce a different behavior, that is, a different trajectory of the point in the image and, consequently, a different robot trajectory. The main objective in designing a visual servoing control scheme is thus to select the best set of visual features in terms of stability, global behavior (adequate trajectories both in the image plane and 3D space), and robustness to noise and to modeling and calibration errors from the task to be achieved, the environment observed, and the available image measurements. All these aspects can be studied from the interaction matrix of the potential visual features.

Currently, the analytical form of the interaction matrix is available for most basic features resulting from the perspective projection of simple geometrical primitives such as circles, spheres, and cylinders [10]. It is also available for image moments related to planar and almost-planar objects of any shape [2], as well as for features selected from the epipolar geometry [18] and, of course, also for coordinates of 3D points, parameters of 3D geometrical primitives, and pose parameters, assuming these features are perfectly estimated.

In the recent years, following the seminal works of [16], a new trend has concerned the use of direct image content as input of the control scheme [4]. The main objective of these works is to avoid the extraction, tracking, and matching of geometrical measurements, such as points of interest or edges, so that the system is extremely accurate and robust with respect to image processing errors. The basic idea is to consider the intensity of a set of pixels as visual features ($\mathbf{s} = \mathbf{I}$). From the classical assumption in computer vision stating that the intensity level of a moving point does not change (i.e., $I(\mathbf{x}, t) = I(\mathbf{x} + \mathbf{d}\mathbf{x}, t + dt)$), it is possible to determine the interaction matrix corresponding to the intensity level of a pixel:

$$\mathbf{L}_I = -\left[\frac{\partial I}{\partial x} \quad \frac{\partial I}{\partial y}\right] \mathbf{L}_x \quad (9)$$

where $\left[\frac{\partial I}{\partial x} \quad \frac{\partial I}{\partial y}\right]$ is the spatial gradient of the intensity along the x and y directions. Proceeding so

leads to control a highly nonlinear system, with the drawback of a relatively small convergence domain, and, in general, not expected robot trajectory, plus the potential issue of robustness with respect to lighting variations. That is why the idea of direct photometric visual servoing has been expended by either considering other objective functions than $\|\mathbf{I} - \mathbf{I}^*\|$, such as the mutual information between the current and desired images [7], or other global image representations [9], or by designing photo-geometric visual features [1].

All the works mentioned above have considered a classical vision sensor modeled by a perspective projection. It is possible to generalize the approach to any sort of sensors, such as omnidirectional cameras, RGB-D sensors, the coupling between a camera and structured light, and even 2D echographic probes. A large variety of visual features is thus available for many vision sensors.

Finally, methods also exist to estimate off-line or online a numerical value of the interaction matrix, by using neural networks, for instance, or the Broyden update [3]. These methods are useful when the analytical form of the interaction matrix cannot be determined, but any a priori analysis of the properties of the system is unfortunately impossible.

Control

Once the modeling step has been performed, the design of the control scheme can be quite simple for holonomic robots. The most basic control scheme has the following form [3]:

$$\dot{\mathbf{q}} = -\lambda \widehat{\mathbf{J}}_s^+ \mathbf{e} + \widehat{\mathbf{J}}_s^+ \frac{\partial \mathbf{s}^*}{\partial t} - \widehat{\mathbf{J}}_s^+ \frac{\partial \mathbf{s}}{\partial t} \quad (10)$$

where, in the first feedback term, $\mathbf{e} = \mathbf{s} - \mathbf{s}^*$ as defined in Eq. (1), λ is a positive (possibly varying) gain tuning the time-to-convergence of the system, and $\widehat{\mathbf{J}}_s^+$ is the Moore-Penrose pseudoinverse of an approximation or an estimation of the features Jacobian. The exact value of all its elements is indeed generally unknown since it depends on the intrinsic and extrinsic camera parameters, as well as of some 3D parameters such as the depth of the point in

Eqs. (7) and (8). Methods for estimating these 3D parameters exist, either using the knowledge of the robot motion [8] or the knowledge of the 3D object model when it is available, or, up to a scalar factor, from partial pose estimation using the properties of the epipolar geometry between the current and the desired images [13].

The second term of the control scheme anticipates for the variation of s^* in the case of a varying desired value. The third term compensates as much as possible a possible target motion in the eye-in-hand case and a possible camera motion in the eye-to-hand case. They are both null in the case of a fixed desired value and a motionless target or camera. They serve as feedforward terms for removing the tracking error in the other cases [5].

Following the Lyapunov theory, the stability of the system can be studied [3]. Generally, visual servoing schemes can be demonstrated to be locally asymptotically stable (i.e., the robot will converge if it starts from a local neighborhood of the desired pose) if the errors introduced in $\hat{\mathbf{J}}_s$ are not too strong. Some particular visual servoing schemes can be demonstrated to be globally asymptotically stable (i.e., the robot will converge whatever its initial pose) under similar conditions. This is, for instance, the case for the pan-tilt camera control depicted in Fig. 1, for PBVS assuming the 3D parameters involved are perfectly estimated, and for well-designed IBVS schemes.

Finally, when the visual features do not constrain all the DoF, it is possible to combine the visual task with supplementary tasks such as joint limits avoidance or the visibility constraint (to be sure that the target considered will always remain in the camera field of view). In that case, the redundancy framework can be applied and the new error to be regulated to zero has the following form:

$$\mathbf{e}_n = \hat{\mathbf{J}}_s^+ \mathbf{e} + (\mathbf{I} - \hat{\mathbf{J}}_s^+ \hat{\mathbf{J}}_s) \mathbf{e}_2 \quad (11)$$

where $(\mathbf{I} - \hat{\mathbf{J}}_s^+ \hat{\mathbf{J}}_s)$ is a projection operator on the null space of the visual task \mathbf{e} so that the supplementary task \mathbf{e}_2 will be achieved at best under the constraint that it does not perturb the

visual task. A similar control scheme to (10) is now given by

$$\dot{\mathbf{q}} = -\lambda \mathbf{e}_n - \widehat{\frac{\partial \mathbf{e}_n}{\partial t}} \quad (12)$$

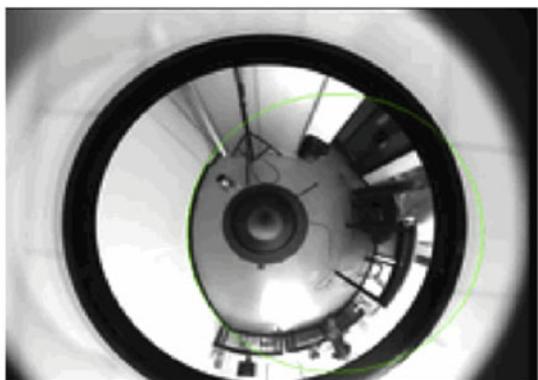

This scheme has for instance been applied for the navigation task depicted in Fig. 4 where the rotational motion of the mobile robot is controlled by vision while its translational motion is controlled by the odometry to move at a constant velocity.

Any other more advanced control strategy can be applied such as optimal control [17], coupling path planning and visual servoing [15], model predictive control, or quadratic programming when visual tasks and visual constraints have to be simultaneously handled with other tasks and constraints. Particular care has to be considered for underactuated and nonholonomic systems for which adequate control laws have to be designed [11, 14].

Application

Potential applications of visual servoing are numerous. It can be used as soon as a vision sensor is available and a task is assigned to a dynamic system. A non-exhaustive list of examples is:

- the control of a pan-tilt-zoom camera, as illustrated in Fig. 1 for the pan-tilt case;
- grasping using a robot arm;
- locomotion and dexterous manipulation with a humanoid robot;
- micro- or nano-manipulation of MEMS or biological cells;
- pipe inspection by an underwater autonomous vehicle;
- autonomous navigation of a mobile robot in indoor or outdoor environment;
- aircraft landing;
- autonomous satellite rendezvous;
- biopsy using ultrasound probes or heart motion compensation in medical robotics.
- virtual cinematography in animation.

Visual Servoing, Fig. 4 Navigation of a mobile robot to follow a wall using an omnidirectional vision sensor. The 3D straight line at the bottom of the wall projects as a

circle in the image (depicted in green). This circle does not move if the robot follows the wall, while it moves if the robot is not correctly oriented

Open Problems

Visual servoing is a mature area. It is basically a nonlinear control problem for which numerous modeling works have been achieved to design visual features so that the control problem is transformed as much as possible to a linear control problem. On one hand, improvements on this topic are still expected for instantiating this general approach to particular applications. On the other hand, designing new control strategies is another direction for improvements, especially when supplementary data coming from other sensors (force, tactile, proximity sensors) are available. Finally, the current expansion of deep learning may rejuvenate the field especially for the dense direct methods that use the same input and end-to-end approach.

Definition

The von Kries hypothesis as applied to chromatic adaptation is an approach that is the basis of most modern color adaptation models. It was first hypothesized by Johannes von Kries in 1902 [3]. The approach requires one to apply a gain to each of the cone responses, independently, so as to keep the adapted appearance of a reference white constant.

Theory

In general terms, let us denote the three cone responses in the human retina as L , M , S , and let the spectral sensitivities of the cones be denoted by $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, and $\bar{s}(\lambda)$. Then for any given stimulus $i_r(\lambda)$ that is incident on the retina, the cone responses are assumed to be given by:

$$\begin{aligned} L &= k \int_{\lambda} \bar{l}(\lambda) i_r(\lambda) d\lambda \\ M &= k \int_{\lambda} \bar{m}(\lambda) i_r(\lambda) d\lambda \\ S &= k \int_{\lambda} \bar{s}(\lambda) i_r(\lambda) d\lambda \end{aligned} \quad (1)$$

with k a normalizing constant, and $\bar{l}(\lambda)$, $\bar{m}(\lambda)$, $\bar{s}(\lambda)$ are the spectral sensitivity functions of the three types of color receptors in the eye. In the above equations, $i_r(\lambda)$ is given by:

$$i_r(\lambda) = i(\lambda) r(\lambda) \quad (2)$$

where $i(\lambda)$ denotes the illuminant and $r(\lambda)$ denotes the spectral reflectivity of a given surface.

The von Kries model is used to predict the response of the cones under changes in the viewing conditions. Specifically, an important change in the viewing conditions is a change in the illuminant. Let us assume that the illuminant $i(\lambda)$ is replaced by a different illuminant, $i_a(\lambda)$. In

such a case, let us denote the cone responses by L_a , M_a , and S_a . Then von Kries hypothesis may be expressed as:

$$\begin{bmatrix} L_a \\ M_a \\ S_a \end{bmatrix} = \begin{bmatrix} k_L & 0 & 0 \\ 0 & k_M & 0 \\ 0 & 0 & k_S \end{bmatrix} \begin{bmatrix} L \\ M \\ S \end{bmatrix} \quad (3)$$

where k_L , k_M , and k_S denote scale factors that are applied independently to the three cone responses. It is perhaps most common to see this above equation represented with $k_L = 1/L_{\max}$, $k_M = 1/M_{\max}$, and $k_S = 1/S_{\max}$ where the max subscript denotes the maximal responses for the LMS cone functions under a normative white stimulus.

In terms of representing the adaptation between the original and new illuminants, in the von Kries model the adapted stimuli are assumed to be given by:

$$\begin{bmatrix} L_a \\ M_a \\ S_a \end{bmatrix} = \begin{bmatrix} \frac{L_{\max}a}{L_{\max}} & 0 & 0 \\ 0 & \frac{M_{\max}a}{M_{\max}} & 0 \\ 0 & 0 & \frac{S_{\max}a}{S_{\max}} \end{bmatrix} \begin{bmatrix} L \\ M \\ S \end{bmatrix}. \quad (4)$$

The von Kries approach, although described in the space of LMS cone functions, can be easily extended to be used in the space of XYZ tristimulus values, defined in terms of colorimetry, rather than in the psychophysically motivated LMS space. And indeed this is typically done, by using a simple 3×3 transformation between the LMS cone fundamentals and XYZ color-matching functions:

$$\begin{bmatrix} L \\ M \\ S \end{bmatrix} = \mathbf{M} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix}. \quad (5)$$

The exact values used for matrix \mathbf{M} depend on the specific cone fundamentals and XYZ color-matching functions chosen [1,4].

Open Problems

This approach, although not truly accurate with regard to experimental findings in color adaptation, is surprisingly general in its application [2]. Many researchers have been exploring the limitations of this hypothesis and adapting it for use in modern color adaptation models. In Chap. 9 of his book Fairchild provides a comprehensive comparison of the von Kries model to several other color adaptation models developed in the past century [1].

- ▶ Fundamental Matrix
- ▶ Projective Reconstruction
- ▶ Triangulation
- ▶ Uncalibrated Camera

Definition

When we have multiple cameras and their camera matrices are not fully known but have been obtained up to an ambiguity represented by a single projective transformation, these cameras are said to be weakly calibrated, and the ambiguity is called a projective ambiguity. Also, obtaining camera matrices up to the projective ambiguity is called weak calibration.

Theory

Let us consider N 3D points \mathbf{X}_i ($i = 1, \dots, N$), which are projected to M cameras as \mathbf{x}_{ji} ($i = 1, \dots, N; j = 1, \dots, M$). If there is no nonlinear distortion of the second order or higher in this projection, the projection can be represented by M 3×4 matrices \mathbf{P}_j ($j = 1, \dots, M$) as follows:

$$\mathbf{x}_{ji} = \mathbf{P}_j \mathbf{X}_i \quad (1)$$

where \mathbf{x}_{ji} and \mathbf{X}_i are represented in homogeneous coordinates.

Now, if we insert a projective transformation \mathbf{H} and its inverse \mathbf{H}^{-1} between the camera matrices \mathbf{P}_j and the 3D points \mathbf{X}_i , the projection can be described by using new camera matrices \mathbf{P}'_j and 3D points \mathbf{X}'_i , as:

$$\mathbf{x}_{ji} = \mathbf{P}_j \mathbf{X}_i \quad (2)$$

$$= \mathbf{P}_j \mathbf{H} \mathbf{H}^{-1} \mathbf{X}_i \quad (3)$$

$$= \mathbf{P}'_j \mathbf{X}'_i \quad (4)$$

Then, newly obtained M camera matrices \mathbf{P}'_j and N 3D points \mathbf{X}'_i have projective distortion represented by a single projective transformation \mathbf{H} with respect to the original camera matrices \mathbf{P}_j and 3D points \mathbf{X}_i . Thus, these camera matrices and 3D points $\{\mathbf{P}'_j, \mathbf{X}'_i\}$ are identical to the original camera matrices and 3D points $\{\mathbf{P}_j, \mathbf{X}_i\}$ up to a projective transformation. When we have M cameras whose camera matrices are not known but are fixed up to a single projective

transformation, these cameras are said to be weakly calibrated, and obtaining such camera matrices is called weak calibration.

A 3×4 camera matrix has 12 components, but it has only 11 DOFs since there exists a scale ambiguity in the camera matrix. Thus, M cameras have a total of $11M$ independent parameters. However, since the weak calibration computes camera parameters up to a projective ambiguity, 15 parameters that correspond to a projective transformation may remain indeterminate. Thus, the number of parameters to be computed in the weak calibration is $11M - 15$. For example, if we have two cameras, seven parameters should be computed, and if we have three cameras, 18 parameters should be computed in order to weakly calibrate these cameras.

Weak Calibration of Two Cameras

When we have two cameras, weakly calibrating them is the same as the computation of a fundamental matrix \mathbf{F} , which has seven DOFs and represents the epipolar geometry between the two cameras. This is because the camera matrices \mathbf{P}'_1 and \mathbf{P}'_2 of these two cameras can be obtained from the fundamental matrix \mathbf{F} up to a projective transformation, as follows [1]:

$$\mathbf{P}'_1 = [\mathbf{I}, \mathbf{0}] \quad (5)$$

$$\mathbf{P}'_2 = [[\mathbf{e}_{21}]_{\times} \mathbf{F}, \mathbf{e}_{21}] \quad (6)$$

where \mathbf{e}_{21} denotes an epipole in the second image and can be computed from matrix \mathbf{F} by using the linear relationship $\mathbf{F}^T \mathbf{e}_{21} = \mathbf{0}$.

Although the true camera matrices, \mathbf{P}_1 and \mathbf{P}_2 , of these two cameras are unknown, \mathbf{P}'_1 and \mathbf{P}'_2 obtained from the fundamental matrix \mathbf{F} are identical to the true camera matrices, \mathbf{P}_1 and \mathbf{P}_2 , up to a projective transformation. Thus, the 3D points reconstructed using \mathbf{P}'_1 and \mathbf{P}'_2 are identical to the real 3D points up to a projective transformation. Therefore, weak calibration of two cameras has been studied as the computation of a fundamental matrix.

The fundamental matrix \mathbf{F} can be computed with a minimum of eight pairs of corresponding points linearly [2,3], or a minimum of seven pairs

of corresponding points nonlinearly [4, 5], by estimating a matrix \mathbf{F} that best fits the following epipolar equation:

$$\mathbf{x}_{2i}^T \mathbf{F} \mathbf{x}_{1i} = 0 \quad (i = 1, \dots, N) \quad (7)$$

where \mathbf{x}_{ji} denotes the i th image point in the j th camera image.

The most accurate weak calibration method is the maximum likelihood estimation of the fundamental matrix and 3D points, which is called bundle-adjustment [6]. This method estimates the 7-DOF fundamental matrix \mathbf{F} and N 3D points \mathbf{X}_i ($i = 1, \dots, N$) simultaneously so that they minimize the reprojection errors, $d(\mathbf{x}_i, \hat{\mathbf{x}}_i)$, between observed points \mathbf{x}_i and reprojected points $\hat{\mathbf{x}}_i$ obtained by projecting the estimated 3D points $\hat{\mathbf{X}}_i$ by using the camera matrices $\hat{\mathbf{P}}'_1$ and $\hat{\mathbf{P}}'_2$ computed from the estimated fundamental matrix $\hat{\mathbf{F}}$. Thus, the method solves the following minimization problem:

$$\begin{aligned} \{\hat{\mathbf{F}}, \hat{\mathbf{X}}_1, \dots, \hat{\mathbf{X}}_N\} = \underset{\{\mathbf{F}, \mathbf{X}_1, \dots, \mathbf{X}_N\}}{\text{argmin}} & \sum_{i=1}^N d(\mathbf{x}_{1i}, \hat{\mathbf{x}}_{1i})^2 \\ & + d(\mathbf{x}_{2i}, \hat{\mathbf{x}}_{2i})^2 \end{aligned} \quad (8)$$

The solution of Eq.(8) can be obtained by using numerical methods such as the Levenberg-Marquardt method [7,8].

This method estimates the 7-DOF fundamental matrix \mathbf{F} and N 3D points \mathbf{X}_i ($i = 1, \dots, N$) from N pairs of 2D points in images. Thus, \mathbf{F} and \mathbf{X}_i can be estimated when the following inequality holds:

$$4N \geq 7 + 3N \quad (9)$$

Therefore, the maximum likelihood estimate of weak calibration can be obtained, if $N \geq 7$.

Weak Calibration of Three Cameras

If there are three cameras, their geometric relationship can be described by using a trifocal tensor \mathcal{T}_i^{pq} [9]. The trifocal tensor \mathcal{T}_i^{pq} is a $3 \times 3 \times 3$ tensor with 18 DOFs. It has 18 DOFs, since three cameras have $3 \times 11 = 33$ DOFs

but they are constrained by existing in a single projective space whose DOF is 15.

The weak calibration of three cameras is equivalent to estimating the trifocal tensor \mathcal{T}_i^{pq} . This is because the camera matrices of three cameras, \mathbf{P}_1 , \mathbf{P}_2 , and \mathbf{P}_3 , can be obtained up to a projective transformation from the trifocal tensor \mathcal{T}_i^{pq} as follows [1]:

$$\mathbf{P}_1 = [\mathbf{I}, \mathbf{0}] \quad (10)$$

$$\mathbf{P}_2 = [[\mathbf{T}_1, \mathbf{T}_2, \mathbf{T}_3]\mathbf{e}_{31}, \mathbf{e}_{21}] \quad (11)$$

$$\mathbf{P}_3 = [(\mathbf{e}_{31}\mathbf{e}_{31}^\top - \mathbf{I})[\mathbf{T}_1^\top, \mathbf{T}_2^\top, \mathbf{T}_3^\top]\mathbf{e}_{21}, \mathbf{e}_{31}] \quad (12)$$

where \mathbf{T}_i denotes the i th layer of the trifocal tensor $\mathcal{T}_i^{pq} = [\mathbf{T}_1, \mathbf{T}_2, \mathbf{T}_3]$. \mathbf{e}_{21} and \mathbf{e}_{31} denote epipoles of the 1st camera in the 2nd and, 3rd cameras respectively, and they can be computed from trifocal tensor \mathcal{T}_i^{pq} .

The trifocal tensor \mathcal{T}_i^{pq} can be computed with a minimum of seven corresponding points linearly [10], or a minimum of six corresponding points nonlinearly [11], by estimating the \mathcal{T}_i^{pq} that best fits the following trilinear relationship:

$$\sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 \sum_{p=1}^3 \sum_{q=1}^3 x^i x'^j x''^k \epsilon_{jpr} \epsilon_{kqs} \mathcal{T}_i^{pq} = 0_{rs} \quad (13)$$

where x^i denotes the i th component of an image point $\mathbf{x} = [x_1, x_2, x_3]^\top$ and ϵ_{ijk} denotes a rank 3 tensor, which takes 1 if the permutation from $\{i, j, k\}$ to $\{1, 2, 3\}$ is an even permutation, takes -1 if it is an odd permutation, and takes 0 for other cases. The linear estimation requires seven corresponding points, since the trifocal tensor \mathcal{T}_i^{pq} has 26 components except a scale ambiguity, and each set of corresponding points provides us 4 linearly independent equations in the estimation of the 26 components. The nonlinear estimation requires six corresponding points as explained below.

The most accurate way to estimate the trifocal tensor is to estimate the trifocal tensor \mathcal{T} and N 3D points \mathbf{X}_i ($i = 1, \dots, N$) simultaneously by minimizing the reprojection error d , as

$$\{\hat{\mathcal{T}}, \hat{\mathbf{X}}_1, \dots, \hat{\mathbf{X}}_N\} = \underset{\{\mathcal{T}, \mathbf{X}_1, \dots, \mathbf{X}_N\}}{\operatorname{argmin}} \sum_{i=1}^N \sum_{j=1}^3 d(\mathbf{x}_{ji}, \hat{\mathbf{x}}_{ji})^2 \quad (14)$$

This method estimates the 18-DOF trifocal tensor \mathcal{T} and N 3D points \mathbf{X}_i ($i = 1, \dots, N$) from N sets of 2D points in three views. Thus, \mathcal{T} and \mathbf{X}_i can be estimated when the following inequality holds:

$$6N \geq 18 + 3N \quad (15)$$

Therefore, the maximum likelihood estimate of the weak calibration of three cameras can be obtained, if $N \geq 6$.

Weak Calibration of M Cameras

Consider the case where there are M cameras and we want to calibrate them weakly by using N sets of corresponding points in their images.

The weak calibration of these M cameras can be achieved by estimating a set of M camera matrices \mathcal{P} and a set of N 3D points \mathcal{X} simultaneously by minimizing the reprojection error d as follows:

$$\{\hat{\mathcal{P}}, \hat{\mathcal{X}}\} = \underset{\{\mathcal{P}, \mathcal{X}\}}{\operatorname{min}} \sum_{i=1}^N \sum_{j=1}^M d(\mathbf{x}_{ji}, \hat{\mathbf{x}}_{ji})^2 \quad (16)$$

This is a bundle-adjustment [6] of an arbitrary number of cameras, and it provides us the maximum likelihood estimate of camera matrices and 3D points. Again, the solution of Eq. (16) can be obtained by using numerical methods such as the Levenberg-Marquardt method [7, 8].

The number of parameters to be estimated in the bundle-adjustment is $11M - 15$ for camera matrices and $3N$ for 3D points, while we have $2MN$ constraints from the image points in M views. Thus, these M cameras can be weakly calibrated, if the following inequality holds:

$$2MN \geq 11M + 3N - 15 \quad (17)$$

However, in this maximum likelihood estimation method, stable estimation cannot be performed unless good initial values for the

camera parameters and 3D points are given. Thus, in general, these initial values are obtained in advance by sequentially applying the weak calibration of two or three cameras, and then the weak calibration of M cameras is performed with high accuracy by using a maximum likelihood estimation method that simultaneously estimates M cameras and N 3D points.

Weak calibration of multiple cameras can also be achieved by using factorization in the case of affine cameras [12] and iterative factorization in the case of projective cameras [13].

Definition

Weak perspective projection is a linear approximation of the (full) *perspective projection*. In this entry, we also describe other forms of linear approximation: *orthographic projection* and *paraperspective projection*. Finally, the *affine camera* is presented as the most general form of linear approximation of the perspective projection.

Background

As can be seen in the entry ► “[Perspective Camera](#)”, the perspective projection is a nonlinear mapping. This makes many vision problems difficult to solve, and more importantly, they can become ill-conditioned when the perspective effects are small. Sometimes, if certain conditions are satisfied, for example, when the camera field of view is small and the object size is small enough with respect to the distance from the viewer to the object, the projection can be approximated by a linear mapping [1]. This simplification also leads to great reduction of complexity in computation of the epipolar geometry from images [2].

Theory

Orthographic Projection The simplest approximation is the so-called *orthographic projection* (Fig. 1a). It ignores completely the depth dimension. There is some evidence that rays near the fovea are projected orthographically (see, for example, [2]). Because of this, orthographic projection has been used in human vision research [4]. But the orthographic projection can lead to two identical objects having the same image, even if one is much further away from the camera than the other (*distance effect*) or if one is much more distant from the optical axis than the other (*position effect*) (see Fig. 1b). Therefore, methods that use orthographic projection are only valid in a limited domain where the distance and position effects can be ignored.

Weak Perspective Projections A much more reasonable approximation is the so-called *weak perspective projection*. When the object size is small enough with respect to the distance from the camera to the object, the depth, or Z , can be replaced by a common depth, Z_c . Then the projection equations become linear:

$$x = \frac{X}{Z_c} \quad (1)$$

$$y = \frac{Y}{Z_c}$$

Here, we assume that the focal length f is normalized to 1.

Suppose the common depth is the depth of the centroid of the object. Then this approximation can be understood as a two-step projection (Fig. 2). The first one is a parallel projection of all the object surface points onto a plane which goes through Z_c , the depth of the object centroid, and is parallel to the image plane or focal plane. The second step is a perspective projection of that plane onto the image plane, which is actually a uniform scaling of that plane. Sometimes, this projection is also called the *scaled orthographic projection*. When Z_c is unity, the projection becomes the *orthographic* one.

Let

$$\mathbf{P}_{wp} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & Z_c \end{bmatrix}. \quad (2)$$

Equation (1) can then be written in matrix form, similar to the perspective projection matrix, as

$$s \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} = \mathbf{P}_{wp} \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix}.$$

Taking into account the intrinsic and extrinsic parameters of the camera yields

$$s \tilde{\mathbf{m}} = \mathbf{A} \mathbf{P}_{wp} \tilde{\mathbf{M}}, \quad (3)$$

where \mathbf{A} is the intrinsic matrix and \mathbf{D} is the rigid transformation. Expand it and eliminate the scale factor s , and we have

$$\mathbf{m} = \mathbf{T}_{wp} \mathbf{M} + \mathbf{t}_{wp}, \quad (4)$$

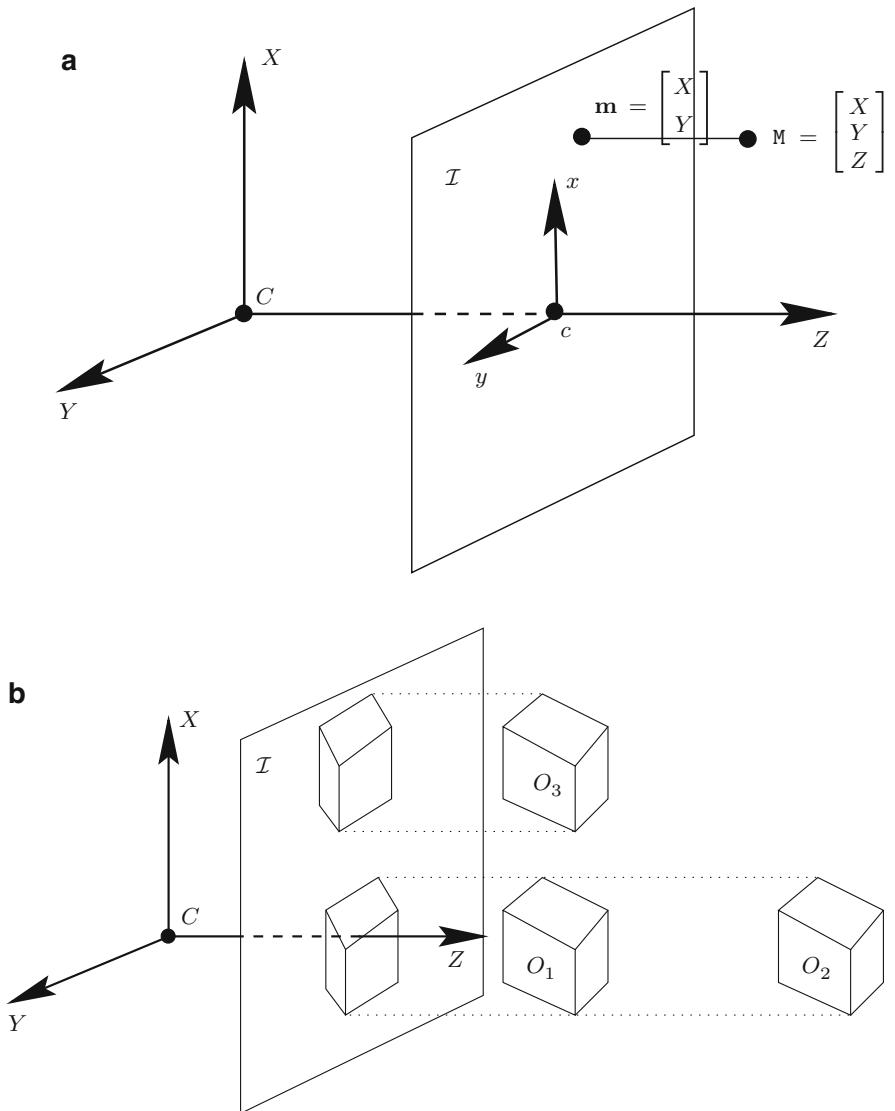

where

$$\mathbf{T}_{wp} = \frac{1}{Z_c} \begin{bmatrix} \alpha_u (\mathbf{r}_1^T + \cot \theta \mathbf{r}_2^T) \\ \alpha_v \mathbf{r}_2^T / \sin \theta \end{bmatrix}$$

$$\mathbf{t}_{wp} = \frac{1}{Z_c} \begin{bmatrix} \alpha_u (t_1 + t_2 \cot \theta) \\ \alpha_v t_2 / \sin \theta \end{bmatrix} + \begin{bmatrix} u_0 \\ v_0 \end{bmatrix}.$$

Here \mathbf{r}_i denotes the i th row vector of the rotation matrix \mathbf{R} , and t_i is the i th element of the translation vector \mathbf{t} . It is clear that the relation between 3D coordinates and image coordinates is linear.

Let us examine the approximation error introduced by the weak perspective projection. For simplicity, we consider a normalized camera with the camera and world coordinate systems aligned. For a point \mathbf{M} with depth $Z = Z_c + \Delta Z$, its perspective projection can be developed as a Taylor series about Z_c :

Weak Perspective Projection, Fig. 1 (a) Orthographic projection. (b) Three identical objects in different positions give the same image under orthographic projection:

Object O_2 is much further away from the camera, and object O_3 is much distant from the optical axis, than object O_1

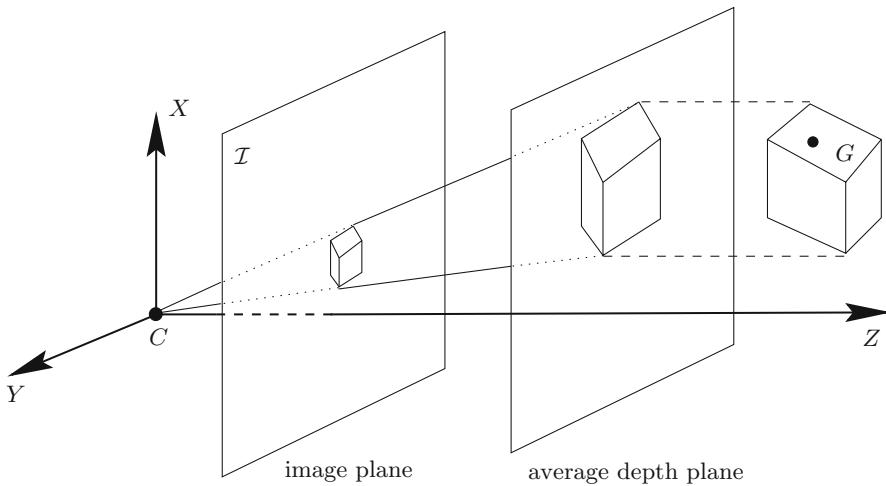

$$\begin{aligned} \mathbf{m}_p &= \frac{1}{Z_c + \Delta Z} \begin{bmatrix} X \\ Y \end{bmatrix} \\ &= \frac{1}{Z_c} \left(1 - \frac{\Delta Z}{Z_c} + \left(\frac{\Delta Z}{Z_c} \right)^2 - \dots \right) \begin{bmatrix} X \\ Y \end{bmatrix}. \end{aligned}$$

When $|\Delta Z| \ll Z_c$, only the zero-order term remains, giving Eq. (1). Weak perspective is thus the zero-order approximation of the full perspective projection. The absolute error in

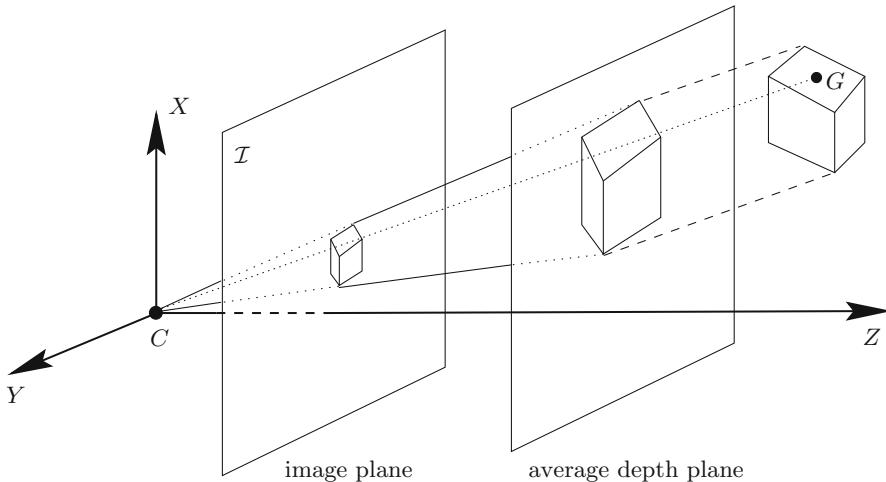

image position is then

$$\mathbf{m}_{error} = \mathbf{m}_p - \mathbf{m}_{wp} = -\frac{1}{Z} \frac{\Delta Z}{Z_c} \begin{bmatrix} X \\ Y \end{bmatrix},$$

which shows that a small field of view (X/Z and Y/Z) and small depth variation ($\Delta Z/Z_c$) contribute to the validity of the model [5]. The error is clearly not uniform across the image. A useful

Weak Perspective Projection, Fig. 2 The weak perspective model. The average depth plane is drawn in front for clarity

Weak Perspective Projection, Fig. 3 Paraperspective projection. The average depth plane is drawn in front for clarity

rule of thumb requires Z_c to exceed $|\Delta Z|$ by an order of magnitude [6], i.e., $Z_c \geq 10|\Delta Z|$.

Paraperspective Projection Under weak perspective projection, a world point is first projected onto the average depth plane using the rays parallel to the optical axis. This causes a significant approximation error when an object is distant to the optical axis (large X/Z and Y/Z). The *paraperspective projection* generalizes this by projecting points using the rays parallel to the central projecting ray CG , where G is the centroid of the object [1]. As with weak perspective, the

perspective projection is also approximated with a two-step process, but the projection in the first step is no more realized along rays parallel to the optical axis (see Fig. 3).

Let the coordinates of the centroid of the object G be $[X_c, Y_c, Z_c]^T$. A world point $M = [X, Y, Z]^T$ is first projected, parallel to CG , to the average depth plane at $\left[X - \frac{X_c}{Z_c} Z + X_c, Y - \frac{Y_c}{Z_c} Z + Y_c, Z_c \right]^T$. Finally, this point is projected perspectively onto the image plane as

$$\begin{aligned} x &= \frac{1}{Z_c} \left(X - \frac{X_c}{Z_c} Z + X_c \right) \\ y &= \frac{1}{Z_c} \left(Y - \frac{Y_c}{Z_c} Z + Y_c \right). \end{aligned} \quad (5)$$

They can be written in matrix form as

$$s \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} = \mathbf{P}_{pp} \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix},$$

with

$$\mathbf{P}_{pp} = \begin{bmatrix} 1 & 0 & -X_c/Z_c & X_c \\ 0 & 1 & -Y_c/Z_c & Y_c \\ 0 & 0 & 0 & Z_c \end{bmatrix}. \quad (6)$$

Taking into account the intrinsic and extrinsic parameters of the camera yields

$$s \tilde{\mathbf{m}} = \mathbf{A} \mathbf{P}_{pp} \tilde{\mathbf{D}} \tilde{\mathbf{M}}. \quad (7)$$

Here, of course, X_c , Y_c , and Z_c in \mathbf{P}_{pp} must be still measured in the camera coordinate system. In terms of image and world coordinates, we have

$$\mathbf{m} = \mathbf{T}_{pp} \mathbf{M} + \mathbf{t}_{pp}, \quad (8)$$

where

$$\mathbf{T}_{pp} = \frac{1}{Z_c} \begin{bmatrix} \alpha_u \left(\mathbf{r}_1^T - \frac{X_c}{Z_c} \mathbf{r}_3^T \right) + \alpha_u \cot \theta \left(\mathbf{r}_2^T - \frac{Y_c}{Z_c} \mathbf{r}_3^T \right) \\ \alpha_v \left(\mathbf{r}_2^T - \frac{Y_c}{Z_c} \mathbf{r}_3^T \right) / \sin \theta \end{bmatrix}$$

$$\mathbf{t}_{pp} = \frac{1}{Z_c} \begin{bmatrix} \alpha_u \left(t_1 - \frac{X_c}{Z_c} t_3 + X_c \right) + \alpha_u \cot \theta \left(t_2 - \frac{Y_c}{Z_c} t_3 + Y_c \right) \\ \alpha_v \left(t_2 - \frac{Y_c}{Z_c} t_3 + Y_c \right) / \sin \theta \end{bmatrix} + \begin{bmatrix} u_0 \\ v_0 \end{bmatrix}.$$

It is clear that the relation between 3D coordinates and image coordinates is linear under paraperspective projection.

Let us examine the approximation error introduced by the weak perspective projection. For simplicity, we consider a normalized camera with the camera and world coordinate systems aligned. For a point M with coordinates $[X, Y, Z]^T = [X_c + \Delta X, Y_c + \Delta Y, Z_c + \Delta Z]^T$, its perspective projection can be developed as a Taylor series about Z_c :

$$\begin{aligned} \mathbf{m}_p &= \frac{1}{Z_c + \Delta Z} \begin{bmatrix} X_c + \Delta X \\ Y_c + \Delta Y \end{bmatrix} \\ &= \frac{1}{Z_c} \left(1 - \frac{\Delta Z}{Z_c} + \left(\frac{\Delta Z}{Z_c} \right)^2 - \mathcal{O}^3 \right) \begin{bmatrix} X_c + \Delta X \\ Y_c + \Delta Y \end{bmatrix}, \end{aligned}$$

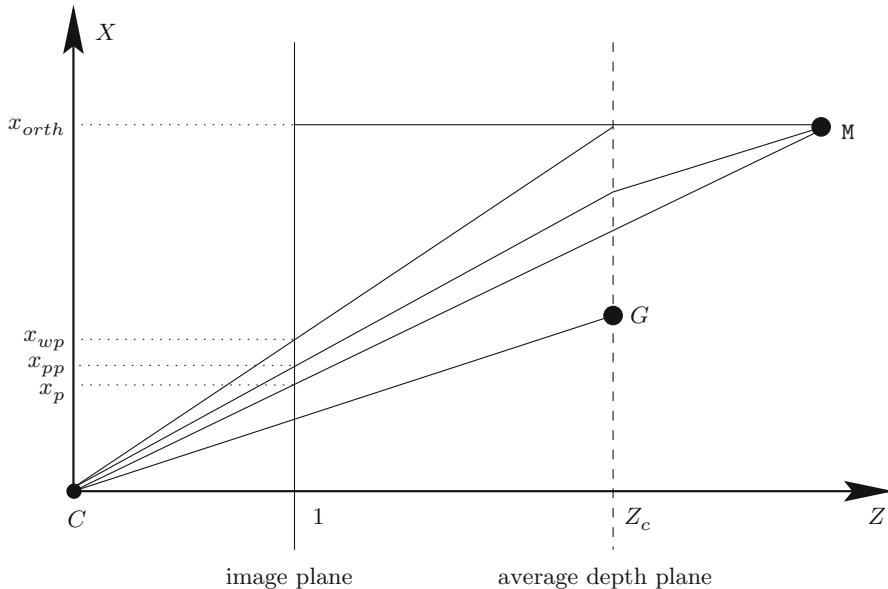

where \mathcal{O}^3 is used to denote terms of order higher than 2, i.e., $\mathcal{O}^3 = O\left(\frac{\Delta Z}{Z_c}\right)^3$. The projection under paraperspective, \mathbf{m}_{pp} , is given by Eq. (5). The absolute error in image plane, after some algebra, is given by

$$\mathbf{m}_{error} = \mathbf{m}_p - \mathbf{m}_{pp}$$

$$= \begin{bmatrix} -\frac{\Delta X \Delta Z}{Z_c^2} + \frac{X}{Z_c} \left(\frac{\Delta Z}{Z_c} \right)^2 - \mathcal{O}^3 \\ -\frac{\Delta Y \Delta Z}{Z_c^2} + \frac{Y}{Z_c} \left(\frac{\Delta Z}{Z_c} \right)^2 - \mathcal{O}^3 \end{bmatrix}.$$

As can be seen, the approximation error is of second order under paraperspective projection, and we say that it is the first-order approximation of the full perspective projection. The weak perspective projection, as was seen in the last subsection, is only the zero-order approximation. Figure 4 illustrates well the difference between all these projection models. Similar analysis is presented in [7] for pose determination.

An even better approximation is called *orthoperspective*. The difference from the paraperspective projection consists in replacing the average depth plane, which is parallel to the image plane, by another plane that is perpendicular to the central projecting ray (which connects the optical center C of the camera and the centroid G of the object (see Fig. 5 for a pictorial description). It can be understood as the result of the following sequence of operations [1]:

Weak Perspective Projection, Fig. 4 Comparison of different perspective approximations. Comparison of different perspective approximations. Cross-sectional view sliced by a plane that includes the central projecting ray and is perpendicular to the Y - Z plane. The image plane is the line $Z = 1$. For x_p (full perspective), projection is along the ray connecting the world point M to the optical center C . For x_{orth} (orthographic), projection is perpendicular

to the image. For x_{wp} (weak perspective), M is first orthographically projected onto the average depth plane and then projected perspectively onto the image plane. For x_{pp} (paraperspective), M is first projected, parallel to the central projecting ray, onto the average depth plane and then projected perspectively onto the image plane. (Adapted from [5])

- A virtual rotation of the camera around C to make the central projecting ray CG coincide with the optical axis
- A weak perspective projection of the object
- An inverse camera rotation to bring the camera back to its original position

The orthoperspective projection involves more complicated formula and will not be discussed anymore in this book.

Affine Cameras

If we examine the camera projection matrices for orthographic, weak perspective, and paraperspective projections (see Eq. (2) and (6)), we find that they all have the same form:

$$\mathbf{P}_A = \begin{bmatrix} P_{11} & P_{12} & P_{13} & P_{14} \\ P_{21} & P_{22} & P_{23} & P_{24} \\ 0 & 0 & 0 & P_{34} \end{bmatrix}. \quad (9)$$

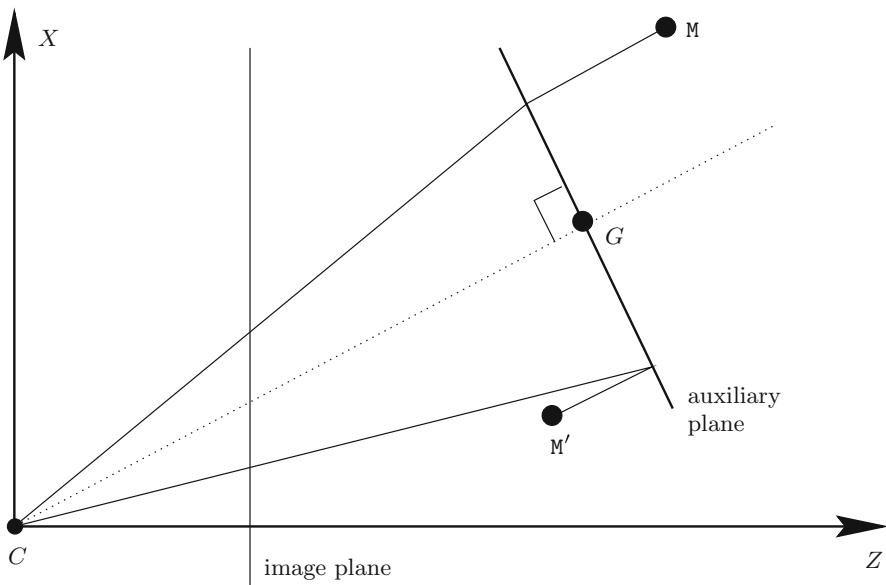

Depending on different projection models, some constraints exist on the elements of matrix \mathbf{P}_A except P_{31} , P_{32} , and P_{33} , which are equal to 0. If we ignore the constraints on the matrix elements, \mathbf{P}_A becomes the so-called *affine camera*, introduced by Mundy and Zisserman [8]. Unlike the general perspective projection matrix (see entry “Camera Parameters”), an affine camera, which is also defined up to a scale factor, has only eight degrees of freedom. It can be determined from four points in general position.

In terms of image and world coordinates, the affine camera is written as

$$\mathbf{m} = \mathbf{T}_A \mathbf{M} + \mathbf{t}_A, \quad (10)$$

where \mathbf{T}_A is a 2×3 matrix with elements $T_{ij} = P_{ij}/P_{34}$ and \mathbf{t}_A is a 2D vector $[P_{14}/P_{34}, P_{24}/P_{34}]^T$.

A key property of the affine camera is that it preserves parallelism [5]: lines that are parallel

Weak Perspective Projection, Fig. 5 Orthoperspective projection. A cross-sectional view sliced by a plane that includes the central projecting ray and is perpendicular to the Y - Z plane

in the world remain parallel in the image, which is not the case with the perspective camera. The proof is simple. Consider two parametric parallel lines $M_1(\lambda) = M_a + \lambda\mathbf{u}$ and $M_2(\mu) = M_b + \mu\mathbf{u}$, where \mathbf{u} is the 3D direction vector. They project onto the image as lines

$$\begin{aligned}\mathbf{m}_1(\lambda) &= (\mathbf{T}_A M_a + \mathbf{t}_A) + \lambda \mathbf{T}_A \mathbf{u}, \\ \mathbf{m}_2(\mu) &= (\mathbf{T}_A M_b + \mathbf{t}_A) + \mu \mathbf{T}_A \mathbf{u}.\end{aligned}$$

They are clearly parallel to the 2D direction vector $\mathbf{T}_A \mathbf{u}$.

Another attractive property of the affine camera is that the centroid of a set of 3D points and that of their image points correspond to each other. This is not the case for full perspective projections. Let M_i ($i = 1, \dots, n$) be the set of 3D points and \mathbf{m}_i , their corresponding image points. From Eq. (10), the centroid of the image points is given by

$$\begin{aligned}\bar{\mathbf{m}} &= \frac{1}{n} \sum_{i=1}^n \mathbf{m}_i = \frac{1}{n} \sum_{i=1}^n (\mathbf{T}_A M_i + \mathbf{t}_A) \\ &= \mathbf{T}_A \bar{\mathbf{M}} + \mathbf{t}_A,\end{aligned}$$

where $\bar{\mathbf{M}}$ is the centroid of the 3D points. Thus, the 3D point centroid is projected by an affine camera to the image point centroid. It follows that if 3D points are expressed with respect to their centroid, i.e. $\hat{M}_i = M_i - \bar{\mathbf{M}}$, and if 2D points are also expressed with respect to their centroid, i.e. $\hat{\mathbf{m}}_i = \mathbf{m}_i - \bar{\mathbf{m}}$, then we have

$$\hat{\mathbf{m}}_i = \mathbf{T}_A \hat{M}_i.$$

Therefore, an affine camera has only six degrees of freedom (the six parameters of \mathbf{T}_A).

While the exact projection performed by an affine camera is not very clear, it is clearly the generalization of the orthographic, weak perspective, or paraperspective models, as can be seen from Eq. (9) or (10). The generalization can be understood in two ways:

- Some *nonrigid* deformation of the object is permitted. Actually, if we multiply \mathbf{P}_A from the right by any 3D affine transformation of the object

$$\mathbf{D} = \begin{bmatrix} \mathbf{M} & \mathbf{t} \\ \mathbf{0}_3^T & 1 \end{bmatrix},$$

where \mathbf{M} is a general 3×3 matrix and \mathbf{t} is a 3-vector, the new projection matrix still has the form Eq. (9) of an affine camera.

- Camera calibration is unnecessary. Multiply \mathbf{P}_A from the left by any 2D affine transformation of the image

$$\mathbf{A} = \begin{bmatrix} \mathbf{C} & \mathbf{c} \\ \mathbf{0}_2^T & 1 \end{bmatrix},$$

where \mathbf{C} is a general 2×2 matrix and \mathbf{c} is a 2-vector; the new projection matrix still has the form Eq. (9) of an affine camera.

Without camera calibration, various affine measurements, such as parallelism and ratios of lengths in parallel directions, can be extracted. For certain vision tasks, such properties may be sufficient. Affine cameras are extensively studies in particular by the University of Oxford group [5, 9, 10].

- Color Constancy
- von Kries Hypothesis

Definition

White balance is the term given to the process of removing the color cast in a captured image that is induced by the color of the illuminant. This is typically done by changing the overall proportion of colors in an image to provide an overall balance by keeping neutral colors neutral in their reproduction.

W

Background

The human visual system has the capability of mapping “white” colors to the sensation of “white” even when lighting conditions change in color. This is easily illustrated by looking at a

white sheet of paper under indoor incandescent lighting and outdoor sunlight. In both cases the paper would appear white to our visual system, but appear yellowish and bluish in color, respectively, to a digital color camera. This psychophysical phenomenon is referred to as *color constancy*.

Similarly, a yellowish-white light (such as an incandescent bulb) reflected from a white sheet of paper would be perceived as white to our visual system while daylight reflected from a yellowish-white flower appears yellowish, even though the spectral information received by our eyes is identical. This is a significant challenge to a camera – digital or film-based – as the camera does not “know” the color of an object: this typically results in a color cast in the captured image, with the overall color appearing wrong to a human observer. Stated differently, neutral colored objects appear neutral to the human visual system and a camera is expected to be aware of this color constancy. Under flash photography, however, the situation is somewhat simpler as we know the illuminant in part.

The process of removing such a color cast so that “white remains white” under the capture and viewing illuminants is termed *white balancing*. Ideally, of course, consumers expect this to be performed automatically by their cameras.

Theory

The primary cause of the need for white balance comes from the fact that the camera is unable to accurately mimic the human visual system. For the sake of simplicity let us consider a digital still camera with three color sensors and compare how the data flows in a camera, compared to (an abstraction of) how it might flow in the human visual system. A particular camera’s spectral sensitivities are shown in Fig. 1b while those of the cones in the human retina are shown in Fig. 1a [7]. When a reflectance spectrum of, say, a white color patch is captured by these sensors, under a D65 white illuminant (shown in Fig. 1c), the initial values captured by the eye and the camera

are clearly different. But more importantly, the processing that takes place on these two signals is radically different, resulting in a completely different sensation of white in the two “systems.” A generic overview of the structure of a digital still camera’s image processing pipeline may be found in a paper by Ramanath et al. [6].

The challenge for the camera’s system is to mimic the performance of the human visual system with little or no knowledge of the illuminant under which the image was captured.

One means of performing white balance is to assume that a white patch must induce maximal response in one or more of the camera’s sensor in the three (or more) channels. If R , G , and B denote the red, green, and blue channels of the captured image, the white-balanced image has signals given by R/R_{\max} , G/G_{\max} , and B/B_{\max} . This type of white balance may be represented as:

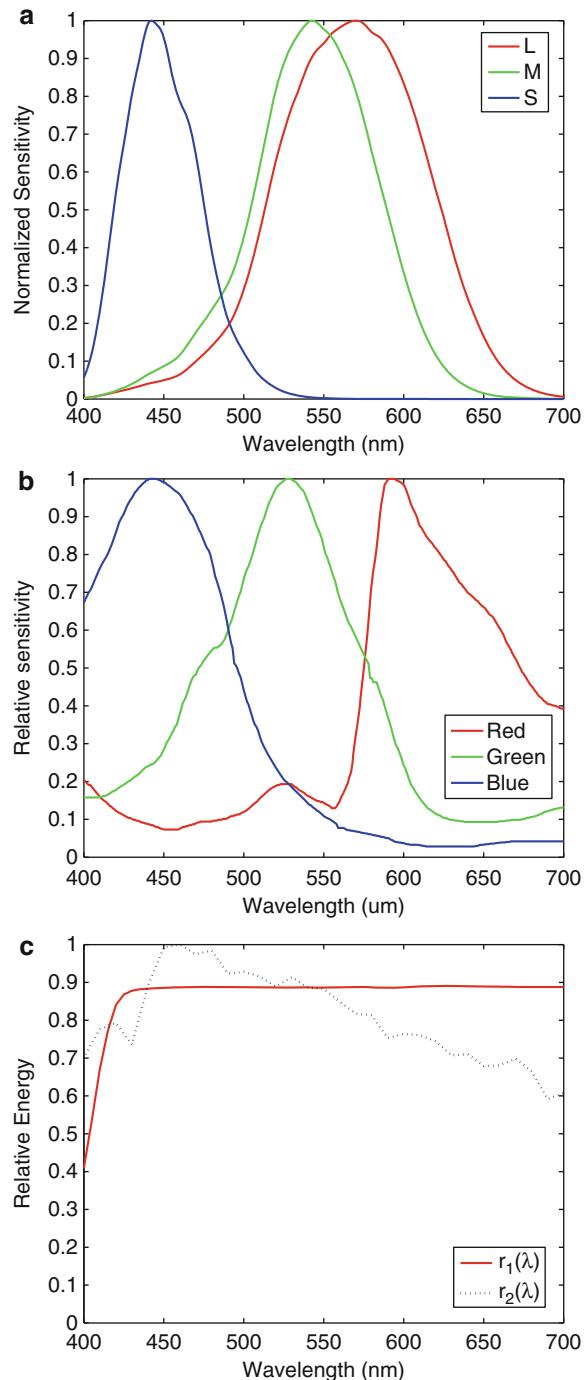

$$\begin{bmatrix} R_{\text{out}} \\ G_{\text{out}} \\ B_{\text{out}} \end{bmatrix} = \begin{bmatrix} 1/R_{\max} & 0 & 0 \\ 0 & 1/G_{\max} & 0 \\ 0 & 0 & 1/B_{\max} \end{bmatrix} \begin{bmatrix} R_{\text{in}} \\ G_{\text{in}} \\ B_{\text{in}} \end{bmatrix} \quad (1)$$

where the subscript “in” denotes the input pixels and subscript “out” denotes the output white-balanced pixel values. However, a simplistic maximum in the three channels (“max RGB” approach) is typically a poor estimate of the illuminant as it tends to take the maximum of each color from different pixels and the scaling typically results in contrast enhancement or a dynamic range expansion. A slightly more intelligent approach takes the maximum of the color that has the largest magnitude in the *RGB* color space (“brightest pixel” approach). This is also potentially error prone in images with no captured whites (or neutral colors). See Fig. 2 for examples of approaches that attempt to mimic the image captured under a daylight illuminant using these simple white balance approaches.

The next level of complication as an approach to color constancy (although an admittedly naïve one) is the “gray world” assumption, which assumes that all colors in an image

White Balance, Fig. 1

The human visual system and a camera's capture system compared: (a) LMS cone functions of a human observer; (b) spectral sensitivities of filters used in a particular digital color camera; (c) spectral reflectance function of a white patch, $r_1(\lambda)$, and the spectral emission, $r_2(\lambda)$, for the standard D65 daylight illuminant

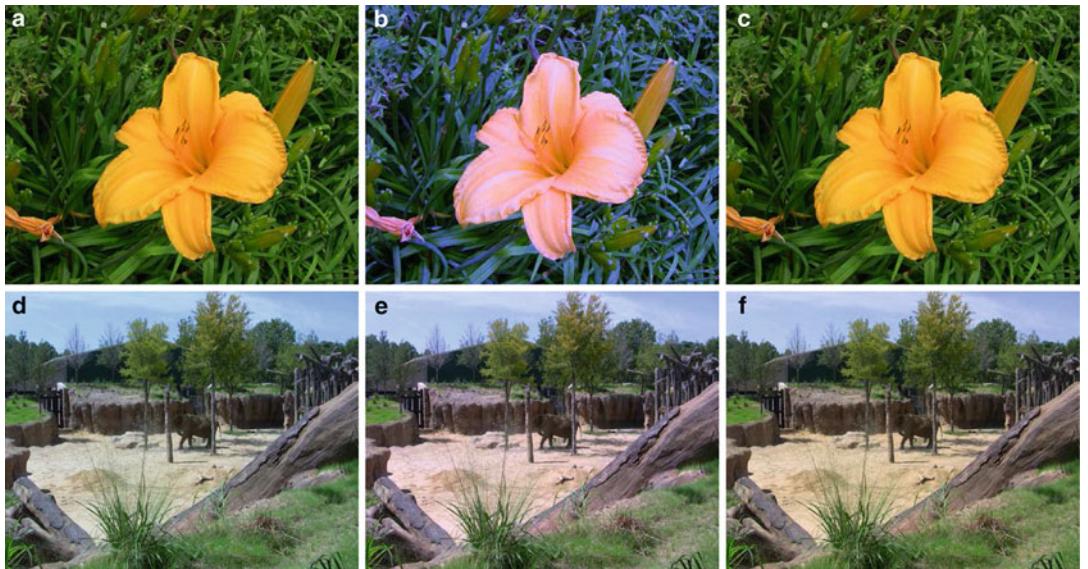

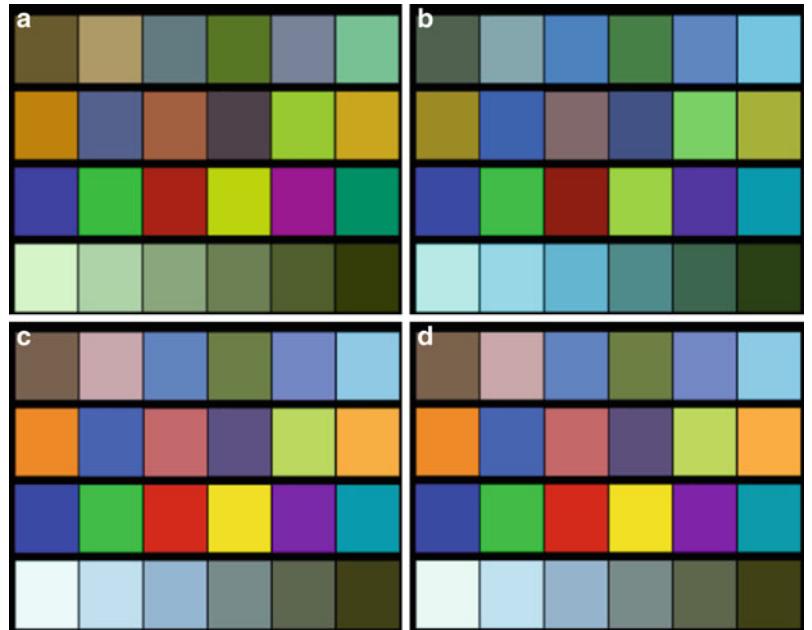

will average out to gray, $R = G = B$. In other words, the channels are scaled based upon the deviation of the average image color from gray. In this approach, the white-balanced image has signals given by $k_r R$, G , and $k_b B$, where

$k_r = G_{\text{mean}}/R_{\text{mean}}$ and $k_b = G_{\text{mean}}/B_{\text{mean}}$, the premise being that all off-balance neutral colors will get mapped to balanced neutrals. This type of white balance may be represented as:

White Balance, Fig. 2

(a) Image captured under a daylight illuminant; (b) image captured in fluorescent lighting (which has a relatively bluish cast); (c) fluorescent lighting image after white balance using the “max RGB” approach; (d) fluorescent lighting image after white balance using the “brightest pixel” approach

White Balance, Fig. 3 (a, d) Image captured with incorrect white balance; (b, e) the same images after performing white balance using the gray-world assumption; (c, f) images rendered with white balances preferred by the authors

$$\begin{bmatrix} R_{\text{out}} \\ G_{\text{out}} \\ B_{\text{out}} \end{bmatrix} = \begin{bmatrix} k_r & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & k_b \end{bmatrix} \begin{bmatrix} R_{\text{in}} \\ G_{\text{in}} \\ B_{\text{in}} \end{bmatrix} \quad (2)$$

This technique fails when most of the image is highly chromatic, e.g., a closeup image of a brightly colored flower. See Fig. 3 for an

example. Clearly, there are cases where each of these approaches fail. The search for a generic white balance algorithm has led to heuristic approaches that perform the scaling only for less-chromatic colors. In [5], Kehtarnavaz et al. present a technique called “scoring” to perform automatic white balance.

The above approaches that deal with pixel values in the RGB color space have been augmented and significantly improved by being performed in transformed color spaces. A general representation of such approaches may be given by the following equation:

$$\begin{bmatrix} R_{\text{out}} \\ G_{\text{out}} \\ B_{\text{out}} \end{bmatrix} = f^{-1} \left(\mathbf{B} f(R_{\text{in}}, G_{\text{in}}, B_{\text{in}}) \right) \quad (3)$$

where the subscript “in” denotes the input pixels and subscript “out” denotes the output white-balanced pixel values, f and f^{-1} denote a potentially nonlinear transformation function and its inverse, respectively, and \mathbf{B} denotes a generic matrix operator on the transformed *RGB* input values. The choice of the transformation is highly dependent on the preference of the designer. Fairchild’s book documents the most commonly used color spaces and equations necessary to transform the input color into the appropriate color spaces [2].

In [1], Barnard et al. present white balance techniques in a historical perspective and illustrate the performance of the algorithms on synthetic data. It is not always the case that white balance must be done automatically. Some cameras, particularly the more expensive ones, put more emphasis on “preprogrammed white balance” or “manual white balance” than their automatic counterparts.

Open Problems

More sophisticated techniques for estimating the color of the illuminant (e.g., [3]) are being used in the industry, but their application in white balance continues to be an area of active research with (spatially aware) chromatic adaptation transforms [2, 4] being increasingly used to compensate for capture-related white balance issues. Some of these adaptation transforms are highly nonlinear in their formulation and require rather sophisticated hardware and software to be appropriately applied. It is important to understand that once the image is captured by the digital camera –

without absolute knowledge of the illuminant – it is practically impossible to perform a perfect white balance and every rendition will be considered a “preferred” image rendition.

Wide Baseline Matching

Tinne Tuytelaars

KU Leuven, ESAT-PSI, Leuven, Belgium

Synonyms

Wide field of view stereo matching

W

Related Concepts

► [Epipolar Geometry](#)

Definition

Wide baseline matching is the process of finding correspondences between two images of the same scene taken from widely separated views.

Background

Finding correspondences between images is a first and crucial step in many image processing applications, such as image registration, 3D reconstruction, object recognition, or robot navigation. As long as the images are taken from more or less the same viewpoint, this task is relatively easy. Indeed, under these conditions (usually referred to as *small baseline*), the corresponding image patch will look very similar, and also its location in the image will have changed only slightly, so a local search for the most similar image patch suffices to find correspondences.

However, when the baseline between the cameras (i.e., the distance between the camera projection centers) increases, finding correspondences becomes a significantly harder problem. First, the correspondence can appear anywhere in the second image. As a result, one has to search over the whole image to find it. This also means there are typically many more distractors to cope with. Second, also the local appearance of the image patch can change drastically. When the viewpoint of the camera changes relative to the object or scene, this causes *geometric deformations* in the image, such as rotation, rescaling, as well as foreshortening, skew, and perspective deformations. Moreover, when the geometric setup changes, also the *photometric changes* are usually more severe. The deformations depend on the 3D structure of the scene, the illumination conditions, as well as the internal and external camera parameters. Since these are typically not known beforehand, efficient and effective algorithms to cope with them have been developed, mostly based on the concept of local invariant features and robust descriptors.

Theory

To cope with wide baseline conditions, one first needs to understand the deformations caused by the change in viewpoint. If one can assume that the object is locally planar (or can be approximated well by a plane, which is usually the case on a local scale), the geometric deformations can be modeled, in general, by a projective transformation or homography:

$$\omega \begin{pmatrix} x_2 \\ y_2 \\ 1 \end{pmatrix} = \begin{pmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ h_{31} & h_{32} & h_{33} \end{pmatrix} \begin{pmatrix} x_1 \\ y_1 \\ 1 \end{pmatrix}$$

with (x_1, y_1) and (x_2, y_2) the coordinates in the first and second image, respectively, and with ω a scale factor. Since on a local scale the perspective effects can be ignored, this reduces to an affine transformation:

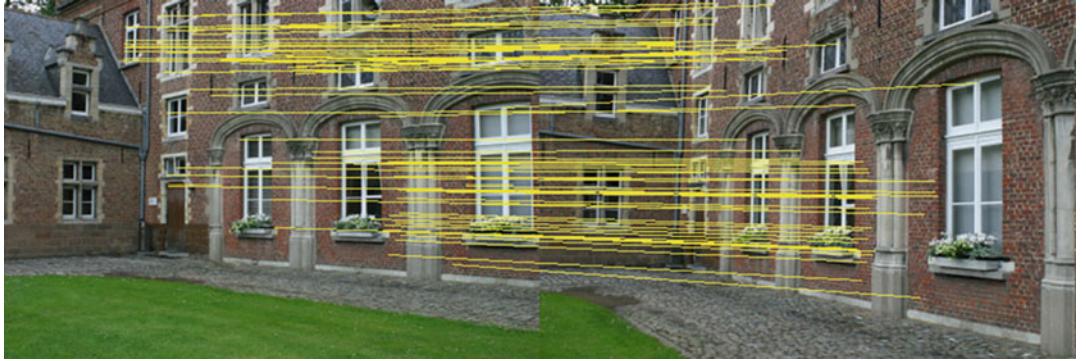

$$\begin{pmatrix} x_2 \\ y_2 \\ 1 \end{pmatrix} = \begin{pmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ y_1 \\ 1 \end{pmatrix}$$

Photometric changes are usually modeled by a linear model, with a scale factor s and offset t :

$$I_2(x_2, y_2) = s I_1(x_1, y_1) + t$$

with $I_*(x_*, y_*)$ the image intensity of both images.

Additionally, it is important to realize that for some locations in the image, it is easier to find correspondences than for others. Indeed, pixels that lie on a uniform part of the image cannot be distinguished from each other. Therefore, it is impossible to tell which one corresponds to which. *Local features* or *interest points* are found at locations in the image that stand out locally and can be localized accurately. They often correspond to corners or blobs. Since they have a good *repeatability*, one does not have to search the second image exhaustively for a correspondence, but only among the interest points extracted in that image. Therefore, in a wide baseline matching context, one focusses on the matching of such interest points only. Once they

Wide Baseline Matching, Fig. 1 Two images of the same scene, taken with a wide baseline, with correspondences

have been matched, extra constraints such as *epipolar geometry* can be derived, and these can help in finding additional correspondences (e.g., aiming for *dense matching*).

When dealing with wide baseline conditions, simple interest points such as *Harris corners* [6] no longer suffice, as these are not robust to the geometric deformations described above. Instead, affine invariant local feature detectors have been proposed, e.g., [8, 9, 18]. These detectors do select not only a location in the image but also the size and shape of the image patch to be considered for matching. Usually the image patches are ellipses, but parallelograms have been used as well. The detectors are called affine invariant because they have been devised so as to select corresponding ellipses/parallelograms in spite of affine deformations of the image. Based on its shape and size, the image can then be locally normalized by applying an additional affine transformation mapping the ellipse onto a circle of fixed size. This way, the effect of the geometric deformations is compensated for. The normalized image patch is then described by a robust descriptor such as SIFT [7], resulting in a high-dimensional feature vector describing the intensity pattern around the interest point. This descriptor is also made robust to the photometric deformations. Finding correspondences then boils down to finding the most similar feature vectors.

Since on a local scale features are usually not very discriminative, false matches (i.e., wrong correspondences) are unavoidable at first.

Therefore, a geometric consistency check is vital to select the inliers (correct matches) and reject the outliers (false matches). This can be done, e.g., by applying a random sampling approach such as RANSAC [5] to compute the epipolar geometry. For planar scenes, RANSAC combined with a homography is often used.

The pipeline described above is the most standard way of solving the wide baseline matching problem. Alternative schemes have been proposed as well, e.g., matching lines instead of interest points [2] or applying affine transformations to the image as a whole instead of making the feature detection invariant [13]. Also, it has been shown that in many cases, scale-invariant interest points combined with robust descriptors can already deal with viewpoint changes up to 30° and beyond [3, 7].

With the advent of deep learning, learned detectors and descriptors have been proposed to replace the handcrafted features described above. For descriptors, a siamese neural network applied on local patches can be trained [1, 16, 17]. Learning good detectors from data is somewhat harder, yet has been demonstrated as well [15, 19], as are joint schemes solving the detection and description tasks simultaneously [4, 11, 14]. These learned detectors and descriptors outperform the handcrafted ones especially under difficult imaging conditions, e.g. when the goal is to find correspondences between pictures taken during the day and at night. They are, however,

sensitive to the data used for training and how representative that data is for the actual test conditions.

Experimental Results

Figure 1 shows an example of two images of the same scene taken from different viewpoints, with the found correspondences superimposed. Further, we refer to the literature where various evaluations and comparisons of wide baseline matching methods have been proposed, e.g., [10, 12].

Zero-Shot Learning

Christoph H. Lampert

Synonyms

Attribute-based classification

Definition

The goal of *zero-shot learning* is to construct a classifier that can identify object classes for which no training examples are available. When training data for some of the object classes is available but not for others, the name *generalized zero-shot learning* is commonly used.

In a wider sense, the phrase *zero-shot* is also used to describe other machine learning-based approaches that require no training data from the problem of interest, such as *zero-shot action recognition* or *zero-shot machine translation*.

Background

Object recognition systems are typically created by training a supervised machine learning model, such as a *convolutional network*. For this, a training set is required that consists of annotated

images of all object classes of interest. When no annotated images of the target classes are available, the supervised approach is not applicable. Instead, classifiers must be constructed purely based on *contextual information*, such as *semantic descriptions* of the target classes or the *class names*. This setting is commonly called *zero-shot learning*, where the name is a play-on-words: it takes the name of the previously existing *one-shot learning* setting, in which exactly one training example per class is available, and literally replaces the number one by zero.

Theory

The fundamental principle that underlies most successful zero-shot learning methods is to use contextual information to construct a way of comparing individual images to abstract class labels. To classify a new image, one compares it to all target class labels and predicts the one of highest similarity.

There are two dominant frameworks for this task: one either constructs a common representation space to which individual images as well as class labels can be mapped or one uses different representation for images and class labels and learns a similarity function between these. Individual zero-shot learning methods differ in which form of contextual information they use, which representation space or spaces they rely on,

and how the representation or similarity function is learned.

Zero-Shot Learning Based On Semantic Representations

The first zero-shot learning methods relied on manually specified contextual information in the form of boolean vectors. Each entry indicates if a class fulfills some specific semantic property, often called an *attribute*, or not. For example, a class *zebra* could be characterized by having the attributes *black* and *white* and *has stripes*, but not *red* or *eats fish*.

Attribute-based classification [1, 2] uses the resulting vectors directly as a binary-valued feature representation for the classes. Images are mapped to the same representation space by learning predictors for each individual attribute in a supervised way using a dataset of images from other, potentially unrelated, object classes and their attribute descriptions. For example, a classifier for the attribute *has stripes* could be learned from images of *tigers* and *bumblebees* as positive examples, as well as *lions* and *horses* as negative examples. The representations in attribute space are then compared geometrically or probabilistically. Parallel work [3] described multi-class classification with generic *semantic output spaces* and coined the term *zero-shot learning* for this setting.

Zero-Shot Learning Based on Similarity Learning

Similarity-based techniques are able to leverage also other more readily available sources of context, such as natural language descriptions [4] or the class name itself [5]. A large number of recent zero-shot learning methods follow the same blueprint: one uses an existing technique to extract a feature vector from an image, e.g., a pre-trained *convolutional network*, and a different existing method to represent the available class information, e.g., a *word vector embedding* of the class name. Then, one uses a dataset of images with potentially unrelated class labels to learn a linear or nonlinear similarity function between both representation spaces. Examples of this framework include [5–10]. They differ in

the parameterization and learning objective that is used to determine a similarity function. A detailed survey and an experimental comparison of these techniques can be found in [11].

Open Problems

So far, the accuracy of zero-shot learning for multi-class object detection is still lower than what supervised techniques are able to achieve, even if those have access only to a small number of training examples per class. Therefore, zero-shot learning mostly finds application for specialized tasks with many classes where it is hard to obtain training examples for all classes, such as ecology. Related approaches to learning without training data have found more widespread use, such as machine learning translation for rare languages [12], or personalized recommendations for users without historic data [13].
